Abstract Book

Society of Environmental Toxicology and Chemistry North America 40th Annual Meeting

Great Together: Separate Challenges and Collective Solutions
3–7 November 2019 | Toronto, Ontario, Canada
This book comprises the abstracts of the presentations for the platform and poster sessions of the Society of Environmental Toxicology and Chemistry (SETAC) North America 40th Annual Meeting, conducted from 3–7 November 2019 at the Metro Toronto Convention Centre in Toronto, Ontario, Canada. The abstracts are reproduced as accepted by the Scientific Program Committee and appear in numerical order.

In each abstract, the presenting author’s name is underlined. The author index cross-references the corresponding abstract numbers.
About SETAC

The Society of Environmental Toxicology and Chemistry (SETAC), with offices in North America and Europe, is a non-profit, professional society established to provide a forum for individuals and institutions engaged in the study, analysis and solution of environmental problems, the management and regulation of natural resources, environmental education, and research and development.

Specific goals of the society are:

• Promote research, education and training in the environmental sciences
• Promote the systematic application of all relevant scientific disciplines to the evaluation of chemical hazards
• Participate in the scientific interpretation of issues concerned with hazard assessment and risk analysis
• Support the development of ecologically acceptable practices and principles
• Provide a forum (meetings and publications) for communication among professionals in government, business, academia and other segments of society involved in the use, protection and management of our environment

These goals are pursued through the conduct of numerous activities, which include:

• Conduct meetings with study and workshop sessions, platform and poster presentations, and achievement and merit awards
• Publish scientific journals, a newsletter and special technical publications
• Provide funds for education and training through the SETAC Scholarship/Fellowship Program
• Organize and sponsor chapters and branches to provide a forum for the presentation of scientific data and for the interchange and study of information about local and regional concerns
• Provide advice and counsel to technical and nontechnical persons through a number of standing and ad hoc committees

SETAC membership currently comprises about 5,400 individuals from government, academia, business and nongovernmental organizations with backgrounds in chemistry, toxicology, biology, ecology, atmospheric sciences, health sciences, earth sciences, environmental engineering, hazard and risk assessment, and life cycle assessment.

If you have training in these or related disciplines and are engaged in the study, use or management of environmental resources, SETAC can fulfill your professional affiliation needs.

All members receive the SETAC Globe newsletter highlighting environmental topics and SETAC activities, reduced fees for meetings and discounts on SETAC books. All members receive online access to Environmental Toxicology and Chemistry (ET&C) and Integrated Environmental Assessment and Management (IEAM), the peer-reviewed journals of the society. Members may hold office and, with the Emeritus Members, constitute the voting membership.

If you desire further information, contact the Pensacola office if you are in Latin America, Asia-Pacific or North America, or the Brussels office if you are in Europe or Africa.

Environmental Quality Through Science®
Concentrations and Impacts of UV Filters in Aquatic Environments

1 Investigating the environmental fate and transport of sunscreen components: Understanding the exposure route

S. Landeweer, Florida International University / Chemistry and Biochemistry; N. Quinete, Florida International University / Southeast Environmental Research Center (SERC); P.R. Gardinali, Florida International University / Chemistry & Biochemistry and SERC

Recently, sunscreens containing oxybenzone have been subject to heightened controversy due to their reported potential toxic effects on coral. This has even led to bans on oxybenzone-containing sunscreens in places such as Hawaii and Key West. However, while much of the research on oxybenzone is focused on its toxicological effects, far less research has been done on its behavior in aquatic systems. One very important property of these chemicals in order to understand their behavior is their solubility in natural environments and ability to partition from a sunscreen formulation into the water column. Generally, organic UV filters used in sunscreen formulations have log Kow’s between 4 and 7. In this study, in order to better understand the solubility and partition of sunscreen components into the water column, partition experiments were performed using silicon passive-diffusion releasers (SPDRS) to create a homogenous truly-dissolved exposure solution of the UV filter compounds. These partition experiments were conducted using a commercially-available sunscreen formulation containing five active ingredients (oxybenzone, avobenzone, octocrylene, homosalate, and octisalate). Samples were taken over a period of a week and analyzed by liquid chromatography-triple quadrupole mass spectrometry to determine the equilibrium time, equilibrium concentration achieved, and the constancy of the equilibrium concentration and the saturation times. The diffusion through the SPDR was modeled mathematically though a first order exponential curve, which showed a plateau after 40 hours for most compounds tested. The study was carried out in DI water and artificial seawater to determine the effects of the ionic strength of the solution. Concentrations of oxybenzone in DI water were found to plateau around 5.5 mg/L, which is smaller than the total amount of oxybenzone present in the formulations and also lower than the predicted solubility. Results indicate that SPDRs could be used to create exposure solutions for toxicological assessments.

2 Occurrence and fate of UV organic filters in natural and chlorinated seawater

J. Boudenne, Aix-Marseille University / Laboratory of Environmental Chemistry; T. Manasfi, Eawag - Swiss Federal Institute of Aquatic Science and Technology / Environmental Chemistry; S. Ravier. Aix-Marseille University / Laboratory of Environmental Chemistry; J. Labille, CNRS; S. Robert, CNRS / Laboratoire ESPACE; B. Coulomb, Aix Marseille Université / Laboratory of Environmental Chemistry

Swimming and bathing activities are part of points of entry of UV organic filters into the environment via washing off from the bathers’ skin. Although hydrophobic in nature and even when present in the formulation of sunscreens claimed to be “water-resistant,” these UV organic filters are released and can be found on beachfront and in swimming pools. Concerns about the bioaccumulation and persistence of organic UV filters in the environment have been raised because of an increasing number of experimental studies indicated that several UV filters might have endocrine disruptive effects. Moreover, some studies have shown that chlorination of UV organic filters may increase the mutagenicity of water. The determination of the fate of UV filters and the identification of their transformation products when exposed to chemical oxidants (as chlorine in swimming pools) or to natural light (as in untreated bathing waters) is necessary for risk assessment. The first objective of this study was to determine the occurrence of five organic UV compounds: di oxybenzone, oxybenzone, avobenzone, octyl methoxycinnamate and octocrylene) in bathing waters of Marseille, France (3 beaches and 2 chlorinated outdoor seawater pools) and to examine temporal patterns of their concentrations during three days in hot season (July). This field survey was then completed by laboratory experiments to study the photodegradability of these five compounds upon exposure to artificial solar radiations and their reactivity towards chlorine in reconstituted seawater. Analysis of seawater samples - after Liquid-Liquid Extraction- by Liquid Chromatography coupled to a quadrupole/time-of-flight mass spectrometry (LLE-LC-Q/ToF-MS) revealed the presence of four of the five compounds sought, at levels reaching up to 2400 ng.L-1 and 780 ng.L-1 in beach waters and up to 11,000 ng.L-1 and 180 ng.L-1 in swimming pool waters, for octocrylene and oxybenzone respectively. Among these compounds only octocrylene showed an accumulation trend during the day, while oxybenzone, avobenzone and octyl methoxycinnamate concentrations fluctuated on a frequency basis. Lab experiments confirmed these observations: octocrylene is UV and chlorine stable while all the other compounds react to form by-products. These latter ones have been identified (by GC-ECD) and their presence confirmed (by GC-MS) allowing to propose their transformation pathway to bromoform and bromal hydrate.

3 Occurrence and distribution of UV-filters in water, sediment, and oysters from Chesapeake Bay rivers fed by urban and agricultural areas

E. Hain, K. He, J.A. Batista, A. Feerick, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering; A. Timm, USDA Forest Service; M. Tarnowski, Maryland Department of Natural Resources; L. Blaney, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering

The environmental occurrence of ultraviolet-filters (UV-filters), which are active ingredients in sunscreen and other personal care products, has raised ecotoxicological concerns about endocrine disruption and growth inhibition in photosynthetic organisms. Our previous work indicated that oxybenzone, which was recently banned in Hawaii and Key West, Florida, was frequently detected in water, sediment, and oysters from the Chesapeake Bay at concentrations as high as 114 ng/L, 11 ng/g, and 118 ng/g, respectively. Nevertheless, the concentrations and distribution of UV-filters are unknown in urban- and agriculturally-impacted rivers that feed the Chesapeake Bay. The main objective of this work was to measure 11 UV-filters in water, sediment, and oysters collected from 5-11 sites in the Chester, Choptank, Patuxent, and Potomac rivers to understand potential sources and the influence of adjacent land use characteristics. The Chester and Choptank rivers are located in predominantly agricultural areas along the Eastern shore of the Chesapeake Bay, whereas the Patuxent and Potomac rivers are in urban areas on the Western side of the Bay. UV-filters were extracted from water, sediment, and oysters collected at each site and measured by liquid chromatography with tandem mass spectrometry. A large suite of human- and animal-use antibiotics and sucralose (e.g., a conservative wastewater indicator) were also measured in water samples to contextualize potential sources of UV-filters in the four river systems. Cinoxate, homosalate, octinoxate, octisalate, octocrylene, and oxybenzone were detected at over 90% of the sampling sites, highlighting their ubiquitous presence in the Chesapeake Bay. Oxybenzone was detected at median concentrations of 24, 27, 27, and 23 ng/L in the Chester, Choptank, Patuxent, and Potomac rivers, respectively, suggesting that land use had a negligible impact on oxybenzone levels in the aquatic environment. However, octisalate was detected at concentrations as high as 133 ng/L downstream of wastewater treatment plants and as low as 28 ng/L at more isolated sites. Interestingly, the concentration of several UV-filters increased near marinas and other human development, potentially indicating input from septic systems. Ultimately, these data highlight the widespread occurrence, distribution, and partitioning of a full suite of approved UV-filters in the aquatic environment.
4 The chronic effect of oxybenzone and temperature on the growth, physiology and microbiome of two reef building corals

D. Slikkerman, Wageningen Marine Research; T. Wijgerde, R. Nijland, L. Van der Loos, R. Osinga, A. Murk, Wageningen University and Research / Marine Animal Ecology

Emerging evidence suggests that benzophenone-3 (oxybenzone), a UV-filter applied in sunscreens, is harmful to reef-building corals. Water pollution with sun care products might in addition act synergistically with global warming, affecting coral bleaching threshold levels. In this study, we tested the effect of oxybenzone on the temperature sensitivity of the reef-building corals Stylotphora pistillata and Acropora tenuis. Coral microcolonies were cultured in flow-through aquaria, with or without oxybenzone exposure, at a field-relevant concentration of ~0.1 μg L^{-1} at 26 °C for several weeks. Subsequently, half the corals experienced a heat wave culminating at 33 °C (N=5 replicate tanks for each treatment combination). Survival, effective and maximum PSII yield, growth rate, zooxanthellae density and microbiome composition were recorded. Observations showed species dependent sensitivity to oxybenzone and temperature. Furthermore, oxybenzone exposure accelerated mortality of A. tenuis during the heatwave. Both oxybenzone and the heat wave reduced effective PSII yield of both species, although maximum yield was affected for S. pistillata only. During the heatwave, growth rate and zooxanthellae density of S. pistillata were reduced irrespective of oxybenzone. Finally, the microbiome of S. pistillata responded to a combination of both stressors applied, with a significant reduction in the abundance of four species, and an increase of one other. Our results add to the understanding of the potential impact of oxybenzone to corals at field relevant levels. The ecological significance should however be placed in context and will be addressed in the presentation.

5 Investigation of the toxicological impacts of mineral sunscreen formulations on reef-building corals in a warming ocean

A. Tagliati, Heriot Watt University / Institute of Life and Earth Sciences; D. Slomberg Aix-Marseille University; S.J. Hennige, The University of Edinburgh / School of Geosciences; J. Labille, CNRS; L. Hedouin, CNRS CRIJOBE; T.F. Fernandes, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology, Institute of Life and Earth Sciences

In recent years chemical UV filters in sunscreens have received considerable attention regarding their potential toxicity towards tropical corals, leading to selected UV-filters ban in Hawaii and Palau. Although mineral UV filters, especially titanium dioxide nanoparticles (nTiO₂), are popular cosmetic ingredients, their impact on corals has been scarcely studied. Moreover, the other core components of sunscreen comprising the sunscreen oil phase, emulsifier and emollient ingredients, have not been given due consideration. Significant quantities of the mineral and oil phase ingredients composing sunscreens are discharged into high-touristic coral reef’s waters, which interact among themselves and the environment resulting in a potential threat to tropical corals. Additionally, ocean warming is widely recognized as the major threat to coral survival and will persist even under the most optimistic scenarios, but the combined effects of sunscreen exposure and elevated temperatures are currently unknown. Here we present an integrated view of the effects of custom-made sunscreen lotions, formulated with different nTiO₂ types and emulsifier ingredients, on the sea anemone Exaiptasia pallida, a coral model organism, adult reef-building corals and their early-life stages, under present and projected future ocean warming conditions. Sea anemones photosynthetic activity and heat shock proteins (HSP70, HSP90) gene expression were investigated, along with coral respiration, photosynthetic efficiency, symbiont density, chlorophyll a concentration and larvae survival at multiple timepoints. Formulations lacking nTiO₂ and simultaneous heat stress caused in E. pallida a concentration-dependent inhibition of photosynthetic efficiency, comparable to sunscreen having the same composition but with nTiO₂ as UV-filters. Moreover, the stress induced by mineral sunscreen ingredients in adult corals, sea anemones and coral larvae was worsened by elevated temperatures. Results from the studies presented here suggest that sunscreen exposure may exacerbate the bleaching response of corals at elevated temperature, potentially leading to higher instances of bleaching at tourist coral reef locations. Our results also indicate that sunscreen toxicity is not due to UV-filters alone, and highlight the importance of taking into account the emollient and emulsifier ingredients in addition to UV filters when developing environmentally friendly sunscreens.

6 Investigating the Toxicity of the UV filter Benzophenone-3 (BP-3 or oxybenzone) on the coral Galaxea fascicularis

A.J. Conway, University of Maryland Center for Environmental Science; C.E. Mitchelmore, A. Heyes, M. Gonstior, C. Clark, University of Maryland Center for Environmental Science / Chesapeake Biological Laboratory

The active ingredients in sunscreens, UV filters, have gained increasing notoriety due to concern that these compounds may have negative impacts on sensitive coral species. Legislative activity in Hawaii and Key West, among others, has led to bans on the sale of sunscreens containing the specific active ingredient benzophenone-3 (BP-3 or oxybenzone) after a single published study demonstrated the potential for coral mortality, deformity, and bleaching when larvae were exposed to BP-3 at parts per billion to parts per million concentrations. However, a recent study using two species of adult coral fragments and larvae found little impact at parts per billion concentrations of BP-3. Given and the small amount of variable data on the toxicity of BP-3 to coral, additional toxicological assessments are necessary to determine the true risk of this UV filter. Therefore, we conducted a number of acute (i.e. 96-hour) and chronic (i.e. 21+ days) toxicity tests using nubbins from a common shallow-water hard coral species, Galaxea fascicularis. These experiments were coupled with chemical analysis to determine the actual aqueous concentrations at several time points during the exposure. Multiple endpoints pertinent to risk assessments (i.e. mortality and growth) were examined along with other biological endpoints such as bleaching and algal cell loss. With the results from these experiments, toxicological measures such as NOECs, LC50s, and EC50s were calculated in order to compare the results of this test to previous assessments of BP-3 toxicity. A risk assessment of BP-3 on Galaxea fascicularis was conducted using these results coupled with global analytical values of BP-3 in seawater from a variety of coral reef locations.

7 Adverse Effects of Organic Ultraviolet-filters on Daphnia magna Development and Their Role as Potential Invertebrate Endocrine Disruptors

F. Lambert, C. Vulpe, University of Florida / Physiological Science

Ultraviolet-filters (UV-Fs) are emerging contaminants of concern found ubiquitously in the aquatic environment. Many organic UV-Fs are endocrine disrupting compounds (EDCs) in vertebrates. However, few studies have assessed their effects on invertebrates. The process of molting, or the shedding of the exoskeleton, may be a target of these compounds. Molting is necessary for growth and development and is regulated by an arthropod specific endocrine system, the ecdysteroid pathway. Alterations of this process by EDCs can result in improper development, reduced growth, or death. These outcomes have potentially significant implications for organismal and population health. In this study, we investigate the effects of organic UV-Fs in a crustacean. Daphnia magna are chronically exposed to three organic UV-Fs commonly found in aquatic environments, 4-methylbenzylidene camphor (4MBC), octylmethoxycinnamate (OMC), and benzophenone-3 (BP3), and assessed for alterations in normal reproduction, molting, and development. We demonstrate that OMC and BP3, but not 4MBC, cause carapace deformities in the offspring of exposed parents. To assess whether these developmental abnormalities are potentially related to chemically induced alterations in ecdysteroid signaling, we further investigate the effects of acute exposure to 4MBC, OMC, and BP3 on the expression of several ecdysteroid-regulated genes (EcR, HR3, and FTZ-F1) in D. magna. This is the first study to assess the effects of UV-Fs on ecdysteroid regulated processes and ecdysteroid signaling.
in a crustacean. Results from these experiments indicate that some environmentally relevant concentrations of UV-Fs can affect crustacean development.

8 Assessing the Environmental Risk of UV Filters and Other Anthropological Contaminants to Coral in the United States
J. Davies, E.E. Burns, Personal Care Products Council / Science; A. Conway, C. Mitchelmore, University of Maryland Center for Environmental Science / Chesapeake Biological Laboratory

UV filters are active ingredients in sunscreen products that are designed to protect people against the harmful effects of solar radiation. In recent years, UV filters have been detected in coastal marine waters, which has led to concerns that these materials may be contributing to coral reef degradation. At a time when coral reefs are in overall decline, it is important to assess the risk that UV filters pose to coral reefs and use this information within a holistic assessment of all anthropogenic chemical contaminants to prioritize research and guide environmental management and policy decisions. Sources of UV filters in the environment are wash-off of sunscreen ingredients from bathers’ skin and wastewater treatment plant effluent. Generally speaking, UV filters have been detected in the marine environment at parts per trillion concentrations. Meanwhile, a limited number of ecotoxicological investigations have looked at the effects of UV filters on various coral species. Most studies have investigated acute effects, such as mortality and bleaching, while a single study looked at chronic effects. The following talk will summarize the state of science with regard to exposure of the marine environment to UV filters and other contaminants and the hazard these materials pose to coral species. Moreover, key data-gaps will be outlined and future research needs will be identified. Exposure and hazard data can then be used to assess the environmental risk of UV filters and other chemical contaminants to coral. However, regulatory guidance for assessing the risk posed by UV filters to coral is limited and there is an urgent need for coral-specific methods to be developed. This talk will provide an overview of environmental risk assessment methods and propose an approach that is specific to coral. It is also important to assess environmental risk using relevant and reliable exposure and hazard data. This presentation will also provide an outline of the reliability and relevance of existing data following published guidance also used by regulatory authorities in the US, Canada and the EU. The utility of coral risk assessment methods outlined previously will then be demonstrated using several case study contaminants for which extensive data are available. Additionally, given the extensive data gaps that exist for UV filters and other contaminants to which coral reefs may be exposed, future research needs will be identified and an overview of how these data should be used for a coral environmental risk assessment will be discussed.

Addressing Existing Challenges in Immuno-ecotoxico[logy]: From Tool Development to Risk Assessment - Part 1

9 Immunomodulatory effects of aceterminophen on C-reactive protein and interleukin-6 functions in juvenile catfish (Clarias gariepinus)
N.O. Erhunmuwa, I. Tongo, L.I. Ezemoney, University of Benin / Dept of Animal and Environmental Biology

It is well known that acetaminophen overdose can lead to oxidative stress and induce hepatic and renal damage. The chronic phase response in three life stages of Africa catfish triggered by immunomodulatory process against the action of acetaminophen was investigated using pro-inflammatory marker C-Reactive Protein (CRP) and Interleukin-6 (IL-6). The serum and tissue levels of CRP and IL-6 were measured by Enzyme-Linked Immunosorbent Assay (ELISA). The levels of C-reactive protein (CRP) and IL-6 were significantly increased by acetaminophen treatment (p < 0.05) as a response to inflammation. Following the induction of liver injury with acetaminophen (APAP), elevated levels of IL-6 was observed in different life stages of catfish, suggesting a possible hepatoprotective role played by this cytokine family.

10 Inflammation of gill epithelia in fish causes disruption of tight junctions leading to increased permeation of polar organic chemicals
U. Fuchylo, University of Saskatchewan / Toxicology Centre; H. Alharbi, King Saud University / College of Food and Agricultural Science; P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; M. Hecker, M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre

In fish, the gill epithelial layer controls paracellular permeation of chemicals through epithelial tight junctions. Previous research has indicated that the integrity of epithelial tight junctions can be adversely impacted by gill inflammation. A loss of junction integrity could lead to greater uptake of harmful contaminants, effectively increasing their toxicity. In this study we investigated if inflammation could induce disruption of tight junctions in fish gill epithelia, and if this in turn increases passive transport of chemicals across the epithelia. Inflammation was experimentally induced in a permanent rainbow trout gill cell line (RTgill-W1) through exposure to non-cytotoxic concentrations of lipopolysaccharide (LPS). Transepithelial electrical resistance (TEER) was used to indicate epithelial tight junction integrity. Cells were also co-exposed to LPS and oil sands process-affected water (OSPW) to determine if the hypothesized reduction in tight junction integrity would result in greater transport of OSPW across the gill cell epithelial layer in vitro. Quantitative real-time PCR (qPCR) was carried out to characterize changes in transcript abundance of genes responsible for tight junction proteins (e.g. claudins). Cells exposed to LPS showed significant reduction in TEER after 24 h of exposure. qPCR data showed that the abundance of transcripts of genes coding for tight junction proteins (i.e. Claudin 28b and 10e) were significantly decreased in cells exposed to 20, 50, and 100 mg/L LPS. Furthermore, chemical analyses revealed a significant increase in transport of constituents of OSPW across the gill cell epithelial layer at all concentrations of LPS. These in vitro findings were confirmed by an in vivo exposure experiment with fingerling rainbow trout that showed a comparable increase in OSPW content in fish exposed to both LPS and OSPW for 48 h, compared to fish exposed to OSPW alone. RNA-sequencing was conducted on RTgill-W1 cells exposed to LPS and analyses are currently ongoing to characterize any effects inflammation might have at the transcriptome level related to tight junction integrity. Overall, these results indicate that fish living in environments high in pathogens could be at risk of greater uptake of contaminants of environmental concern (i.e. chemicals in OSPW) than previously thought. This in turn highlights the need to further assess the risks that exposure to pathogens may pose from a toxicological perspective.

11 Isolation and characterization of OSPW fractions and assessment of their toxicity using mammalian cells
D. Lillico, N. Phillips, University of Alberta / Biological Sciences; R. Qin, University of Alberta / Civil and Environmental Engineering; M. Belosevic, University of Alberta / Biological Sciences; M. Gamal El-Din, University of Alberta / Civil and Environmental Engineering; J. Stafford, University of Alberta / Biological Sciences

Oil sands process water (OSPW) is a brackish mixture of suspended and dissolved solids (sand/clay), inorganics (metals), and organic compounds (e.g. naphthenic acids (NAs)) that has been reported to cause both acute and sub-chronic toxicity to a variety of organisms, including aquatic invertebrates, fish, and mammals. To date, the principal toxic components of OSPW have not been fully identified mainly due to the complexity of these waters. Research examining OSPW toxicity has focused on the NA containing organic fraction (OSPW-OF), indicating it as the primary toxic component. However, our recent work has shown that substances within the inorganic fraction (OSPW-IF) also significantly affect the...
health and functions of exposed cells. Therefore, the specific objectives of the present study were to develop a multistep extraction procedure for the separation and isolation of OSPW fractions (i.e. OSPW-OF and OSPW-IF) and to then compare their effects on the viability, metabolism, and antimicrobial activities on a population of cells called macrophages. Macrophages are an innate immune cell-type found in all animals that are essential for the detection and killing of microbial pathogens through a cellular engulfment process called phagocytosis as well as the production of potent antimicrobial substances such as nitric oxide (NO). Macrophages are also decedents of the earliest free-living aquatic amoeba that have since evolved into specialized sentinel invertebrates and vertebrates. High numbers of macrophages are found in tissues exposed to the external environment, which increases their chances of interacting with incoming pathogens. Consequently, these cells populate tissues commonly exposed to environmental substances making them useful for determining the effects of potentially harmful contaminants that interact with the skin and gills of fishes as well as the mucosal tissues of terrestrial animals. Overall, our data shows that the dynamic mixture of OSPW-IF and OSPW-OF contains potent immunomodulatory components that profoundly influence the viability, homeostasis, and immune functions of mouse macrophages. We also show for the first time that OSPW constituents drive macrophage polarization into different functional phenotypes, representing a potentially new bioindicator for tracking contaminants of potential concern within these contaminated waters.

12 Use of immune function assays in wild fish: Multi-year study of smallmouth bass immunity at US Geological Survey integrator sites

Unexplained epizootic mortality of adult and young-of-year smallmouth bass has been occurring for over a decade in the Potomac (adults) and Susquehanna (young-of-year) Rivers, Chesapeake Bay watershed, USA. We believe complex interactions between water quality, contaminants, pathogens and parasites, and other environmental stressors are impacting smallmouth bass immunity making it difficult to pinpoint any specific cause(s) for disease or death. This study field tested methods for assessing immune function in wild fish by comparing results across four U.S. Geological Survey (USGS) integrator sites - sites where chemical data was also collected - in the affected areas. Smallmouth bass were collected from three sites potentially influenced by various chemical contaminants and from one reference site. Sampling took place during spring and fall over three years (2016-2018). Fish were euthanized, weighed and measured, and any visible abnormalities were recorded. Anterior kidney was aseptically removed and homogenized for leukocyte isolation. Following removal of the anterior kidney, a necropsy was performed and tissues were preserved for histopathological analyses and gene expression analyses. Leukocyte isolations were performed using anterior kidney homogenates and leukocytes were tested for: bactericidal activity against Aeromonas veronii bv. sobria and Yersinia ruckeri; respiratory burst activity in phagocytes; and mitogenesis activity of lymphocytes when stimulated with and without the mitogens concanavalin A, phytohemagglutinin P and lipopolysaccharide. The respiratory burst assay detects general reactive oxygen species (ROS) in live cells using imaging flow cytometry. The mitogenesis assay detects DNA synthesis, nuclear morphology, Ig+ cells and cell cycle analysis with imaging flow cytometry; however, in the data being presented, only DNA synthesis and nuclear morphology were labeled. Nuclear morphology staining was replaced with Ig+ cell staining for data collected after 2018 to increase sensitivity and cell cycle analysis was added. Our analyses from 2016 to 2018 revealed significant seasonal and site differences in all three immune function tests. In the future, our analyses will be put into perspective using chemical, total estrogenicity, land use and other environmental data to evaluate potential risks to smallmouth bass populations in the affected areas.

13 Assessment of immunotoxicity by xenobiotic exposure using larval zebrafish

D.W. Phelps, A.A. Fletcher, I. Rodriguez-Nunez, North Carolina State University / Department of Molecular Biomedical Sciences; M. Balik-Meisner, North Carolina State University / Department of Biological Sciences; D.A. Tokarz, North Carolina State University / Department of Molecular Biomedical Sciences; D.M. Reif, North Carolina State University / Department of Biological Sciences; D.R. Germolec, US National Institute of Environmental Health Sciences / Systems Toxicology Group; J. Yoder, North Carolina State University / Molecular Biomedical Sciences

Current assessment practices for immunotoxicity involves a tiered approach for hazard identification and mechanistic studies, including observational studies, evaluation of immune function, and measurement of susceptibility to infectious and neoplastic disease. These studies generally use costly, low-throughput mammalian models. Zebrafish, however, offer an excellent alternative due to their rapid development, ease of maintenance, and homology to mammalian immune system function and development. Larval zebrafish also provide a convenient model to study the innate immune system with no interference from the adaptive immune system. In this study, we utilized a respiratory burst assay (RBA) to measure reactive oxygen species (ROS) production after xenobiotic exposure. ROS are produced in macrophages and neutrophils in response to pathogens in order to eliminate them from the host. Embryos were exposed to subteratogenic doses of chemicals from 6 hours post fertilization (hpf) to 96 hpf with daily media changes, and at 96 hpf the ability to produce ROS was measured. Through the RBA, we identified five compounds that suppressed global ROS production: 17β estradiol, benzo[a]pyrene, lead acetate, methoxychlor, and phenanthrene; these compounds have also previously been identified as immunosuppressive in mammalian innate immunity assays. In order to evaluate whether the suppression of ROS by these compounds was due to a decreased number of neutrophils or macrophages, we combined flow cytometry with transgenic zebrafish larvae to count the numbers of these cell types after chemical exposure. With this assay, we found benzo[a]pyrene altered macrophage number, but not neutrophil number. Taken together, this work demonstrates the utility of zebrafish larvae as a tool for identifying compounds that impact innate immune function at subteratogenic levels and identifies two mechanistic routes by which xenobiotic exposure may alter immune function.

14 Health indices of African sharptooth catfish (Clarias gariepinus) inhabiting some polluted streams in Ibadan, Nigeria

O. Iji, FCAlh&PT / HND, Animal Health; A.A. Oyagbemi, O. Azeez, O.E. Ola-Davies, University of Ibadan, Nigeria / Veterinary Physiology and Biochemistry

Since biomarkers are effective monitoring tools that have successfully been used in environmental monitoring and assessment, the health status of fish naturally inhabiting selected polluted streams were examined using biomarker responses. A total number of 55 African catfish obtained from FOL-Hope farms (reference site), Eleyele, Dandaru and Oluyole streams (polluted streams). Condition indices showed differences in condition factor being significantly higher in fish from the reference sites compared to those from the polluted sites. Histopathological changes were observed in the gills, liver and the kidneys of fish from polluted sites. Intraalumella hyperplasia of the gills, marked disseminated congestion involving the vessels and sinuoids, as well as steatosis in the liver. Desquamation of tubules with atresia and multifocal patches with severe distortion of the tubular architecture and outright loss of tubular structure were seen in the kidneys of fish from polluted streams. No significant lesion was observed in the muscle of all the fish examined from all sites. Significant differences in values were seen for WBC, lymphocytes and heterophils when compared to the reference site. Increased erythrocyte osmotic fragility was observed in fish from Dandaru (p < 0.001) compared to the other sites. Serum biochemistry results showed Alanine Amino Transferase (ALT) was significantly higher in the two (2) most polluted sites (Dandaru and Oluyole) (p < 0.01) compared to others two sites (Eleyele and Hope).
There was no significant difference in Aspartate Amino Transferase (AST) and Alkaline Phosphatase (ALP) across the groups (p< 0.05). Increased incidence of micronuclei formation (MN) was observed in fish from polluted sites when compared to the control. Values showed MN formation 20.42±2.07 (Oluyole), 14.17±0.50 (Eleyele), 8.33±0.77 (Dandaru) and 1.30±0.50 for the reference site at P< 0.05. Water physicochemical properties revealed that Cd, Mn and Fe were significantly higher at the polluted streams compared to reference sites. Although water chemical analysis only identified heavy metals as contaminants in the polluted stream, the application of a suite of biomarkers in C. gariepinus demonstrated that pollutants of possible public health concern were present in all polluted streams.

15 Optimization of the infection test method using common carp with Aeromonas salmonicida for the assessment of immunotoxicity

K. Nakayama, Ehime University / Center for Marine Environmental Studies; S. Yasumoto, National Fisheries University; S. Kitamura, Ehime University / Center for Marine Environmental Studies

In order to evaluate the immunotoxicity of environmental contaminants, the chemical effects on susceptibility to pathogen have been tested using fish and their pathogens. Since, in this type of experiment, mortality or the immune system responses are observed in experimentally infected host fish under the exposure to a test chemical, a highly reproducible and validated method for experimental infection is required. Our group developed a test method using common carp (Cyprinus carpio) as the host and Aeromonas salmonicida as the pathogen, and confirmed the reproducibility of the tests. In addition, we observed the increased susceptibility to A. salmonicida in carp exposed to an immunosuppressive agent, dexamethasone. For further optimization of the method, in the present study, we investigated the suitable size of fish for the infection test, and improved the method to detect A. salmonicida from the infected fish. Fish of varied size (n = 60, body weight [BW]: 3.68 ± 1.56 g, 1.16-7.59 g) were separated into three groups (sum of BW: 72.5 to 74.0 g), and each group of fish was kept in a 31 L glass aquarium. Two groups were exposed to 1 mg/L of dexamethasone (Dex) for whole experimental period, and another group was unexposed. Three days after the exposure started, each group of fish was bath infected to A. salmonicida (6.85 x 10^5 cfu/mL). Occurrence of typical symptom of A. salmonicida infection, ulcers on body surface, fin base and jaw, was observed until 14 days post infection. When the infection test was terminated, the existence of A. salmonicida was confirmed by culturing bacteria on HI agar added CBB. The incidence rates of the symptom were 15%, 30% (Dex exposed groups), and 10% (unexposed). Body weight of the diseased fish was 4.30 ± 0.69 g, which was slightly larger than that of all the fish used in this study. Combining the data of our previous and present studies, small fish (BW < 2.0 g) was less susceptible to A. salmonicida infection. Therefore, it is preferred not to use small sized carp for the infection test. Additionally, blue colonies were found on the plates seeded with bacteria from bleeding ulcers. Since it is known that A. salmonicida forms blue colonies on CBB containing agar, the observed ulcers were certainly caused by A. salmonicida. Because it cannot be denied that blue colonies are formed by other bacterial species, it is preferred to be double-checked A. salmonicida infection by a PCR method.

16 Transcriptome analysis of Florida manatees exposed to multiple stressors

M. De Maria, University of Florida / Department of Physiological Sciences; N. Garcia-Reyero, US Army Engineer Research and Development Center; K.J. Kroll, J.A. Bowden, C. Silva-Sanchez, University of Florida / Department of Physiological Science; M. Walsh, University of Florida / Aquatic Animal Health Program; N.D. Denslow, University of Florida / Physiological Sciences

Florida Manatees (Trichechus manatus) is a threatened species exposed to multiple stressors in the environment. They drink fresh water and they rely on freshwater refuges during winter, when they can be exposed to runoff containing industrial and agricultural contaminants. Toxic substances such as flame retardants (per- and polyfluoroalkyl substances, PFAS) have been detected in their plasma with a higher concentration in manatees from the Atlantic Coast (Brevard County) than in the population considered healthy in Crystal River (Gulf Coast). We have selected 32 manatees from these two populations with widely varying PFAS concentrations for further investigation of their transcriptomes. Manatees from Crystal River range with less than 5 ng PFAS/g plasma (wet weight) while those from Brevard have more than 20 ng PFAS/g (wet weight). In preliminary analysis of a subset of manatees (n=10), we have found that glyphosate, a commonly used herbicide formulated as roundup, is more prevalent in manatees from Brevard County. The mean concentrations we measured were 0.17 (±0.08) ng/mL for Brevard manatees, and 0.1 (±0.11) ng/mL for Crystal River manatees. These substances can produce lymphocyte extravasation and inflammation. Glyphosate exposure in animal models caused immune dysfunction associated with others pathologies. Both chemicals promote the expression of inflammatory cytokines in lymphocytes and immune suppression. Our working hypothesis is that exposure of manatees to multiple stressors hinders their immune systems. To test the hypothesis, we will perform total RNA extraction and RNA sequencing by Illumina on white blood cells collected from 32 manatees from Crystal River and Brevard County. Plasma glyphosate concentrations will be determined for all manatees by LC-MS/MS. Using pathway analysis, we will analyze the transcriptome data to determine the most affected molecular functions. We suspect that multiple contaminant stressors contribute to manatee disease in South Florida.

17 Thyroid function and PCBs in flesh-footed shearwaters on Lord Howe Island, Australia

D. Ngepegoda, RMIT University / School of Applied Sciences; A.F. Miranda, School of Science; J. Lavers, University of Tasmania / Institute of Marine and Antarctic Studies

The population of flesh-footed shearwaters inhabiting Lord Howe Island, a supposedly pristine island off the coast of Australia; has been in decline for more than two decades. Large quantities of plastics have been found in the digestive system of dead shearwaters. However it has also been suggested that endocrine disruption as a consequence of exposure to environmental pollutants has played a role in the decline of their individual and population health. Flesh footed shearwaters are apex feeders at the top of the trophic chain and hence vulnerable to bioaccumulated and biomagnified organic pollutants. The aims of this study were to quantify body burden levels of mercury and polychlorinated biphenyl (PCB) and evaluate their effects on thyroid function in both fledgling and adult flesh-footed shearwaters. PCBs were most abundant within adult blood cells, indicating that bird age may be an important factor in influencing circulating PCB concentrations. The link between age and mercury body burden was less clear. Negative relationships were
observed between mercury/PCB body burden and circulating thyroid hormone concentrations in both age categories. The results of this study provide some evidence of disrupted thyroid function within flesh-footed shearwaters as a consequence of mercury and PCB exposure. However, available sample sizes were a limiting factor in statistical analysis, as a result of field sampling difficulties on the remote terrain. Utilisation of larger sample sizes in future, better resourced studies, should be considered. This is the first study in Australia to quantify circulating thyroid hormone concentrations and address the accumulation of mercury and PCBs in relation to their effects on endocrine health in seabirds.

18 Standard methods and performance criteria needed for laboratory assessment of periphyton communities

D. Hasek, S. Weech, P.L. Orr, Minnow Environmental, Inc.; C. Fraser, Teck Coal Limited

Periphytic algal community characteristics are often used to assess the condition of aquatic ecosystems exposed to stressors. Methods for sampling and laboratory analysis have been developed by jurisdictions around the world, but leave sufficient flexibility for differences to occur among practitioners even within jurisdictions. In this study, seven periphyton samples were homogenized and divided for distribution to four commercial laboratories (2 in Canada, 2 in USA) for algal identification and enumeration. For each sample, taxon lists were combined among laboratories to approximate total sample richness at different levels of taxonomy. Although all laboratories identified all organisms they encountered in subsamples that were analyzed, on average, each laboratory identified about 37% of all species reported among the laboratories for each sample (total richness ranging from 30 to 68 species per sample). At least 42% of species identified in a sample by an individual laboratory were not reported by any other laboratory for the same sample. Major taxonomic groups represented were cyanophytes, chlorophytes, chrysophytes, rhodophytes, and diatoms. All laboratories reported at least one of these groups as absent in 2 or more of the 7 samples even though at least one other laboratory reported the group as present. This indicated large differences among laboratories even at a coarse level of taxonomy. Evaluation of laboratory methods revealed myriad differences that may have contributed to inter-laboratory variability in sample results, such as: 1) sample homogenization methods; 2) enumeration and identification of live vs. combined live and dead organisms; 3) selection of counting units (i.e. cells vs. natural counting units including filaments and colonies); 4) counting mechanics (i.e. counting along a transect or selection of random fields, as well a number of fields); and 5) percent of sample evaluated. Furthermore, quality assurance and quality control (QA-QC) measures are not routinely reported. Better standardization of identification and enumeration methods, and QA-QC performance requirements, are needed if monitoring results are used to make resource management decisions. Taxonomy standardization and proficiency testing frameworks have been implemented for phytoplankton (Proficiency Testing Australia) and freshwater macroinvertebrates (Society for Freshwater Science) but not for periphyton.

19 Coastal stormwater pond pollutants and the potential for development of antibiotic resistance

C.L. Horton, University of South Carolina / Environmental Health Sciences; M.E. DeLorenzo, NOAA / Office of Response and Restoration; G.I. Scott, University of South Carolina / Department of Environmental Health Sciences

The Southeastern coastal plain is the most rapidly urbanizing region in the United States. Associated landscape changes which increase imperiousness lead to alterations in the hydrological cycle, increasing runoff of nonpoint source (NPS) pollution. Meanwhile, the U.S. has seen a shift from individually-owned livestock farms to large-scale Confined Animal Feeding Operations. Urban and agricultural NPS runoff is discharged into stormwater ponds and lagoons, which sequester chemical contaminants, nutrients, and microbes to reduce loading into coastal ecosystems. Previous studies in retention ponds indicate elevated levels of trace metals, in addition to the presence of clinically-relevant antimicrobial products and high levels of bacterial contamination. Other investigations have shown significant association between trace metals contamination in surface waters and sediments with increased rates of antibiotic resistance (ABR). As a result, these ponds may pose a public health risk from drug-resistant microbes. As climate change conditions increase the frequency and severity of rainfall and flood events, sequestered contaminants may be flushed into neighboring estuaries. Affected microbes may then pass on resistance genes to bacteria encountered in their new environment, where people come in contact with harmful microbes via contact recreation or seafood products. Interactions of aquatic pathogens Vibrio vulnificus and Enterococcus faecium with trace metals commonly found in coastal ponds and estuaries (As, Cu, Zn) and clinically-relevant antimicrobials (triclosan, ciprofloxacin, and oxytetracycline [OTC]) will be discussed in terms of how they may enhance antibiotic resistance and upregulation of resistance genes. Single- and dual-exposure data for V. vulnificus and E. faecium grown in the presence of antimicrobials and/or trace metals will be presented. Preliminary data indicate that environmentally-relevant concentrations of antimicrobials inhibit growth in V. vulnificus and E. faecium. In the case of OTC, 38% inhibition of E. faecium growth occurred at 0.34 µg/L. For comparison, levels of OTC as high as 68 µg/L have been measured in agricultural lagoons containing 2.43*105 CFU/100 mL fecal enterococci. Sublethal stressors provide an excellent opportunity for microbes to express antimicrobial resistance. In addition to exposure results, ABR profiles of the two test organisms under a variety of exposure conditions will also be discussed.

20 The effects of sedimentation on the survival of winter flounder eggs incubated in the laboratory

Dredging and other natural events can result in the resuspension of sediments in the water column where they eventually settle and can bury sessile or immobile life stages of aquatic organisms. In this study, the sensitivity of winter flounder (Pseudopleuronectes americanus) eggs to sedimentation was conducted under laboratory conditions. Egg burial experiments using sediment collected from three Connecticut waterways were performed using 48 h old flounder eggs obtained from broodstock collected from the Gulf of Maine. Overall, burial depths of 0.3, 0.6, and 1.2 mm resulted in 86.6, 81.1 and 73.9% average survival, while 3 mm resulted in 10% survival of hatched eggs on average across the three sediments. Results of the experiment corroborated closely with prior research on winter flounder egg burial hatch success and demonstrated that egg hatching success was similar between the three sediments evaluated. The results suggest that a flounder egg (~ 0.75 mm diameter) may be 80% buried (0.6 mm) without substantially affecting hatch success. Before sedimentation risk can be appropriately assessed and managed, field measurements of the incremental contribution to sediment layers attributable to dredging operations and natural events, as well as other environmental factors such as timing of burial (with respect to egg development) and local hydrodynamic conditions need to be considered.

21 Biomonitoring and biomarker evaluations of abattoir discharges into the Ogun River from Kara Market, Nigeria using Clarias gariepinus

E.I. Olaniran, Department of Zoology

The discharge of untreated effluents into aquatic ecosystems poses potential adverse effects to aquatic organisms. In this study, the physicochemical characteristics of abattoir effluent from Kara cow market, Ogun state, Nigeria, surface water and sediments from the Ogun River were evaluated. Fish species and macrobenthic fauna diversity in the river were also examined. Acute toxicity, biochemical and histological studies were investigated in Clarias gariepinus exposed to sub-lethal concentrations of the effluent over a period of 28 days. Effluent physico-chemical parameters such as ammonia, conductivity, total dissolved solids and total suspended solids were higher than set limits. Total polycyclic aromatic
hydrocarbons (PAHs) in the effluent and sediment were 6.73 mg/L and 8.07 mg/kg respectively. Tetracycline (an antibiotic administered to the cows at the market) levels in the effluent and surface water were 0.23 µg/mL and 0.85 µg/mL respectively. Fish species diversity was lower at the test site compared to the reference site. Chironomus spp. and Tubifex tubifex dominated the benthic assemblage at the test site. There were significant changes (p< 0.05) in the biochemical indices but no histological alterations in exposed C. gariepinus after 28 days. The results demonstrate that the effluent poses potential risks to the aquatic organisms and ecosystem services provided by the river. We recommend that environmental regulatory agencies and stakeholders should establish effluent and solid wastes management systems at the market to prevent environmental and public health epidemics within the framework of the United Nations Sustainable Development Goals 6 (clean water and sanitation) and 14 (life below water).

22 Assessment of hazards caused by industrial effluent on environmental indicators

J.R. Rana, E. Ansari, M. Kamle, Jai Research Foundation / Ecotoxicology; N. Reddy, Veer Narmad South Gujarat University, Surat / Department of Biosciences

Due to increasing industrialization and urbanization, water bodies are being disturbed in many ways through dyes, agrochemicals, paper-pulp, cosmetics, refining etc. In the present study, industrial effluents of three season were collected from GIDC Sachin i.e. the study area located in Surat city within Gujarat state of India. Samples were evaluated for toxicity towards environmental indicators. There are numerous dye and agrochemical industries at the study area, Sachin. Results imparted that all the samples exhibit toxic effect on algae, daphnids and fish. The maximum biomass reduction, decreased growth rate and lower yield were recorded at the highest concentration of effluent from all the season. In summer, the minimum EC50 value recorded for biomass, growth rate and yield were 9.04, 20.37 and 8.67%, respectively. Daphnids showed maximum lethargy and immobility of 60% at 5.0% concentration of effluent from summer and with the minimum EC50 value for immobility as 5.07%. The effluent collected in summer season had minimum LC50 value of 8.59% and showed acute toxicity on fish, Danio rerio at 12.5% concentration. The collected samples were subjected to GC-MS analysis which confirmed the presence of various aromatic, aliphatic, heterocyclic, cyclic, aromatic cyclic and aliphatic cyclic compounds. Consequently might be possible reason for effluent toxicity on environmental indicators. Findings postulate that effluent from summer season impart more hazard to primary producer along-with primary & secondary consumer. Thus, may alter the entire aquatic ecological system and thereby form basis for the effluent toxicity and seasonal variation effects. Lack of eco-toxicological data about these contaminants represents a major concern due to the uncertainty in possible effects they could cause on the aquatic environment and human health.

23 Environmental DNA assessing impacts of anthropogenic pollutants in rivers

F. Li, Nanjing University / School of the Environment; X. Zhang, Nanjing University / Environmental Science

Rivers are among the most threatened freshwater ecosystems and anthropogenic activities are affecting both river structures and water quality. Assessing the organisms living within rivers can provide a comprehensive measure of the river’s ecological status, however, it is limited by the traditional morphotaxonomy-based biomonitoring. Environmental DNA (eDNA) as a novel tool can identify almost all biomes in one sequencing run, it provides a historic opportunity to rapidly assess the impacts of pollutants through direct observation the ecological consequences (e.g., changes in community structure and biodiversity) in rivers. Here, we used aqueous eDNA to profile all biomes (from bacteria to fish) in rivers from the Yangtze River Delta (YRD) area, and to unravel the impacts of pollutants at community and ecosystem levels. In recent decades, large amounts of anthropogenic pollutants discharged into the YRD, which rises major health concerns to humans and aquatic wildlife. Hence, this study is: 1) to assess the potential ecological risks of anthropogenic pollutants (e.g., ammonia, metal(loid)s and organic pollutants) based on the traditional hazard quotients (HQs) approach; 2) to unravel the impacts of pollutants through analyzing the changes in community structure, biodiversity and indicative OTUs from eDNA data. Results showed ammonia, metal(loid)s and organic pollutants had high ecological risk for fish, crustacea and algae based on HQs even at low concentration level (0.7) with the HQs for fish, crustacea and algae. Overall, our study further enhances the understanding on how pollutants affect aquatic ecosystems, and provide a comprehensive view on the impacts of pollutants at community and ecosystem level.

Building Bridges Between Lab-and Field-Derived Data: Methods for the Assessment of Complex Environmental Issues

24 Mobilization of estrogenic compounds from sediment during a simulated flood-like event

M.T. Schmitz, RWTH Aachen University / Biologie V Institute for Environmental Research, RWTH Aachen University; A.K. Müller, S.E. Crawford, RWTH Aachen University / Institute for Environmental Research, Dept. of Ecosystem Analysis; M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre; C. Ganal, H. Schuettrumpf, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources Management; H. Hollett, RWTH Aachen University / Institute for Environmental Research, Dept. of Ecosystem Analysis

Various anthropogenic micropollutants accumulate in high quantities in river sediments including endocrine disrupting chemicals (EDCs). Sediments might turn into a source for those substances, e.g. during flood events. So far, little is known about the extent flood events might result in adverse effects for aquatic wildlife such as fish caused by such remobilized substances. The main objective of the project Floodhydrotox was to estimate the effects of EDCs, and more specifically estrogenic compounds, remobilized from sediments during flood events on fish, i.e. rainbow trout (Oncorhynchus mykiss). In this study 25 rainbow trout were exposed for 7 days in an annular flume to Luppe-sediment which is known to contain high amounts of nonylphenol (NP) as well as estrone (E1). The annular flume allows for the simulation of a flood-like event by remobilizing the sediment through a stepwise application of defined force onto the sediment (i.e., bed shear stress). Natural sediment from the river Rhine in the area of Koblenz (Ehrenbreitstein) was used as control. Water samples were collected during every stage and were used for chemical analysis to receive time-dependent resolved data about the behavior of the main EDCs (i.e., NP and E1) and passive samplers (ChemCatcher) were used to assess their bioavailability. Vitellogenin (VTG) was measured in mucus as an initial biomarker and plasma concentrations of the target EDCs were measured via LC-MS/MS. Furthermore, gene expression of selected target genes (e.g. cyp19a and cyp11b) in gonads were investigated to reveal the physiological reactions caused by these compounds. Overall, a high remobilization potential of EDCs from the Luppe-sediment was observed compared to the Ehrenbreitstein-control including a 100-fold and a 4-fold increase of aqueous bioavailable NP and E1, respectively (3300 ng/L vs. 34 ng/L NP; 6.5 ng/L vs. 1.5 ng/L E1 ) and a 5-fold higher plasma NP-concentration was observed (33 ng/L vs. 7 ng/L NP; E1< LOD). Nonetheless, only 0.17% of the sediment-bound NP in the Luppe-sediment became bioavailable again compared to 11.95% in the Ehrenbreitstein-sediment. No increase in VTG in mucus and no differences in gene expression were observed. This project is among the first to investigate the impact of sediment-borne EDCs on fish, which is of great importance in context of the increasing frequency of flood events expected with climate change scenarios and the observed decline of many fish populations globally.
25 Why are my gonads small? An EEM investigation of cause for reproductive effects in caged bivalves

C. Brown, B.G. Fraser, EcoMetrix; B.P. de Jourdan, Huntsman Marine Science Centre / Environmental and Molecular Toxicology; L. Janes, Kruger Publication Papers

A pulp and paper mill in eastern Canada is part of the federal Environment Effects Monitoring (EEM) program under the Fisheries Act. Reproductive effects in fish manifested as reduced gonad size in caged blue mussels have been identified in multiple EEM cycles and, accordingly, an investigation of cause study was initiated. A review of potential causative agents for fish reproductive effects exposed to pulp and paper effluent did not list specific chemicals, rather groups of chemicals, such as phytosterols and ligands, that have been associated with toxicity. It has also been found that biological oxygen demand (BOD) can generally be used as a surrogate measure for reproductive effects in mill effluent. In an attempt to isolate the component(s) of the process water system that may be contributing to the observed reproductive effects, chemical and toxicological testing was completed on the process streams associated with: 1) the thermal mechanical pulping (TMP) process; 2) the boiler blowdown; and, 3) the white water from the paper machines/save all. In addition to these three locations, the final influent to and the final effluent from the treatment plant were also tested. Samples from each of the five locations were collected multiple times in summer and winter. Sublethal toxicity testing on the Green Sea Urchin (fertilization) was performed concurrent with chemical analysis. No one process stream was determined to be the primary contributor to reproductive effects, but the effluent treatment plant was found to significantly reduce toxicity. The results of this study indicated that process streams from the white water, boiler blowdown, and TMP had similar toxicity and had greater toxicity than the final influent or effluent. The white water and TMP had higher concentrations of organics and BOD than the influent and effluent. The boiler blowdown had higher concentrations of metals than the influent or effluent. Phytosterols in the final effluent were the only compounds measured that may potentially contribute to reproductive effects seen in the receiving environment. Concentrations of the various parameters investigated in the final effluent were similar to those measured in effluents from other mills. The investigation is ongoing.

26 Spatiotemporal endocrine disruption activity in an effluent-impacted river under low instream flow: Integrating field and laboratory assessments

M.E. Franco, S.R. Barket, Baylor University / Environmental Science; J.L. Sims, Baylor University / Biology; L.M. Lovin, Baylor University / Environmental Science; C. Ashcroft, Carollo Engineers; M. Luers, Snyderville Basin Water Reclamation District; B.W. Brooks, R. Lavado, Baylor University / Environmental Science

Effluent-impacted streams represent a threat to aquatic organisms due to their potential to cause adverse biological effects, such as endocrine disruption, especially during low instream flows. To evaluate the estrogrenicity of wastewater effluent to fish, field- and laboratory-based experiments were integrated using a weight of evidence (WoE) approach. During summer and fall seasons, juvenile rainbow trout (Oncorhyncus mykiss) were individually placed in cages and exposed for 1, 3 and 7 days, at three different locations downstream and one location upstream of a wastewater treatment plant (WWTP) in East Canyon Creek, Utah, a river influenced by seasonal snowmelt. In the summer, the wastewater effluent accounted for ~50% of the total stream discharge, and concentrations of plasma vitellogenin (VTG) were high in fish from the upstream and furthest downstream sites, whereas estradiol (E2) to 11-ketotestosterone (11KT) ratios were high across all sites, primarily on day 7. In the fall, the effluent accounted for ~25% of the stream discharge, and increases of VTG as well as high E2/11KT ratios were observed in fish from the downstream sites near the WWTP on day 7. However, both VTG and E2/11KT levels in the fall were significantly lower than in the summer. Experimentation with primary hepatocytes exposed to water extracts from the same locations used the field study also presented evidence for the expression of VTG, though on-going experimentation aims to integrate these results with field observations in search for suitable in vitro methods that facilitate the evaluation of the endocrine disruption potential of effluent-impacted streams.

27 Anxious copepods in the Anthropocene: Combined predation risk and copper exposure on isotopic trophic shifts

T. Lode, University of Oslo / Department of Biosciences; A. Redoglio, University of Milan / Department of Biosciences; T. Andersen, J. Titelman, K. Borgå, University of Oslo / Department of Biosciences

Stable isotope analysis (SIA) is commonly used in ecotoxicology to assess food web structure based on δ13C and δ15N values and general assumptions of isotopic trophic shifts (i.e., trophic enrichment factors: δ13C 0.5-1‰; δ15N 3.4‰). Knowledge of food web structure is commonly used to calculate contaminant biomagnification potential, yet these calculations are highly sensitive to estimates of organisms’ trophic position. Little is known of whether and how combinations of natural and anthropogenic stressors affect isotopic trophic shifts. Predation risk is an important factor structuring marine ecosystems and may also interact with contaminant toxicity. In a previous study using single-individual exposure, predation risk doubled the toxicity of copper (Cu), causing delayed development to maturity in the coastal copepod Tigriopus brevicornis. Stable isotope analysis (SIA) showed that copepod foraging had no effect on Cu concentration. However, this contrasts previous findings for both stressors and might indicate a higher sensitivity to predation risk exposure alone and in combination with an environmental contaminant. Copepod nauplii (<48h old) were exposed throughout ontogeny (17 days) in groups of 150 individuals per replicate. We changed exposure solution and food (Rhodomonas salina, 300 µg C L-1) every second day. After exposure we checked survival and life stages, and then prepared living individuals for SIA by freeze drying. Surprisingly, predation risk negatively affected survival and development to maturity, whereas no effects of Cu were found. This contrasts previous findings for both stressors and might indicate a higher sensitivity to predation risk exposure when in groups. According to expectations from previous studies, Cu exposure caused δ15N enrichment, but there was no effect on δ13C. Predation risk caused δ15N depletion, which was also observed in the combined treatment. Previous studies on starvation generally report δ15N enrichment. Our results suggest that food limitation is not a likely explanation for the predation risk effect, and support previous suggestions that contaminant exposure can affect isotopic trophic shifts.

28 Linking endpoints from mesocosms and other field studies to environmental protection goals

J.M. Giddings, Compliance Services International; R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety; A. Maldonado, Valent U.S.A., LLC / Environmental Science; M. McCoo, Bayer CropScience / Environmental Toxicology and Risk Assessment; L.W. Brewer, Compliance Services International / Department of Wildlife Toxicology

In the 1980’s, EPA affirmed the potential of microcosms (both terrestrial and aquatic) as tools to evaluate the transport and effects of toxic substances, stating that “with appropriate attention to the design of specific questions, answers to which are relevant to interpreting ecological transport and effects of contaminants, microcosms can be useful tools.” Considerable resource and intellectual investments were subsequently made in field studies, particularly micro/mesocosm studies, for pesticide registration in the United States. However, field studies lost favor during the 1990’s due to challenges of interpretation and risk paradigm incorporation. Regulators historically have had difficulty interpreting and incorporating results from these studies into risk management decisions because of misalignment between field endpoints (e.g., species diversity, productivity, community structure, population dynamics) and the individual-based measurement endpoints of standard test methods.
(survival, growth, and reproduction). Because most regulatory criteria are based on standard test endpoints, alternate approaches are needed to make use of field study endpoints. This presentation will review measurement endpoints from commonly used field study designs (mesocosms, avian field studies, and pollinator studies) and explore their relationship to specific environmental protection goals.

29 Context-dependent responses of aquatic insects to metals and metal mixtures: A meta-analysis summarizing 24 years of stream mesocosm experiments

W.H. Clements, Colorado State University / Fish, Wildlife and Conservation Biology; P. Cadmus, Colorado Parks and Wildlife; C. Kotalik, B. Wolff, Colorado State University / Fish, Wildlife and Conservation Biology

Modernizing water quality criteria to better predict how contaminants affect natural aquatic communities requires that we utilize data obtained across multiple lines of evidence, including laboratory, mesocosm and field studies. Mesocosm experiments can provide mechanistic insights into the discrepancies between results of laboratory toxicity tests and responses observed in the field. We report results of 29 mesocosm experiments conducted from 1994 to 2017 at the Colorado State University Stream Research Laboratory (Fort Collins, CO, USA). The primary goal of the study was to quantify variation among metal combinations and source communities. Communities were collected from 6 streams (8 locations) and were exposed to a range of metal concentrations and different combinations of Cd, Cu, Fe and Zn. Responses of all dominant taxa were compared to Zn alone, the least toxic metal across all combinations. Treatments that included Cu or Fe, either alone or in combination with other metals, were especially toxic to aquatic insects. In addition to the effects of metal combination, results showed that effects of metals were strongly context-dependent and varied significantly among the eight sites where communities were collected. For some taxa, variation in the effects of metals among source communities was greater than variation among metal combinations. In particular, effects on communities collected from smaller streams were significantly greater than those from larger streams. Although water quality criteria are routinely adjusted to reflect differences in physicochemical characteristics that determine metal bioavailability, there have never been attempts to account for context-dependent responses of aquatic communities to metals. Our analyses also showed that several morphological (body size, shape, gills, degree of sclerotization) and life history (votinism) traits were significantly correlated with sensitivity to metals. Across all taxa and experiments, aquatic insects broadly classified as small (maximum body length < 8 mm) were significantly more sensitive to metals than medium or large individuals. These findings demonstrate the advantages of integrating experimental evidence with species traits to develop a better mechanistic understanding of community responses to contaminants.

30 Development of integrated risk assessment framework and methodology for assessing environmental safety of chemicals discharged down the drain in China

M. Fan, M. McDonough, S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; Z. Liu, Chinese Research Academy of Environmental Sciences / State Key Laboratory of Environmental Criteria and Risk Assessment; R. Yamshi, Waterborne Environmental, Inc.; S.A. Csiszar, J. Menzies, Procter & Gamble Company / Environmental Stewardship; X. Wang, Chinese Research Academy of Environmental Sciences / State Environmental Protection Key Laboratory of Ecological Effects and Risk Assessment of Chemicals; K.E. Kapo, Waterborne Environmental, Inc.

The new Chinese regulatory chemical management scheme calls for increased development of risk-based assessment framework and tools that can address regional and national needs. Important considerations include identifying chemicals with high potential for adverse impact to humans and the environment early in the assessment, while also recognizing regional differences in the levels of economic and infrastructure development as well as environmental conditions. An integrated, tiered environmental risk assessment framework and methodology was developed for assessing the environmental safety of chemicals discharged down the drain in China. The tiers incorporate China’s specific exposure conditions as well as consideration of Chinese native species for effects assessment. The framework starts with a Low Tier utilizing the existing Chinese regulatory qualitative method, whereas Mid-Tier is quantitative using deterministic and probabilistic approaches that account for per capita residential water usage, wastewater treatment capability, as well as wastewater/in-stream dilution factors. A High Tier spatially explicit aquatic exposure model was recently created which leveraged historic work on the iSTREEM(R) model (American Cleaning Institute). A high-resolution river flow dataset was established based on the Curve Number method (Natural Resources Conservation Service, U.S. Department of Agriculture) and further validated by monitoring data. Case studies will be presented for consumer product ingredients which indicate Lower Tiers are conservative with greater environmental realism associated with High Tier methodology. A key aspect for the integrated framework is environmental effects assessment based on Chinese native species, as chemical registrations in China routinely involve local fish testing. The Chinese Rare Minnow (Gobioicypris rarus) and Chinese Medaka (Oryzias sinensis) are examples of leading local species. This research developed an understanding of the ecology, physiology, and other biological information allowed for the extrapolation between these two species and other OECD standard test species (e.g., zebrafish). We investigated comparative fish acute toxicity using 3,4-Dichloroaniline and NaCl with studies planned on additional chemicals and species. Chinese native species data will be utilized not only for direct hazard assessment but also for the development of statistical extrapolation methods, such as interspecies correlation estimation (ICE) models. ICE models use available toxicity data of surrogate species to predict untested species to expand the domains of ecotoxicological information for China’s integrated environmental risk assessments.

31 How is our risk assessment doing? What large scale environmental monitoring can and cannot tell us

I.M. Rodea-Palomares, Bayer CropScience / Environmental Toxicology & Risk Assessment; S.P. McGee, Bayer CropScience / Environmental Health Sciences; J. Chen, Bayer CropScience LP / Environmental Safety - Environmental Fate

The ultimate goal of Ecological Risk Assessment is to ensure that the social and economic thriving is not at the expense of unreasonable harm to the environment. Current regulatory Risk Assessment frameworks relies mostly on a combination of modeling and laboratory tools that represent simplified worst case scenarios in which realism is given up in favor of conservatism. This approach has the advantage of simplicity, but the disadvantage of reduced realism. Interestingly, although the ultimate goal of the process is to ensure protection of the environment and its ecosystems, biological monitoring of natural systems typically had a low profile role on (1) understanding baseline conditions, current variability, and trajectories of the entities we are trying to protect. (2) Putting into context the relative contribution of potential factors/stressors affecting current state of these entities. (3) Evaluating the efficacy of current Ecological Risk Assessment process to inform potential improvements, and (4) to holistically prioritize policy, management, and interventions to maximize overall improvement of the environment. A lot of work is required to improve any of these aspects, starting with understanding strengths and weaknesses of currently available environmental datasets. In this presentation, we explore a large environmental dataset compiled by the Iowa Department of Natural Resources (DNR) for the last 20 years. The dataset is unique in terms of the spatial (near a thousand sampled locations across the state of Iowa), and temporal (near 20 years) coverage, as well as the number of environmental factors monitored (ecological indicators, habitat condition, in situ water physicochemical characteristics, and chemical pollution). We believe this dataset is an unprecedented opportunity to take a closer look to Iowa freshwater
ecological communities, and explore large-scale trends in terms of temporal evolution of these communities, and main natural and anthropogenic factors likely driving their ecological quality. During the presentation, the strengths and weaknesses of the dataset, modeling approaches, and findings will be emphasized.

**Nanotechnology - Fate, Transport and Effects**

32 Developing an in vitro model from Daphnia magna to evaluate the molecular interactions of nanomaterials

*E. Ostovich, University of Wisconsin, Milwaukee / School of Freshwater Science; E. Laudadio, R.J. Hamers, University of Wisconsin, Madison / Department of Chemistry; R. Klaper, University of Wisconsin, Milwaukee / School of Freshwater Science*

Nanotechnology is playing an important role in many existing and emerging technologies; while nanomaterials have the potential to improve society, relatively little is known about how they will interact with organisms, and thus how their unintentional release from consumer or industrial products could impact environments such as aquatic ecosystems. By studying the complexity of how nanomaterials interact with different organisms on a cellular and molecular level, it will provide a better understanding of the initiating mechanisms that lead to adverse outcomes, as well as their potential environmental impacts. This presentation will discuss how an in vitro cell culture model of the aquatic invertebrate, *D. magna*, can be used to study these molecular interactions that are related to nanomaterial exposures in aquatic ecosystems. More specifically, this in vitro system consists of epithelial cells from the gut of *D. magna*. This is the key target tissue that comes directly in contact with contaminants found in the environment, and indirectly through the consumption of food. The main goal of this research is developing this in vitro method as a model for classic invertebrate toxicology. Since the acute and chronic toxicity of some nanomaterials, as well as their biological impacts, have been tested in vivo, the successive goal of this research is to link the molecular events observed in vitro to the longer term, whole organism, impacts. Some methods for studying nanomaterial toxicity in vitro include using standard cell viability assays, as well as looking at other endpoints such as oxidative stress. Additionally, global gene expression analyses are used to identify pathways of interest in response to nanomaterial exposures. With the initial data and observations collected from mixed metal oxide nanomaterial exposures, this in vitro model shows promise that these cellular/molecular assay endpoints can match that of long-term organism assays.

33 Determining the toxicity of silver nanoparticles on a model intestinal cell: Bioaccumulation and impact on essential trace elements homeostasis

*W. Dudafoi, Oklahoma State University / Integrative Biology; J. Catalano, Washington University in St. Louis / Department of Earth and Planetary Sciences; M. Minghetti, Oklahoma State University / Integrative Biology*

Silver nanoparticles (AgNPs) belong to the most commercialized nanomaterials. Each year, more than 60 tons of AgNPs are released into aquatic environments, raising concerns about their impact on the environment. Although several studies were conducted to investigate the toxicity of AgNPs, its impact on the homeostasis of essential trace metals such as Cu, Fe and Zn within the cells remains poorly understood. To determine the toxicity, accumulation and chemical modifications of AgNPs occurring at the luminal/intestinal epithelium interface, a model of the fish intestine, the trout derived RTgutGC cell line was used. Toxicity threshold were determined by a multiple endpoint viability assay which measures simultaneously metabolic activity, cell membrane and lysosome membrane integrity. Making use of the cytotoxicity data, non-toxic and toxic concentrations of AgNO₃ and AgNPs were applied to the cells for 1, 24, 72 and 142 hours (H). Silver and essential trace elements concentrations were then analyzed by ICP-MS. In a parallel set of samples, metal speciation was analyzed by X-ray absorption spectroscopy (XAS) and cellular metals distribution was mapped by X-ray fluorescence microscopy (XFM). Our results showed that for similar concentrations of intracellular Ag, AgNO₃ was more toxic than AgNPs. Indeed, when exposed to 5 mM of AgNO₃ or AgNPs for 24H, the cells accumulated similar Ag amounts (114 and 101 ng of Ag/mg of protein, respectively), yet a 50% versus 4% reduction in viability were induced, respectively. This difference of toxicity is due to different intracellular Ag speciation. Indeed, XAS analyzes showed that after 24H exposure to 1mM AgNO₃, 100±5% of the Ag complexed with cysteine while Ag-NPs mainly remained as Ag-NPs in the cells (72±5%). The ionic form of Ag has a higher bioreactivity than the nanoparticulate form. XAS analyzes also showed that Zn intracellular speciation was found to remain identical to the control when the cells were exposed to 1 mM AgNO₃ or 5 mM Ag-NPs. Accordingly, XRF and ICP-MS analyzes showed similar intracellular distribution and levels of Zn, but also Cu and Fe in the exposed cells, compared to control. Altogether, our data show that similar intracellular concentration of Ag induce different toxicity whether cells are exposed to AgNO₃ or Ag-NPs, due to different intracellular speciation of Ag, yet no impact on the homeostasis of essential trace elements was detected at the tested concentrations.

34 Leveraging electrochemistry to uncover the role of nitrogen in the biological reactivity of nitrogen-doped graphene

*Y. Wang, N. Aquino de Carvalho, L. Gilbertson, University of Pittsburgh / Civil and Environmental Engineering*

Research on the biological implications of metal and non-metal engineered nanomaterials (ENMs) has put into perspective with the relative magnitude of the inherent hazard of different ENMs, environmental considerations that influence ENM behavior and toxicity, and the ability to manipulate properties to influence interactions at the bio-interface. The unique physicochemical properties of graphene have enabled remarkably rapid progress in their electrochemical (e.g., energy storage and conversion, sensors) and biological (e.g., antimicrobials, biosensors, drug delivery) applications. Chemical doping of graphene with nitrogen is used to modulate electronic properties of graphene (e.g., doping-induced charge redistribution) and to tune chemical reactivity, which has advanced energy and sensing applications. However, to date, very little is known about the influence of the nitrogen (N) heteroatom on the biological activity of graphene. Given the growing evidence from our previous research that supports the importance of reactive sites, electron exchange, and electron transport, this work aims to elucidate the bioelectrochemical properties of N-doped graphene. We prepared a suite of systematically modified N-doped graphene materials using the hydrothermal method. The degree of N-doping and types of N in doped graphene is tailored by using two different nitrogen precursors (urea and uric acid) and thermal annealing under different temperatures. The electrochemical activity for oxygen reduction and oxygen evolution reactions confirms the different electron transfer properties between the N-types. The bioactivity of the prepared materials is evaluated as the inactivation of a bacterial model organism, *Escherichia coli*, and the propensity to oxidize the intracellular antioxidant, glutathione. Given the importance of oxygen and electron transfer in mechanisms of biological activities, the results from electrochemical experiments further our goal of connecting the electronic behavior and the mechanism underlying differential biological activities of 2D carbon nanomaterials. Additionally, this work explores the potential to tailor functional performance (electrochemical reactions) and hazard outcomes (the biological implications) through advancement towards global rational material design guidelines.
35 Nanoparticle uptake and elimination kinetics in mosquitofish, clams and two snail species in wetland mesocosms

B. Castellon, Baylor University / Biomedical Studies; B. Perrotta, Baylor University; M. Simonin, S.M. Anderson, Duke University / Biology; J.L. Cooper, Duke University; H. Hsu-Kim, Duke University / Department of Civil Environmental Engineering; E. Bernhardt, Duke University / Biology; R.S. King, Baylor University / Department of Biology; C.W. Matson, Baylor University / Environmental Science

Engineered nanoparticles (NPs) may pose a risk to human and ecosystem health. While there is a growing body of research on the toxicity of NPs, risk assessment of NPs still requires a better understanding of bioavailability of NPs at environmentally relevant exposure concentrations and in complex ecosystems. For improved modeling of uptake and bioaccumulation, there is especially a need for kinetics experiments. Here, we present results from a study in replicated outdoor wetland mesocosms exploring the bioavailability of NPs in eastern mosquitofish (Gambusia holbrooki), Asian clam (Corbicula fluminea), and two freshwater pond snails (Physella acuta and Lymnaea sp.). Over a 9-month study, these aquatic taxa were exposed to weekly doses of either: large (19 mg per week, primary particle size 185.3 nm) cerium dioxide (CeO2) NPs, small CeO2 NPs (19 mg, 3.8 nm), gold (Au) NPs (19 mg, 11.8 nm), copper hydroxide NPs from Kocide 3000 (35 mg, 118.3 nm), or controls with no NPs. The Au NP, Kocide and control groups were also tested with or without weekly nutrient additions (88 mg KNO3, 35 mg KH2PO4 per week) as a covariate. We sampled quarterly for long-term NP uptake over the 9-month experiment (i.e. at 3, 6 and 9 months). During those times, we also conducted 1-week caged exposures in the mesocosms with naive animals to quantify short-term uptake kinetics. Subsequently for all exposure groups, animals underwent a deputation period of up to 7 days in clean water to quantify NP elimination kinetics. All data were determined by quantifying body burdens in animals using ICP-MS. Our results indicate that Physella snails consistently took up the most NPs, followed by Lymnaea snails, clams, and fish. The accumulation of copper in all taxa was 1-3 orders of magnitude higher than Au or Ce, despite a similar NP dose mass, with Physella at the highest relative ratio and Gambusia the lowest. In snails, the small CeO2 and Au NPs accumulated equally, both at significantly higher levels than large CeO2 NPs, while in fish the small and large CeO2 NPs and Au NPs all accumulated equally. Clams exposed for 3 months took up relatively more of the large CeO2 NPs than the small CeO2 NPs, but it was the opposite for clams exposed 1 week. The animals fully depurated both CeO2 NPs within 12 h, but were only able to depurate about 68% of the Au NPs even after 7 days. Finally, nutrient additions did not significantly influence long-term NP accumulation or retention.

36 Multi-level responses of yellow perch (Perca flavescens) to a whole-ecosystem silver nanosilver addition at the IISD-Experimental Lakes Area

L. Hayhurst, IISD Experimental Lakes Area Inc / Fisheries; J.D. Martin, Trent University; V.S. Langlois, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; C.D. Metcalfe, Trent University / Water Quality Centre; M.D. Rennie, Lakehead University / Biology

Silver nanosilver (nAg) is an antibacterial agent with widespread commercial and industrial applications. As a result, nAg has high potential for entering freshwater environments at point sources. As part of a collaborative study involving a whole-lake nAg addition at environmentally-relevant (low ug/L) concentrations, we evaluated biological responses in Yellow Perch (Perca flavescens) through baseline, two-year nAg addition and lake recovery periods. Perch were monitored for responses at the cellular (biomarker), individual (growth, consumption and metabolism) and population level (abundance and gross consumption). At the cellular level, biomarkers of oxidative stress in perch livers revealed down-regulation of catalase (cat) and glutathione peroxidase (gpx) in fish collected during the first year nAg addition, and elevated ratios of reduced to oxidized glutathione (GSH:GSSG) in perch collected during the second years of nAg addition. At the individual level, perch bioenergetic models revealed significant changes in consumption and total metabolism, which declined during nAg addition and remained depressed. At the population level, perch densities declined along with gross prey consumption after nAg was added to the lake. This whole-ecosystem multi-scale response study of Yellow Perch exposed to a long-term addition of nAg revealed negative impacts across cellular, individual and population levels.

37 Toxicogenomic responses of Caenorhabditis elegans to pristine and transformed zinc oxide nanoparticles

O.Y. Tsyusko, University of Kentucky / Plant and Soil Sciences; D. Starnes, Belmont University / Biology; J. Unrine, University of Kentucky / Plant and Soil Sciences; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology; P. Kille, Cardiff University; S.S. Lichtenberg, Z. El Haj Baddar, University of Kentucky / Plant and Soil Sciences; C. Chen, College of Life Sciences, Northwest A&F University / State Key Laboratory of Crop Stress Biology in Arid Areas; J. Morgan, Cardiff University; P. Bertsch, CSIRO / Division of Land and Water

Manufactured nanoparticles (MNPs) undergo transformation immediately after they enter wastewater treatment streams and during their partitioning to sewage sludge, which is applied to agricultural soils in form of biosolids in many parts of the world. We examined toxicogenomic responses of the model nematode Caenorhabditis elegans to pristine and transformed ZnO-MNPs (phosphatized pZnO- and sulfidized sZnO-MNPs). To account for the toxicity due to dissolved Zn, a ZnSO4 treatment was included. Transformation of ZnO-MNPs reduced their toxicity by nearly ten-fold, while there was almost no difference in the toxicity of pristine ZnO-MNPs and ZnSO4. This combined with the fact that far more dissolved Zn was released from ZnO- compared to pZnO- or sZnO-MNPs, suggests that dissolution of pristine ZnO-MNPs is one of the main drivers of their toxicity. Transcriptomic responses at the EC30 for reproduction resulted in a total of 1161 differentially expressed genes. Fifty percent of the genes differentially expressed in the ZnSO4 treatment, including the three metal responsive genes (mtl-1, mtl-2 and numr-1), were shared among all treatments, suggesting that responses to all forms of Zn could be partially attributed to dissolved Zn. However, the toxicity and transcriptomic responses in all MNPs treatments cannot be fully explained by dissolved Zn. Two of the biological pathways identified, one essential for protein biosynthesis (Aminoacyl-tRNA biosynthesis) and another associated with detoxification (ABC transporters), were shared among pristine and one or both transformed ZnO-MNPs, but not ZnSO4. When comparing pristine and transformed ZnO-MNPs, 66% and 40% of genes were shared between ZnO-MNPs and sZnO-MNPs or pZnO-MNPs, respectively. This suggests greater similarity in transcriptomic responses between ZnO-MNPs and sZnO-MNPs, while toxicity mechanisms are more distinct for pZnO-MNPs, where 13 unique biological pathways were identified. Based on these pathways, the toxicity of pZnO-MNPs is likely to be associated with their adverse effect on digestion and metabolism.

38 Intelligent re-design of silver nanowires to reduce cellular and organismal toxicity in aquatic ecosystems

D. Arndt, University of Florida / Physiology; M. Tagmount, University of Florida / Center for Environmental and Human Toxicology; S. Lehmann, ISTerre UJF; D. Toybou, University of Grenoble Alps; B. Omana, A. Hofmann, University of Lille; C. Celle, CEA Grenoble; L. Charlet, University of Grenoble Alps; J. Simonato, CEA; B. Gilbert, Lawrence Berkeley National Laboratory; C. Valpe, University of Florida / Physiological Science

Silver nanowires are more favorable than indium tin oxide for transparent electronic applications, and silver nanowire production rates are expected to increase as flexible electronics become more mainstream. Although spherical silver nanoparticles have been extensively studied over the past decade, it is likely that the transport and toxicity of silver nanowires will be different from their spherical counterparts due to the high aspect ratio of silver nanowires. The goal of this work is to determine the environmental fate and toxicity of silver nanowires with various dimensions in Daphnia magna and rainbow trout cells.
39 Differential toxicity elicited from a series of hybrid lipid-coated silver nanoparticles with varying degrees of surface stabilization

S.L. Harper, A. Engstrom, Oregon State University / EMT Department; M. Mackiewicz, Portland State University / Department of Chemistry

Silver nanoparticles (AgNPs) are one of the most widely used and advertised nanomaterials due to their well-documented antimicrobial properties. They are used in a variety of consumer and commercial products as well as in industrial applications such as wastewater treatment. While the antimicrobial properties of the AgNPs are likely controlled by their physiochemical properties such as size, shape and surface chemistry, these properties are often hard to study as they are confounded by AgNPs propensity to undergo Ag⁺ ion dissolution. Due to their wide and varying uses, there is a need to understand the biological interactions of AgNPs with diverse physiochemical characteristics while controlling for the release of Ag ions. Here a suite of 10 hybrid lipid-coated spherical and triangular plate shaped AgNPs were created with increasing complexity of their surface-coating. Dissolution studies showed that increased complexity of the hydrophobic thiol surface-coating protected the AgNP from surface oxidation and ionic release. Embryonic zebrafish were then exposed the suite of AgNPs at exposure concentrations ranging from 0.03125 mg Ag/L to 4 mg Ag/L confirmed by ICP-MS for each of the synthesized AgNPs. Decreased rates of morbidity and mortality were observed in the AgNPs with the longest chain thiol surface coatings. At the concentrations tested, no significant toxicity was observed for the longest chain surface composition in either the spherical and triangular plate geometries. In contrast, AgNPs smaller chain thiol surface coatings allowed for Ag⁺ leaching or increased surface oxidation which resulted in higher mortality rates across both geometries. The higher surface area spherical AgNPs showed increased toxicity over the triangular plate AgNPs with the same surface coating. The ability to control the Ag⁺ ion dissolution of the AgNPs allowed us to gain a better understanding of the size and shape effects that drive the toxicity of AgNPs.

Stockholm Convention on POPs: Progress in Monitoring, Research and Risk Assessment of Legacy and Emerging Chemicals - Part 1

40 Monitoring and effectiveness evaluation under the Stockholm Convention: Origins and future prospects

A. Daniel, Government of Canada

This presentation will kick off the panel on the Stockholm Convention by outlining the evolution of the Stockholm Convention from the initial scientific research conducted in the 1980s, to the push for action in a regional context in the 1990s at both the political and legal levels. Developments in scientific understanding of the fate and transport of persistent organic pollutants (POPs) and their impacts on the Arctic environment and indigenous peoples continued to evolve during this time. In particular, scientists came to understand how POPs travel globally, why the Arctic is particularly vulnerable to long-range transport from around the world, and the resultant human health and environmental impacts. By the mid-1990s, there was keen interest in taking regulatory action at the global level, with multi-stakeholder meetings helping to shape a common understanding that a global treaty was required. The presentation will then focus on key aspects of the negotiation of the Stockholm Convention, in particular Article 16 on effectiveness evaluation, which provides the legal basis for the ongoing monitoring and assessment work taking place under the Global Monitoring Plan (GMP) under the Convention. It also provides the basis for periodic reviews of the effectiveness of the Convention in meeting its objective of protecting human health and the environment from POPs, using monitoring data to assess progress against agreed indicators. The GMP and the EE process together form a continuous loop to achieve incremental improvements to the global environment over time. By highlighting the importance of these two elements, this presentation will set the stage for other panel members who will focus on the monitoring aspects by highlighting measurement techniques, monitoring and research studies on legacy and emerging POPs, and recent advances in their international risk assessment and risk management under the Convention, as well as strategies for future work.

41 Atmospheric monitoring of persistent organic pollutants (POPs) and emerging contaminants in Canada in support of the Stockholm Convention

H. Hung, C. Shunthirasingham, F. Wong, N. Alexandrou, H. Dryfhout-Clark, Environment and Climate Change Canada / Air Quality Processes Research Section; K.A. Brice, Environment and Climate Change Canada / Air Quality Research Division; E. Barresi, Environment and Climate Change Canada / National Laboratory for Environmental Testing; E. Sverko, Harbin Institute of Technology; P. Felllin, AirZone One, Ltd.

Two major air monitoring programs conduct measurements of persistent organic pollutants (POPs) and emerging contaminants in the Canadian Arctic and the Great Lakes regions since the 1990s. At the Canadian High Arctic station of Alert, Ellesmere Island (82°30’ N, 62°20’ W), POPs measurements in air started in 1992 under the Northern Contaminants Program (NCP). Canada’s Chemicals Management Plan (CMP) also conducts Monitoring and Surveillance in the Great Lakes Basin (GLB) which collaborates with the U.S. Integrated Atmospheric Deposition Network (IADN) to assess atmospheric deposition of Chemicals of Mutual Concern to the Great Lakes. There were two Canadian GLB master stations, located at Point Petre (PPT) on Lake Ontario (43°50’ N, 77°09’ W) and Burnt Island (BNT) on Lake Huron (45°49’ N, 82°57’ W). Since air is a core medium for monitoring under the Stockholm Convention (SC), long-term time trends of POPs derived from these two programs contribute to SC’s Global Monitoring Plan (GMP) Reports and are part of the Effectiveness Evaluation (EE) process of the Convention. In addition, these two programs screen for emerging chemicals of concern, results of such screening efforts contribute to the risk assessment of candidate POPs. This presentation will provide an update on atmospheric levels and trends of POPs and emerging contaminants monitored in these two ecologically sensitive regions in Canada which contribute to the third phase of the GMP.

42 10 years of monitoring persistent organic pollutants under the Global Atmospheric Passive Sampling (GAPS) network (2005-2014)

J. Schuster, Environment and Climate Change Canada / Air Quality Research Department; T. Harner, Environment and Climate Change Canada / Air Quality Research Division; A. Eng, Environment and Climate Change Canada / Atmospheric Science & Technology Directorate; K. Su, Environment Climate Change Canada; C. Rauert, Environment and Climate Change Canada

The Global Atmospheric Passive Sampling (GAPS) network supports the global monitoring plan (GMP) under the Stockholm Convention on
Persistent Organic Pollutants (POPs) by providing information on POP concentrations in air on a global scale. The GAPS network was started in 2005 with 55 sites characterised by use and location as urban, rural, agricultural, background and polar sites. Background sites make up the majority of sites to fill in information gaps in remote areas. Over time new sites were added and sites were discontinued and the network has been maintained at approximately 60 sites. The GAPS network utilizes passive air samplers (PAS) with polyurethane foam (PUF) disks, which are a simple and cost effective tool for monitoring concentrations of semi-volatile pollutants in remote areas. PAS are deployed by volunteers on a global scale for consecutive 3-months periods since 2005. The data from the GAPS network for concentrations of legacy POPs in air currently provides information for more than 110 global sites. Global concentrations reflect differences in region, remoteness of sites and local use of POPs. Measurements spanning 10 sampling years are available for 20 of these sites. Concentrations for legacy POPs in air between 2005-2014 show different trends for organochlorine pesticides and polychlorinated biphenyls (PCBs). PCB concentrations in air are decreasing at most sites though at a differing rates. OCP concentrations are steady and declining less rapidly over time at the majority of sites, especially lindane and the chlordanees. Endosulfan and its metabolites are decreasing at most sites, reflecting the regulation of this chemical and its relatively lower environmental persistence compared to other POPs. DDT shows different trends depending on sampling region with some examples of recent use.

43 Legacy POPs, new POPs, PAHs and compounds of emerging concern in the atmosphere of Bogota (Colombia) using XAD-based passive samplers

A. Azevedo, Instituto Federal do Rio Grande do Sul; B. Johnson-Restrepo, University of Cartagena / School of Exact and Natural Sciences; P. Pribylova, Masaryk University / RECETOX; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; G. Fillmann, Federal University of Rio Grande / Instituto de Oceanografia

The present study assessed the levels of legacy Persistent Organic Pollutants (POPs), new POPs, Polycyclic Aromatic Hydrocarbons (PAHs) and some compounds of emerging concern in the atmosphere of Bogotá, Colombia using XAD2-based passive atmospheric samplers (XAD-PAS). Samplers were deployed at 8 urban sites for 12 months between 2014-2016, as part of LAPAN (Latin American Passive Atmospheric Sampling) Network. XAD2 samples were analyzed by gas chromatography/mass spectrometry at RECETOX (Masaryk University - Czech Republic). Resins were analyzed for 10 PBDEs (polybrominated diphenyl ethers), 17 nBFRs (novel brominated flame retardants), 38 CUPs (currently-use pesticides), 30 OCPs (organochlorine pesticides), 7 PCBs (polychlorinated biphenyls) and 15 priority PAHs. Results for nBFRs and CUPs were reported as sequestered amount of the compound per PAS and exposure time, while PBDEs, OCPs, PCBs and PAHs were reported in volumetric concentration considering the specific sampling rates. XPBDEs showed an average concentration of 2.3 ± 1.3 pg m⁻³ and a predominance of BDE47, 99 and 100, the main components of commercial penta-BDE mixture. XnBFRs, with an average level of 2.9 ± 2.5 pg PAS-1 day⁻¹, were dominated by PB2 (pentabromotoluene) and α-TBEC (dibromomethylcyclohexane) at all sites. XOCUPs presented an average level of 50.2 ± 70.6 pg PAS-1 day⁻¹. Among the 38 investigated CUPs, only 12 were above detection limit (predominance of tebuconazole and chlorpyrifos), indicating a limited influence of surrounding agricultural areas over this urban region. XOCUP and XPCBs showed average concentrations of 151 ± 27 pg m⁻³ and 27.2 ± 20.4 pg m⁻³, while PeC and HCB were the predominant legacy pesticides, and PCB28 the main congener found, respectively, at all sites. Higher vapor pressure PAHs ( phenanthrene, fluorene and fluoranthene) had the highest concentrations at all sites, with an average concentration of 3676 ± 1813 pg m⁻³ for XPAHs. Slightly higher levels of contaminants were found in areas under heavier traffic and/or more densely populated, such as Pardo

Rubio (PBDEs and CUPs) and La Candelaria neighbourhoods (nBFRs and OCPs) and Municipality of Zipaquirá, northern Bogota (PAHs). In spite of that, most contamination levels are comparable to other studies done in large cities using different PAS.

44 GAPS megacities: First results for flame retardants and metals in urban air across the globe

A. Saini, Environment and Climate Change Canada / Air Quality Research Division; N. Jariyasopit, Mahidul University / Siriraj Hospital; E.O. Gagá, Eskişehir Technical University; J. Falandyz, Gdańsk University; K. Kannan, Wadsworth Center, New York State Department of Health / Division of Environmental Health Sciences; G. Stevenson, A. Yates, National Measurement Institute; A.J. Sweetman, Lancaster University / Lancaster Environment Centre; B. Jimenez, IQOOG-CSIC / Department of Instrumental Analysis and Environmental Chemistry; B. Aristizábal, National University of Colombia at Manizales; N. Rojas Roa, National University of Colombia at Bogotá; M. Tominga, CETESB - Companhia Ambiental do Estado de São Paulo; O. Arradour-Munoz, National Autonomous University of Mexico / Centro de Ciencias de la Atmosfera; K.S. Miglioranza, University of Mar Del Plata / Instituto de Investigaciones Marinas y Costeras.; C.A. Manzano, University of Chile / Chemistry; R. Alani, University of Lagos, Nigeria / Department of Chemistry; T. Shoeib, American University of Cairo; R.K. Sinha, Patna University / Department of Zoology; J. Ma, Peking University / College of Urban and Environmental Science; T. Nishino, Tokyo Metropolitan Research Institute for Environmental Protection; R. Suresh, The Energy and Resources Institute, New Delhi

GAPS Megacities is a new, multi-national pilot study under the umbrella of the Global Atmospheric Passive Sampling (GAPS) network. The aim of the project is to investigate levels and spatial patterns of organic pollutants and metals and to explore assay-based health indicators in the most highly populous cities in the world. Urban areas are the primary emission points for a range of persistent organic pollutants (POPs) such as flame retardants (FRs), with contributions from multiple source sectors. Given the fact that the majority of the world’s population reside in urban settings, air pollution in these environments is one of the predominant factors impacting human health. The high levels of POPs add to the chemical burden in urban air and resulting toxic effects. This work advances domestic and international initiatives for chemicals management by linking air pollution and health. Polyurethane foam passive air samplers (PUF-PAS) were deployed in 20 major cities with populations ranging from 3 to 22 million. Pre-cleaned PUF disks and double-dome housings were sent to collaborators for deployment. Samplers were deployed for two 3-month periods in 2018 to capture gas- and particle-phase chemicals. Upon retrieval, samples were shipped back and stored below -10 °C. Details for sample extraction and processing are provided in Rauert et al. (2018). Samples from first period of deployment were analysed for organophosphates esters (OPEs), polybrominated diphenyl ethers (PBDEs), novel flame retardants (NFRs) and hexabromocyclododecane (HBCDD) compounds. All urban sites were dominated by OPEs with concentration of £100OPEs ranging between 900-17000 pg/m³ and highest levels measured at New York (USA) and London (UK) sites. The total levels of other FRs were 2 orders of magnitude lower than OPEs. Across all sites, NFRs were higher or equivalent to PBDEs. Upcoming analysis includes measuring levels of total metals in urban air and will generate new information on use/emission patterns and how these differ among sites/regions and in relation to urban source characteristics.

45 Silicones (siloxanes) as environmental sources of polychlorinated biphenyls (PCBs)

L.A. Rodenburg, Rutgers University / Environmental Sciences

Polychlorinated biphenyls (PCBs) are persistent organic pollutants (POPs) addressed as one of the ‘dirty dozen’ original POPs under the Stockholm Convention. PCBs consist of 209 separate congeners and in many countries, including the US, are regulated as the sum of all 209 congeners. The main sources of PCBs in most developed countries are the original PCB
formulations intentionally manufactured in many countries. Recently it has become clear that there are other, inadvertent, sources of PCBs. Organic and inorganic pigments have been identified as important sources of inadvertent PCBs. We here introduce a new source of inadvertent PCBs: silicones, also known as siloxanes. Recent measurements of all 209 PCBs in samples from various locations in the US. display evidence of two types of silicone-related PCB sources: PCBs 44+47+65, 45+51, and 68 arising from polymers cured using bis(2,4-dichlorobenzoyl) perox- ide, and PCBs 1, 2, 3, 4, 8, 15 and others arising from silicone products derived from phenylsiloxanes. Products that use phenylsiloxane-based silicon include adhesives, caulks, sealants, and additives for paint, among many other uses. Due to their ubiquitous use, silicone-based products appear to be an important source of PCBs to laboratory blanks, and can appear as contaminants in water samples collected using silicone rubber tubing. In some locations where silicones were manufactured, PCBs from these sources can be important in environmental samples.

**46 Direct injection analysis of legacy and emerging PFAS in soil and sediment**

K. Rosnack, Waters Corporation / Food & Environment Markets; K. Organtini, Waters Corporation; S. Oehrle, Northern Kentucky University

Perfluoroalkyl substances (PFAS) are common, man-made, persistent environmental contaminants that are used in the production of many consumer products such as non-stick coatings, surfactants, and for stain and water resistance coatings. PFAS are also a major component of fire fighting foams used for suppression of fuel fires. Global widespread use of these compounds over many decades has led to their release into the environment. Current advisory guidelines around the globe mainly use of these compounds over many decades has led to their release into the environment. Current advisory guidelines around the globe mainly use parts per trillion (ppt) detection of a variety of legacy and emerging PFAS. Due to the amphiphilic properties of PFAS they are found not only in water, but also soils and sediments. In this work we evaluated a simple extraction method coupled with large volume injection onto a high sensitivity mass spectrometer for the analysis of a wide range of legacy and emerging PFAS in soils and sediments. A basic sample preparation approach was used which consisted of diluting a 2 g sample of soil or sediment in 10 mL of 1:1 water:methanol, shaking for 1 hour, and syringe filtration. Acid was added to each sample before injection. A 30 µL injection was performed on a high sensitivity LC-MS/MS system. 31 native PFAS and 20 isotope labelled PFAS standards were evaluated, including GenX and other emerging PFAS compounds of interest. A variety of soil and sediment types from an EPA study were evaluated including silt, sand, lean clay, and fat clay. The simple extraction method was successful in extracting all PFAS compounds in the prescribed range of 70 – 130% from all sample types. Limit of detection for all compounds was in the low ng/kg (parts per trillion) range making this method suitable for the trace level detection requirements. Multiple quality control samples were monitored throughout the analysis including solvent blanks, method blanks, sample blanks, laboratory controls, and continuing calibration checks. All QC samples passed typical requirements for best practices in analytical data quality. A variety of PFAS were positively detected in the blank soil samples indicating the prevalence of PFAS in all types of environmental samples. The simple extraction method coupled with a large volume injection proved to provide a robust and sensitive workflow for PFAS analysis in soil and sediment samples. The basic extraction method allows for a reduction in sample preparation time, therefore allowing higher throughput of samples without sacrificing method performance. The authors would like to acknowledge the United States Environmental Protection Agency (USEPA) for providing samples for the analysis.

**47 A baseline atmospheric passive sampling network of legacy and emerging organic contaminants in Sri Lanka**

P. Vlahos, University of Connecticut / Departments of Marine Sciences and Chemistry; C. Rauert, Environment and Climate Change Canada; E. Shipley, University of Connecticut / Marine Sciences; P. Tung, Environment Canada; R. Chandrajith, University of Peradeniya; T. Harner, Environment and Climate Change Canada / Air Quality Research Division

Sri Lanka is part of the United Nations’ Asia-Pacific Global Monitoring Plan (APGMP) region, and is a signatory of the Stockholm Convention on persistent organic pollutants (POPs), however, there is currently no atmospheric monitoring of POPs in this island nation. Here we present the results of a 15 month atmospheric monitoring effort across three representative sites in Sri Lanka that include a dry zone agricultural region (n=5), an urban site (n=5) and a remote mountain site (n=3). Legacy and emerging target pollutants include polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), polychlorinated diphenyl ether (PBDEs) flame retardants, organophosphate ester (POEs) flame retardants, poly cyclic aromatic compounds (PACs), including parent and alky-lated polycyclic aromatic hydrocarbons (PAHs) and dibenzothio-phenes (DBTs). The results show both seasonal and spatial variations in POPs that vary seasonally. The urban site was the most impacted and concentrations were relatively high throughout the sampling period indicative of regional sources for all compound classes except PCBs where lower congeners inferred a remote source. The dry zone had relatively low concentrations but similar seasonality to the urban site. The remote site had one very high period in January to March 2016 where back trajectories showed air masses originated over Southeast Asia and swept over the capital city, whereas concentrations were much lower between April to September when winds originated from the Southern Ocean. These results provide the first baseline POPs data for Sri Lanka and fill in a significant gap in the APGMP region.

**Challenges in Characterizing Exposures to Organic Chemicals: Multiple Sources, Multiple Pathways and Multiple Scales**

**48 Global ecological fate and assessment of home and personal care products**

O. Jolliet, University of Michigan; L.J. Speirs, Unilever; J. Hodges, J. Kilgallon, Unilever / Safety and Environmental Assurance Centre SEAC; C. Wannaz, Eurisko Research / SP/IEHS

The increasing use of household and personal care (HPC) products in developing countries requires new tools to assess the potential ecological impacts of HPCs, accounting for local hydrological and use characteristics. To address these needs, the EcoHOPE project developed a multi-scale multimedia fate and transport model, Pangea, able to estimate freshwater Predicted Environmental Concentrations (PECs) in Asia. This presentation aims a) to present the extension of Pangea implementing the global HYDROBASINS hydrological data set and perform global PEC estimations for the entire world and b) to estimate the spatial variations of five case study Household Product Chemicals (HPCs) within and between all main water basins of the world, i.e Linear Alkylbenzene Sulphonate (LAS), triclosan, D5, octocrylene and octyl methoxycinnamate. First we created a default world grid enabling global coverage with higher resolution in regions of high emissions and populations while ensuring accurate coverage of main rivers in the world. The resulting global version of Pangea/EcoHOPE comprises a total of 496,000 virtual compartments, including more than 70,000 freshwater compartments worldwide. We present cumulative distribution frequency curves of estimated LAS PECs for 390 GCRD water basins, separated by continent. Variation is noticeable across the continents with the lowest modelled concentration of LAS in North America, Western Europe and Australia due to the high connection to Waste Water Treatment Plants (WWTP). The highest modelled
concentrations, are observed in India, China, and Indonesia - associated with high population densities combined with only partial connection to WWTP. When comparing estimated PECs of the 5 case study chemicals, LAS has the highest relative predicted concentrations in Asia due to the higher emissions. All 5 substances have similar median concentrations for North America, due to both high connectivity to waste water treatment plants (WWTP) and high removal of LAS. The development of a multi-scale multimedia model at global level in collaboration with Unilever is a major milestone in the field of PECs modeling of HPCs. While covering the entire globe, the multiscale capabilities of Pangea offer a high resolution in areas of high concentrations or high emission while covering all main rivers of the world.

49 Effect of cannabis legalization to drug consumption in two cities in Canada
E. Aydin, AGAT Laboratories, Ltd / Ultra-trace Organics
Wastewater based epidemiology (WBE) is a prospective and valuable tool for the estimation of drug use. When researchers compared WBE with other drug use estimation tools such as questionnaires, they found that WBE is a more accurate estimation tool than surveys since it does not rely on honest responses. They also suggested WBE can be instrumental to provide substantial and reliable data to a body of government for identification of policy and legislation changes. In this study, our objectives were (1) to identify the short-term effects of cannabis legalization on consumption rates of not only cannabis but of other drugs as well, (2) to identify drug consumption rates and patterns in two different cities in Canada with a different population structure during a time period of 50 days. For this purpose, we monitored cocaine metabolites (benzoylcgonine, and coca- ethylene), heroine metabolites (morphine and 6-acetylmorphine), codeine, MDMA, methamphetamine, amphetamine, LSD and its metabolite (2-oxo-3-hydroxy-LSD), Fentanyl and its metabolite (norfentanyl), alcohol metabolite (ethyl sulfate), and cannabis metabolite 11-nor-9-carboxy-Δ9-THC (THC-COOH) in three wastewater collection systems serving more than 2,000,000 people in total. It is the first time that a powerful tool such as WBE has been used to identify the effects of this major policy change on drug consumption. Results contribute to not only the effects of legislature change but also the identification of consumption rates, consumption trends, and consumption pattern differences over 50-day period in three different residential areas. This long-term uninterrupted data enabled us to use advanced statistical tools to interpret consumption patterns during the sampling period. Here, we show that the legalization of cannabis had only a minor effect on total drug consumption in two cities in Canada. We also determined temporal and spatial changes of drug consumption patterns for alcohol, amphetamine, cannabis, cocaine, MDMA, and methamphetamine with a 50-day monitoring period. This monitoring revealed one of the highest cannabis, cocaine and alcohol consumption rates in the literature (100 g/day/1000 inhabitants, 8.9 g/day/1000 inhabitants, and 100 L/day/1000 inhabitants, respectively) and higher methamphetamine consumption rates (as high as 2.5 g/day/1000 inhabitants) in a relatively small city with a 10 times lower population.

50 High-resolution global mean-annual surface runoff and river flow datasets for use in risk assessments
The availability of detailed surface runoff and river flow data across large geographic areas is crucial for modeling in ecological risk assessments; a few countries (e.g., U.S.) offer such data at a high-resolution and most countries do not. Lack of detailed spatial data and challenges with intense processing have been the limiting factors in developing high-resolution river flows over large spatial scales. iSTREEM(R), a broad-scale spatial model in the U.S. incorporates a detailed hydrology network with river flows from the NHDPlus to estimate exposure across large areas from the use of down-the-drain chemicals. It combines WWTP emissions into corresponding flow at receiving rivers to estimate dilution factors and down-the-drain chemical concentrations, and route them through the river network. A similar approach to integrate chemical emissions with a global hydrologic river network and associated flows can be employed to estimate local dilution factors and chemical concentrations across river network over countries where environmental concerns are a high priority. To address this specific need, the well-established Curve Number (CN) method was applied to develop a detailed surface runoff dataset. Publicly available, scientifically accepted and high-resolution global datasets for hydrologic soil groups, land cover, and precipitation were spatially processed by applying the CN equations to generate a contiguous global mean-annual surface runoff grid at a very high-resolution of 50m x 50m. Surface runoff was converted to river flow by spatially combining with a detailed global hydrology of rivers and catchment boundaries from HydroSHEDS and HydroBASINS to estimate mean-annual flows across the global river network. Evaluation of the estimated river flow was conducted against publicly available gage measurements in China and river flows in the Ohio River basin, U.S.; both showed high correlation (r2 = 0.70 for China and 0.97 for Ohio River). Applying the detailed global mean-annual river flows with broad-scale environmental exposure models like iSTREEM(R) provides a robust approach to assess ecological risk of chemicals used in home and personal care products, cosmetics, pharmaceuticals, etc. over large river basins, across a country, or at a continental scale.

51 Using mechanistic, integrative environmental modeling to address the multi-dimensional human chemical exposure
L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences
Integrated environmental modeling has been advocated as a novel paradigm to tackle a wide spectrum of environmental issues (e.g., climate change and air pollution) in a holistic and comprehensive manner. In this presentation, we demonstrate how integrated environmental modeling aids in addressing the multi-dimensional nature of human chemical exposure (multiple sources, pathways, and scales). We introduce an integrated human exposure model named “PROTEX” (“PROduction-To-Exposure”), which allows modeling the journey of chemicals from production to dose in the human body by coupling a technosphere module, a nested indoor-urban-rural environmental fate module, a food-web bioaccumulation module, and a human exposure-toxicokinetic module. The PROTEX model integrates state-of-art knowledge for processes and transport of chemicals in the technosphere (i.e., human socioeconomic system), physical environment, and biosphere (i.e., food webs and humans). Such a mechanistic, integrative modeling approach sheds light on the time-variant exposure of multiple cohorts of the general population to chemicals via multiple exposure routes (e.g., near- vs. far-field exposure routes) resulting from emissions from multiple lifecycle stages (e.g., industrial processes, indoor uses, and waste handling). The performance of PROTEX is evaluated through comparisons between modeled and measured concentrations in various environmental media and the human body. As case studies, we demonstrate how the PROTEX model characterizes the aggregate exposure of Swedes to PCBs, and Canadians to PBDEs. Our modeling explains the reason that the relative importance between near- and far-field exposure routes varies between sampling times, congeners, and sampled age groups, and how such variations are linked to the properties of chemicals and associated products, environmental settings, and human behaviors and exposure factors. PROTEX provides mechanistic insights into human exposures that cannot be achieved by traditional approaches considering separate components of the complex production-to-exposure continuum. The model offers a scientifically defensible and unique tool for chemical management decision-making.
52 Target and non-target screening of chemicals in the indoor environment for human exposure assessment
M. Lamoree, I. van der Veen, S. Brandsma, Vrije Universiteit, Amsterdam / Environment and Health; C. de Wit, Stockholm University / Environmental Science and Analytical Chemistry; F. Yao, U. Sellschop, O. Sandblom, M. M. Plassmann, J. P. Benskin, Stockholun University / ACES; S.J. Harrad, The University of Birmingham; D. Drage, The University of Birmingham / School of Geography Earth and Environmental Sciences; N. Weiken, National University of Ireland Galway / School of Physics & the Ryan Institute; M. Coggins, National University of Ireland Galway; A. Covaci, G. Poma, C. Christia, University of Antwerp / Toxicological Centre; K. De Brouwere, VITO NV / Health; L. Geerts, VITO NV; J. A. Arnot, ARC Annot Research & Consulting; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; J. de Boer, P. Leonards, Vrije Universiteit Amsterdam / Environment & Health

People are spending more and more time indoors in well-insulated buildings, and are more heavily engaged with multiple electronic devices already at a young age. The indoor environment is known to be contaminated by compounds belonging to various classes, that are emitted from construction materials, interior decorations, kitchen utensils, food packaging, electronic equipment, carpets, textiles, flooring, furniture, etc. The indoor environment is rather complex as there are several sources of substances and some of the substances can even have multiple functions. Within the SHINE project (funded by CEFIC-LRI), aiming at target and non-target screening of chemicals in the indoor environment for human exposure assessment, firstly, novel BFRs, HBCDDs, OPFRs, PFASs, CPs, plasticizers and pesticides were analyzed in dust and air samples from homes, offices and daycare centers in several European countries. In addition to this targeted analysis aimed at quantifying the levels of known contaminants, a database was compiled to support the suspect screening of these samples using high resolution mass spectrometry to identify chemicals of emerging concern. Information from the CPCat, KEMI, BUMA, NORMAN and ECHA databases was combined with reports from the literature on the occurrence of chemicals in consumer products, dust and air [1]. Suspect screening of a selection of dust and air samples is ongoing, while the concentrations of > 100 different compounds belonging to a wide variety of chemical classes form a rich data set for evaluation of e.g. trends and differences in use of certain compounds between countries, but also for human exposure modeling. The model of choice is the RAIDAR-ICE model (Risk Assessment, IDentification And Ranking - Indoor & Consumer Exposure), a model for risk-based screening and prioritization of human exposure to chemicals from near-field sources [21]. Lucattini, L., Poma, G., Covaci, A., De Boer, J., Lamoree, M., Leonards, P. 2018. A review of semi-volatile organic compounds (SVOCs) in the indoor environment: occurrence in consumer products, indoor air and dust. Chemosphere, 201, 466-482.2. Li, L., Westgate, J.N., Hughes, L., Zhang, X., Givehehi, B., Roose, L., Armitage, J.M., Wania, F., Egeghy, P., Arnot, J.A. 2018. A model for risk-based screening and prioritization of human exposure to chemicals from near-field sources. Environmental Science & Technology, 52, 14235-14244.

53 Combining river model with a toxicokinetic model to simulate the whole-body burden of micropollutants in sensitive freshwater invertebrates
M. J. Arias, Eawag - Swiss federal Institute of Aquatic Science and Technology / Biology/Civil and Environmental Engineering; C. Stamm, J. Hollender, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Chemistry

The aquatic environment is repeatedly exposed to micropollutants (e.g., pharmaceuticals, personal care products, and pesticides) primarily released from wastewater treatment plants (WWTPs). The use of modeling techniques in micropollutant monitoring is increasingly recommended not only for predictive assessments but also to supplement costly chemical and bioanalytical studies. Furthermore, it has been strongly advocated that information on the fate and transport of micropollutants in the receiving environment can be subsequently linked to the contaminant dynamics within the organism and/or at its target site of action. In this study, we coupled a simple river model with a toxicokinetic (TK) model to determine the impact of highly dynamic environmental concentrations in the movement of micropollutants in freshwater invertebrates (Gammarus spp.). After evaluating several surface water quality modeling approaches, we employed the dilution model to estimate the concentrations of 22 micropollutants downstream of 9 WWTPs in Swiss midlands. Monte Carlo simulation was further applied within the dilution model to account for the scarce data in effluent concentrations. The outputs from the river model were then employed as inputs into the TK model that simulates the time course of micropollutants in invertebrates. Both river and internal concentration simulations mostly agree with the measured data, suggesting the suitability of the assumptions and simplifications employed within the models. Furthermore, since data on the uptake (ku) and depuration (kd) rate constants required to run the TK model are limited, we evaluated the model under steady-state conditions. It was observed that the bioaccumulation factors (BAFs, ku/kd) may be employed to predict the fluctuating internal concentrations in invertebrates. These results additionally suggest that when the uptake occurs faster relative to the exposure dynamics, the use of scaling factors (dilution factors and BAFs) within the river and TK models are sufficient when predicting the internal concentrations. However, caution must be exercised when following this modelling platform as the study is only restricted to small streams that are well-mixed a few meters below the WWTP discharge pipes. In the future, the time-varying field simulation of external (river) and internal concentrations may be combined with higher-level effects modelling to finally link exposure and effect.

54 Understanding Spatial and Temporal Patterns of Contaminants in the Maumee River to Assess Biological Hazards

Assessing the potential for adverse biological effects of complex contaminant mixtures in aquatic environments is an ongoing challenge. The interplay of environmental complexity, seasonal variation, and human activities leads to dynamic mixtures varying through space and time. To evaluate potential hazards influenced by system complexity, an understanding of how chemical mixtures vary across anthropogenic gradients interannually and seasonally is necessary. To better characterize the spatial and temporal variability of contaminants in an agricultural to urban watershed, we collected data from 8 locations in the Maumee River watershed (OH) during 2012 and across two seasons in 2016. Sites were selected to capture a range of human activity gradients including wastewater treatment, urban drainage, and agricultural sources. Analysis of organic contaminants targeted pharmaceuticals and wastewater indicators to evaluate interannual patterns among sites between 2012 and 2016. In 2016, a detailed assessment of pesticides was conducted to observe seasonal variability. Chemicals varied greatly across sampling sites, ranging from 27 to 64 chemicals detected in 2012. Sites downstream and nearby WWTPs generally had the highest chemical detections for pharmaceuticals and wastewater indicators. In 2016, pesticide concentrations increased significantly in June with pronounced changes in more
agricultural, upstream locations. Highest concentrations were detected for atrazine and metolachlor in 2016. Hierarchical cluster analysis revealed distinct site separations associated with diverse chemical mixtures across the landscape for both years indicating such approaches may be effective to predict chemical occurrence for future prioritization. To put chemical concentrations into a biological context, exposure-activity ratios (EARs) for detected chemicals were assessed using the ToxCast database. EAR analysis identified multiple sites, biological pathways, and chemicals that warrant future prioritization for assessment in the complex system. This abstract does not necessarily reflect USEPA policy.

55 Determination of pesticide exposure in aqueous systems through measurement of water, suspended sediment, and zooplankton

The Cache Slough/Liberty Island complex and the Yolo Bypass are areas of critical habitat for several San Francisco Bay-Delta (California) fish species including the threatened Delta Smelt, and multiple restoration projects are planned in these areas. In addition, recent research suggests that the Yolo Bypass can serve as an important source of phytoplankton and zooplankton, benefitting fish downstream. However, these areas are impacted by agricultural and urban runoff containing mixtures of current-use pesticides which may have direct, harmful effects on fish as well as on plankton production and quality. Samples were collected from sites within the Yolo Bypass as well as one comparison site on the Sacramento River during 2017-2018. Samples were collected during baseflow and managed pulse flow conditions and were analyzed for over 150 current-use pesticides and pesticide degradates in water, suspended sediment, and zooplankton. In water and suspended sediment 49 pesticides were detected including 14 fungicides, 16 herbicides, 18 insecticides, and 1 synergist. All water and suspended sediment samples contained a mixture of pesticides that ranged from 3 to 27 compounds. For the zooplankton samples, 22 pesticides were detected (3 fungicides, 8 herbicides, and 11 insecticides); these included nine pesticides that were not detected in water or suspended sediment samples (the pyrethroid insecticides cyfluthrin, cyhalothrin, cypermethrin, esfenvalerate and permethrin; p,p’-DDT, p,p’-DDD, p,p’-DDE, and pendimethalin). Knowledge of the composition and timing of occurrence of these pesticide mixtures is critical to understanding and mitigating any potential detrimental environmental effects. Determining which pesticides are detected in various environmental compartments, including zooplankton, can aid in better determining exposure and potential effects of pesticides to sensitive species.

Environmental Occurrence, Bioaccumulation, Fate and Transport of Poly- and Perfluoroalkyl Substances (PFAS)

56 PFAS in the urban terrestrial ecosystem; the case study Oslo city
D. Herze, NILU - Norwegian Institute for Air Research / FRAM Centre Tromsø; E.S. Heimstad, NILU Norwegian Institute for Air Research; T. Nygård, Norwegian Institute for Nature Research NINA

As a part of modern way of life, a large number of chemicals is emitted into the urban environment exposing the coexisting wildlife to a complex mixture of harmfull chemicals with only very little understanding to their concentrations, composition and impact. Both conventional and emerging PFAS are an important part of these urban emissions to the terrestrial environment in Norway. A food chain encompassing soil, earthworms, fieldfare and sparrowhawk, as well as predators as towiny owls, foxes and badgers were investigated together with the insects represented by bumblebees and a opportunistic feeder, the brown rat in a comprehensive investigation of the terrestrial ecosystem in the city of Oslo, within 2014 to 2018. More than 50 PFAS were measured. Distinct interspecies differences were found. PFOS is the overall dominating compound. PFDoA, PFTriA and PFTeA contribute more higher up in the food-chains (fieldfare, sparrowhawk and towiny owl), but also in rodents. Emerging PFAS were also detected. In general, we found a broad variety of the investigated pollutants in all matrices, with even being able to point out so far unknown pointsources of pollution within the city. Elevated PFAS concentrations in soil and earthworms were for example found in locations used for skiing activities, airport as well as industrial activities. When comparing with remote samples, the urban impact on PFAS exposure could also be shown for a number of species, pointing to complex sources within large cities. The estimation of bioaccumulation and trophic magnification showed TMF > 1 for PFOS and the longchained PFCAs in the foodchain earthworm - fieldfare - sparrowhawk while no magnification could be found for PFHxS and PFCAs shorter than PFOA.

57 Fluorine Mass Balance in Marine Mammals from the Northern Hemisphere - A combination of targeted, total (organofluorine, and non-targeted analysis
K. Spann, C. Van Noordenburg, Stockholm University / Department of Environmental Science and Analytical Chemistry; M.M. Plassmann, Stockholm University / ACES; L. Schultes, Stockholm University / Department of Environmental Science and Analytical Chemistry; S. Shaw, Shaw Institute / Blue Hill Research Center; M.L. Berger, Shaw Institute; M. Heide-Jørgensen, Greenland Institute of Natural Resources / Climate Research Center; A. Rosing-Asvid, K. Laidre, Greenland Institute of Natural Resources; S.M. Granquist, Marine and Freshwater Research Institute; R. Dietz, C. Sonne, Aarhus University / Department of Arctic Environment; A.M. Roos, Swedish Museum of Natural History / Dep of Environmental Research and Monitoring; J.P. Benskin, Stockholm University / ACES

Per- and polyfluoroalkyl substances (PFASs) are ubiquitously spread in the environment and have been detected in abiotic and biotic media, including blood of humans and wildlife globally. While most research has focused on studying the occurrence and behavior of < 30 PFASs, recent studies have shown that these substances may only represent a small fraction of the extractable organofluorine (EOF) in the environment. Here, a fluorine mass balance analysis was applied to livers from eleven different marine mammal species from five different locations. Out of 36 target PFASs, 20 were quantifiable, of which perfluorooctane sulfonic acid (PFOS) was the dominant substance. The second most predominant substance was 7:3 fluorotelomer carboxylic acid (7:3 FTC), which is reported here for the first time in polar bears (~1000 ng/g, ww) and cetaceans (~6-190 ng/g, ww). The 7:3 FTC was also observed in seals, but in higher concentrations than reported previously (~6-190 ng/g, ww). EOF measurements were carried out using a combustion ion chromatography (CIC) and seven samples showed a significant gap between target PFAS concentrations and EOF concentrations, where the unidentified fraction ranged from 30-75% of the EOF. Suspect screening utilizing liquid chromatography - high resolution mass spectrometry (LC-HRMS) revealed an additional 20 PFASs (from 5 classes) which were not included in the targeted analysis, bringing the total number of PFASs detected to 44. Overall, these results demonstrate that focusing on the standard suite of perfluoroalkyl acids underestimates PFAS exposure in marine mammals. Since few toxicological data are available for the novel PFASs detected in the present work, these substances pose unknown risks to marine mammals as well as humans who consume them for food.

58 Per- and polyfluoroalkyl substances (PFAS) concentrations in human placental tissues and associations with birth outcomes
S. Hall, M.T. Ruis, S. Zhang, K. Hoffman, Duke University / Nicholas School of the Environment; M. Miranda, Rice University; H.M. Stapleton, Duke University / Nicholas School of the Environment

Per- and polyfluoroalkyl substances (PFAS) are ubiquitous environmental contaminants that have been found in human serum, breast milk, and umbilical cord blood. Placental transfer of PFAS to developing fetuses has been observed and is of concern due to the known toxicity of these compounds. Previous studies have found associations between maternal
59 Investigation of Perfluoroalkyl and Polyfluoroalkyl substances (PFAS) in foods in the United States

S. Genualdi, L. deJager, US Food and Drug Administration / Division of Analytical Chemistry; T. Begley, Food and Drug Administration / Center for Food Safety and Applied Nutrition

Perfluoroalkyl and polyfluoroalkyl substances (PFAS), in particular perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), have been widely studied due to their persistence, distribution, toxicity, and bioaccumulation in humans and the environment. Humans can be exposed to these compounds from environmental contamination (landfills, wastewater treatment plants, the use of aqueous film forming foams (AFFF)), household exposure (upholstery, carpeting, dust) and the diet. Recently several contamination events in the United States caused concern of possible contamination of food commodities produced using contaminated water and soil. A QuEChERS LC-MS/MS method has been developed for PFAS in a number of commodities including fruits, vegetables, milk, cheese, grains, meats and other foods. This method was further used to analyze 91 composite food samples collected in the Mid-Atlantic region as part of the FDA’s Total Diet Study program. This method was also used to analyze produce samples collected in a region near a PFAS production plant in the eastern US and to analyze samples (milk, water, silage, cheese) collected from a dairy farm in New Mexico with contaminated ground water due to its close proximity to an Air Force Base where AFFF was used. The results of this data will be used by the FDA to estimate human dietary exposure. This method will also be used by the FDA to monitor food samples including certain Total Diet Study samples.

60 Mapping the Extent of PFAS Contamination in North Carolina’s Drinking Water Sources: The NC PFAST Monitoring Network

A. Joyce, Duke University / Civil and Environmental Engineering; N. DeStefano, North Carolina State University; Z. Hopkins, NC State University / Department of Civil, Construction, and Environmental Engineering; G.J. Getzinger, Duke University / Civil and Environmental Engineering; Y. Han, M. Sun, University of North Carolina at Charlotte / Civil and Environmental Engineering; D. Knappe, North Carolina State University / Civil, Construction and Environmental Engineering; L. Ferguson, Duke University / Civil and Environmental Engineering

Per- and Polychlorinated alkyl substances (PFASs) have been found to contaminate drinking water sources in several locations throughout the state of North Carolina (NC). The sources of this contamination are in some cases well-understood, e.g. fluorochemical manufacturing discharge to rivers, firefighting activities at military installations, and application of biosolids to agricultural fields leading to runoff runoff into reservoirs. Data from the US Environmental Protection Agency’s third Unregulated Contaminant Monitoring Rule (UCMR3), suggests at least 13% of NC public water systems have detected at least one PFAS species in their drinking water. While UCMR3 only targeted 6 PFAS compounds (from two legacy PFAS classes), these results suggest there are additional unknown sources of PFAS contamination to drinking waters within the state. We have initiated a broad-ranging monitoring study to assess occurrence and map sources of PFAS in drinking water sources across NC in order to assess this uncertainty. This work, mandated by state legislative action, involves sampling and analysis of all municipal drinking water sources in NC for PFASs using suspect screening, non-targeted analysis, and quantitative measurements. We are collecting raw water from 191 municipal surface water systems and 149 municipal ground water systems, with two rounds of sampling at each site to be finished by the end of 2019. Quantitative measurements are conducted using a novel sensitive and high throughput, direct-injection LC-MS/MS method for measuring 48 PFAS compounds at low ppt concentrations. This method includes PFCAs ranging from C4 through C16, PFSA, zwitterions, and 16 new generation ether-acid/sulfonate compounds including GenX. The wide range of PFAS classes targeted will inform about possible PFAS sources and their impacts on drinking water sources. Non-targeted analysis and suspect screening utilizes high resolution, Orbitrap tandem mass spectrometry combined with cheminformatic and computational mass spectrometry methods for annotation of chemical structures. Results of our analyses to date indicate sporadic groundwater and surface water contamination with legacy PFAS (including PFCAs and PFSA)s at levels exceeding the 70 ng/L USEPA health advisory level as well as persistent elevated levels of new-generation PFAS such as GenX in surface water downstream of a major fluorochemical manufacturing facility.
PFAS concentration in serum. Ongoing analysis of this population will focus on investigating the role of individual and combined PFAS on the reproductive fitness of striped bass. Similar to the fish, American alligators sampled from the Cape Fear River had a high concentration of PFOS in serum. Continuing studies will examine PFAS in the muscle tissue of recreationally harvested species within the Cape Fear River (Flathead catfish, Largemouth bass, American shad) to advise the local community consumption guidelines.

62 The application of multi-matrix methods for understanding occurrence of emerging PFAS in water, soil, sediment and fish in North America

B. Chandramouli, C. Hamilton, M. Woudneh, R. Grace, SGS AXYS Analytical Services, Ltd.

Monitoring of PFAS across multiple ecosystem compartments is a critical tool in assessing fate, transport, effects and exposure. Two decades worth of PFAS monitoring, especially in biota, have focused on a short list of carboxylates and sulfonates such as PFOA and PFOS. Given the phaseout of PFAS monitoring, especially in biota, have focused on a short list of tool in assessing fate, transport, effects and exposure. Two decades worth of PFAS monitoring, especially in biota, have focused on a short list of precursors/intermediates including FOSA, MeFOSA and EtFOSA, MeFOSAA and EtFOSAA, and MeFOSE and EtFOSE. All methods used best-practice approaches including isotope dilution, weak anion exchange (WAX) and carbon cleanup and shared common instrumental methods to facilitate comparison across ecosystem compartments. Results from validation show that with a few exceptions for neutral sulfonamides/ethanol in tissue, recoveries were between 70-130% for analytes and 50-150% for isotope-dilution surrogate standards. Water, soil, sediment and fish from five sites in Canada and the US were analyzed for this expanded PFAS list. Results showing overall occurrence of emerging PFAS such as HFPO-DA and 6:2 FTS, and relative abundance compared to PFAAs such as PFOA and PFOA are in progress and will be presented.

63 Multimedia, Non-Targeted Examination of Emerging PFAS Sources

J. McCord, US Environmental Protection Agency / ORD; M.J. Strynar, US Environmental Protection Agency / ORD/NERL/EMMD

Per- and polyfluoro alkyl substances (PFAS) are an environmentally persistent and high interest class of chemical pollutants with a rapidly expanding roster. As manufacturing processes evolve, the number of PFAS in use in commerce has exploded to thousands of analytes, and new and emerging analytical techniques are necessary to identify and monitor the most environmentally relevant chemical pollutants. High resolution mass spectrometry (HRMS) has been a workhorse technique supporting non-targeted approaches to sample analysis, compound discovery, and chemical characterization across a range of media and unique circumstances. The application of the EPA’s PFAS lists to HRMS screening has allowed rapid examination of unknown samples for the ever-expanding list of known PFAS chemicals. New chemical species continue to be uncovered and described using a combination of computational tools - formula and fragmentation prediction, homologous series screening (e.g., CF2, CF2O, etc.), and geographic/temporal feature correlation. Tentative assignment from the preponderance of chemical evidence (i.e., HRMS isotope/fragment information and spectral predictions) offers a methodology for PFAS analysis while the availability of authenticated, commercially available standards lags the diversity of known species. PFAS screening and discovery approaches have been applied to numerous industrial production/use sites for fluoropolymers throughout the United States and reveal a varied landscape of emerging PFAS chemicals. Environmentally relevant emerging PFAS are structurally diverse, corresponding to their specialized applications by different users/producers. This diversity leads to variable occurrence across media - air, soil, water, and biota - that reveals the underlying chemical nature of the species and informs assessment of their transport mechanisms and human health risk.

Environmental DNA (eDNA) Approaches to Enhance Biodiversity Monitoring and Risk Assessments - Part 1

65 The potency of environmental nucleic acid detection: advancing the sensitivity of the biodiversity toolkit

S. Crookes, M. Thomas, L. Gasparini, K. Romanick, Precision Biomonitoring, Inc.

The biosphere is at tipping point. Faced with the onslaught of anthropogenic climate change, global biotic exchange and widespread habitat loss or modification, the need for highly efficacious and cost-effective biomonitoring tools are needed more than ever. Whilst conventional tools (e.g., nets, electrofishing) represent long established means to gather essential biodiversity data (e.g., age-class structure, parasite loads, etc.), they may not be neutral with respect to unintended side effects (e.g., bycatch mortality, habitat disturbance). Furthermore, they may not meet the requisite standards of extreme sensitivity that are necessary to detect extremely low populations of endangered or invasive species. Highly sensitive tools are increasingly needed to map the distributions of organisms that are otherwise difficult to detect, and thereby increase the confidence of population and ecosystem models. Environmental DNA detection can detect the shed DNA of a target organism or community from simple environmental samples (e.g., water, soil), minimizing the sampling footprint and vastly increasing the sensitivity of surveys. In the past decade, increasing numbers of comparative studies provide evidence in support of increased sensitivity. We provide further evidence in affirming increased sensitivity and review in detail the adaptability of environmental DNA detection to aquatic and terrestrial fields. We also brief on methodological directions environmental molecular genetic detection will take in the future, including how the method may be expanded to include molecular traces of organism functionality (e.g., gene transcripts, or RNA, detection).

66 Development of a novel, non-invasive method of measuring fish stress using water samples

H. Ikert, M.D. Lynch, A.C. Doxey, M.R. Servos, University of Waterloo / Biology; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; B.A. Katzenback, P.M. Craig, University of Waterloo / Department of Biology

Measurements of waterborne environmental DNA are currently being employed to monitor populations of both invasive and endangered fish species throughout the world. However, few studies have examined environmental RNA within the water as a marker of the health status of a local community, an important predictive endpoint. These studies are currently restricted to microbial communities; due to the instability and low abundance of fish mRNA in the water column. However, microRNA (miRNA) can last up to five days, potentially allowing for the measurement within water. miRNA are also conserved, targeted, post-transcriptional regulators of mRNA, and are therefore useful markers of phenotypic responses. Changes in miRNA levels in tissues and circulation have previously been measured in fish in response to acute and chronic stress. Additionally, our group has measured miRNA in water samples; however, changes to specific miRNA in response to stress have never been identified in water. This study examines all miRNA present in rainbow trout blood plasma, mucus, and water samples before and after an acute handling stressor in order to identify environmental markers of stress and elucidate a potential path of secretion into the environment. Rainbow trout (Oncorhynchus mykiss) were held above the water for three minutes, which induced an
acute stress response. Control samples were collected prior to the stressor and stressed samples were collected one-hour post stressor. From these samples, total miRNA was sequenced using Illumina NextSeq technology with an average of 15 million reads per sample. Differentially expressed miRNA were identified and validated in all three sample types. In the water, three miRNA (miR-128, miR-26, and miR-30) were significantly upregulated and one miRNA (miR-451) was significantly downregulated, which can be used as non-invasive biomarkers. In order to understand phenotypic changes that are associated with the altered miRNA in all samples, enriched gene pathways (KEGG) that are affected by altered miRNA were identified using in silico analysis. Changes in these specific miRNA, linked to altered phenotypes in organisms, indicate the overall health status of fish, and due to the conserved nature of miRNA, other aquatic organisms, without the need to sample species. Overall, this study identifies novel, predictive, non-invasive biomarkers for use in environmental monitoring.

67 Quantifying Ecosystem Responses to Stress: An Environmental DNA (eDNA) Approach

J. Feller, Ohio State University / Department of Evolution, Ecology, and Organismal Biology; P.S. Ulrich, Ohio State University / College of Public Health Human Sciences; R.M. Swab, S.F. Spear, The Wilds Conservation Center; R.P. Lanno, Ohio State University / Department of Evolution, Ecology, and Organismal Biology

To better understand ecosystem responses to anthropogenic stress, new biomonitoring methods are needed that assess biodiversity in a quick and cost-efficient manner. The emerging field of environmental DNA (eDNA) potentially offers such an approach, as it may provide rapid, low-cost identification of species present in an area. To test the effectiveness of this new technology, eDNA was collected from ponds along an acid-mine drainage (AMD) gradient within The Wilds Conservation Center (Cumberland, OH). Here there are several AMD-gradient watersheds, with each system often consisting of one AMD-affected headwater pond that filters downstream to several smaller ponds where pH returns to background levels. We previously observed fish recolonization downstream from AMD sources and plan to use eDNA samples to quantify biodiversity in fish, amphibian, and invertebrate communities along a specific AMD gradient. The gradient here consists of 5 primary ponds separated by abandoned beaver dams each with highly different AMD characteristics. The goal of this proof-of-principle study is to estimate biodiversity and community structure at each pond using eDNA. Water quality parameters (pH, metals, conductivity) were also assessed along the gradient for comparison to derived community structures. The main source of metal contamination in our gradient is manganese (~6-10mg/L) with aluminum (~1-4mg/L) and iron (~0.5-3 mg/L) contributing as well. pH values range from 3.5-7.5 across the 5 ponds that were sampled. Our working hypothesis is AMD reduces biodiversity and simplifies community structure at ponds closest to the AMD source and that these ecosystem changes can be detected via eDNA. These simplified community structures can then lead to reductions in ecosystem functions such as carbon cycling. Results from this study will provide a wealth of species information to be used in future remediation efforts by The Wilds. Knowing which levels of AMD correspond to desired community structures can help create AMD benchmark levels.

68 Identifying structural responses of bacterial, fungal and eukaryote communities to trace-metals using multi-marker metabarcoding

D. Spurgeon, Centre for Ecology & Hydrology; O. Rimmington, Cardiff University; L. Newbold, A. Robinson, Centre for Ecology & Hydrology; A.A. Horton, Centre for Ecology and Hydrology / Pollution; C. Svensden, CEH, Wallingford / Pollution and Ecotoxicology; E. Lahive, C. Schulz, Centre for Ecology and Hydrology; P. Kille, Cardiff University; A.J. Lawlor, Centre for Ecology & Hydrology; S. Lofts, NERC Centre for Ecology & Hydrology / Shore Section

The pollution of soils by multiple metals released from mining and smelting activities is one of the most pervasive and intractable pollution issues faced today. To understand the effects of metal pollution on ecosystem services, we need to better understand how metals impact on the often unseen soil biodiversity that contributes to key soil processes, such as the bacteria fungi and micro-eukaryotes. The Avonmouth smelter located in the UK was, during its operational life (1928-2003), the largest primary Cd/Pb/Zn smelter in Europe and also one of the largest point pollution sources on the continent. Sampling of 92 soils from sites in the area around the smelter revealed prevailing metal concentrations resulting from aerial deposition from this source ranging from grossly polluted e.g. Cd, Pb, Zn of 300 mg/kg, 1000 mg/kg and 30,000 mg/kg respectively to near background at >12 km distance. These measured concentrations were used to calculate multi-substance potentially affected fractions (msPAF) for all soils to indicate the potential metal stress experienced by the soil community. The structure of the bacterial, fungal and eukaryotic communities inhabiting the sampled site soils were also characterised using 16S rDNA, ITS, and 18S rDNA marker gene metabarcoding. This complex multi-dimensional data-sets were then interrogated to identify the main drivers of soil community change with the aim of identifying metal stress to community structure relationships and identifying characteristic indicators of the metal pollution load. Rank order tests were used to correlate entropies with variables to identify the primary driver-diversity relationship. Trace metal concentration and soil pH were identified as the driving variable of community structure, however, relationships against overall diversity metrics were relatively weak. Cluster analysis was used to identify the minimum number of community types (i.e. sets of related species) present in the region. The distribution of these clusters could be clearly related to soil pH and also the total concentration of metals and bioavailable concentrations in the site soils. Finally, AI algorithms were used to build models that predict the minimal set of indicator species needed to correctly categorize soils according to their prevailing levels of both soil metal stress and pH.

69 The utility of ultra-deep sequencing in environmental metabarcoding studies

G. Singer, N.A. Fahner, A. McCarthy, Centre for Environmental Genomics Applications; M. Hajibabaei, University of Guelph / Biodiversity Institute of Ontario

Environmental metabarcoding is an increasingly popular means of obtaining rapid, inexpensive, and comprehensive biodiversity information. While most comparative studies of eDNA-based and morphology-based analyses of the same sampling sites shows that eDNA is capable of identifying more taxa overall, it is often the case that morphological analysis still finds organisms that were missed by eDNA-based analysis. With the increasing capacity of modern DNA sequencing instruments, we wondered if ultra-deep sequencing could help close this gap by allowing even extremely low eDNA copy numbers to be measured. We applied a standard metabarcoding approach to marine water samples with one exception: instead of employing a typical sequencing depth (~100,000 reads per sample) we obtained millions of reads per sample to see if this additional sequencing effort would allow more taxa to be recovered. Our results demonstrate that ultra-deep sequencing does indeed uncover new biodiversity that shallower sequencing depths would miss. Moreover, we believe these organisms represent low-abundance taxa (e.g., rare or endangered species) that are of particularly great interest to many studies. Finally, modern high-capacity sequencing instruments allow such ultra-deep sequencing to take place for little or no increase in cost per sample when compared with conventional-depth sequencing on previous-generation instruments.
70 Environmental DNA (eDNA) Solutions for Species Detections in Tidal Energy Environmental Effects Monitoring
M. Skinner, Stantec Consulting, Ltd.; M. Murdoch, Stantec Consulting, Inc.; T. Loeza-Quintana, S. Crookes, University of Guelph / Department of Integrative Biology; R. Hanner, Precision Biomonitoring, Inc. / Integrative Biology

Environmental effects monitoring in marine ecosystems are challenging, particularly in dynamic settings like the Bay of Fundy. Environmental deoxyribonucleic acid (eDNA) provides a useful tool for determining species presence in such challenging places to access and sample. Moreover, recent studies showing a link between eDNA concentration and fish density/biomass reveal the great promise for eDNA tools to improve biodiversity assessments in the marine environments. Our project objectives were to: a) develop and refine species-specific TaqMan quantitative polymerase chain reaction (qPCR) assay for eDNA detection of striped bass (Morone saxatilis); b) assess the accuracy and precision of a handheld point-of-need (PoN) tool which can analyze eDNA in situ to confirm species identification in real-time versus conventional laboratory-based eDNA techniques; c) derive estimates of eDNA signal persistence in saline water; and, d) assess whether relationships exist between striped bass densities and eDNA concentration. These objectives were achieved through a series of manipulative laboratory-based mesocosm experiments conducted at Dalhousie University’s Aquatron facility. Using species-specific primers-probe, the first of these experiments determined that striped bass eDNA was reliably detected using either of the laboratory-based or PoN platforms, with some variation observed in the estimates of eDNA concentrations derived from each. Next, a time series experiment established that eDNA in water samples collected within a 24-hour period of exposure to striped bass was reliably and consistently detectable with either platform. Our final experiment found that the linear relationship between eDNA concentrations and manipulated striped bass stocking densities was significant and positive based on results from each of the laboratory-based or PoN platforms. Our results validate and advance eDNA approaches towards environmental monitoring efforts and demonstrate the potential for eDNA tools to quantify and identify the spatial and temporal distribution of species-at-risk in an open ocean environment.

71 Solving eDNA challenges with field-friendly extraction and detection methods
M. Sinnesael, Biomeme / Biology; P. Nguyen, Smith-Root, Inc.; C.S. Goldberg, Washington State University / School of the Environment; A.C. Thomas, Smith-Root, Inc. / Molecular Division

The use of environmental DNA (eDNA) has greatly improved monitoring of water quality, as well as endangered and invasive species in aquatic environments. Superior monitoring increases early detection/prevention of emergent issues, leading many government agencies to adopt eDNA detection methods. However, numerous challenges must be overcome prior to widespread implementation. These include extended periods of time from sample collection to results, variability of sample type and extraction method, and carryover of inhibitors into PCR reactions. Biomeme has developed novel extraction/detection methods to overcome these limitations, including field ready DNA purification kits and portable rechargeable qPCR devices, that can be used with a wide array of sample types in under an hour, on site, without the need for a dedicated lab. The inclusion of an enhanced master mix capable of overcoming common inhibitors found in eDNA extracts has further improved the workflow. This presentation will discuss two recent studies: Early detection of low-density populations of the invasive New Zealand mudsnail (Potamopyrgus antipodarum) in Michigan, USA. Field validation studies were conducted to determine if field eDNA analysis can be used to map mudsnail eDNA distribution and quantify temporal fluctuations. Levels of Flavobacterium psychrophilum (the causative agent of Bacterial Coldwater Disease in salmonids) were examined over a 23-day period after juvenile trout were exposed to the pathogen. eDNA was extracted and analyzed from the fish tank water by two different methods: 1) the Biomeme qPCR platform and, 2) traditional benchtop qPCR workflow. The two methods identified similar fluctuations in F. psychrophilum over the course of the trial and strongly correlated with bacterial counts. This correlation suggests that rapid, field-based qPCR can be incorporated into daily water quality monitoring protocols to detect and monitor microbes in aquaculture systems. Current laboratory methods of eDNA detection can take weeks to produce results; this may prevent timely management action, in addition to requiring dedicated lab space, equipment, and highly trained personnel. The Biomeme eDNA platform represents a major step forward in eDNA analysis by providing rapid eDNA detection results and simplifying the overall process of the eDNA extraction and detection.

Challenges and Strategies for Linking Adverse Effects to Endocrine Modes of Action

72 Distinguishing between endocrine disruption and non-specific effects on endocrine systems
S. Levine, Bayer AG - Crop Science Division / Regulatory; S. Marty, The Dow Chemical Company; C. Borgert, Applied Pharmacology & Toxicology, Inc.; K. Coady, The Dow Chemical Company; R. Green, Vertex Pharmaceuticals; J.R. Wheeler, Shell International; L. Zorrilla, Bayer CropScience / Regulatory; S. Yi, Vertex Pharmaceuticals; E.M. Mihai, ER2

The endocrine system is responsible for growth, development, maintaining homeostasis and for the control of many physiological processes. Due to the integral nature of its signaling pathways, it can be difficult to distinguish endocrine-mediated adverse effects from transient fluctuations, adaptive/compensatory responses, or adverse effects on the endocrine system that are caused by mechanisms outside the endocrine system. This is particularly true in toxicological studies that require generation of effects through the use of Maximum Tolerated Doses (or Concentrations). Endocrine-mediated adverse effects are those that occur as a consequence of the interaction of a chemical with a specific molecular component of the endocrine system, for example, a hormone receptor. Non-endocrine-mediated adverse effects on the endocrine system are those that occur by other mechanisms. For example, systemic toxicity, which perturbs homeostasis and affects the general well-being of an organism, can affect endocrine signaling. Some organs/tissues can be affected by both endocrine and non-endocrine signals, which must be distinguished. This presentation will examine in vitro and in vivo endocrine endpoints that can be altered by non-endocrine processes. We recommend an evaluation of these issues in the assessment of effects for the determination of endocrine disrupting properties of chemicals. This underscores the importance of using a formal and systematic weight of evidence (WoE) process to evaluate potential endocrine activity.

73 An Update on Public Tools for Prediction of Endocrine Hazard and Risk
K. Paul Friedman, J.F. Wambaugh, R. Judson, A.J. Williams, US Environmental Protection Agency / National Center for Computational Toxicology

Prediction of potential chemical-induced endocrine hazard and/or risk is relevant for chemical safety assessment internationally, and there are a number of publicly available tools for this purpose. A workflow for understanding chemical endocrinicity should begin with assessment of available in silico and in vitro data and predictions, integrated consideration of these information, followed by the use of high-throughput toxicokinetic data and models to transform in vitro concentrations to doses that can be compared to the units of exposure for an endocrine bioactivity:exposure ratio (BER). A BER may be a useful metric for prioritization of substances for further evaluation. This presentation provides a brief overview and update on the status of available tools for such a hazard and risk screening workflow. An initial source of endocrine activity information can be defined using results from quantitative structure activity models including the Collaborative Estrogen Receptor Activity Prediction Project (CERAPP) and the Collaborative Modeling
Project for Androgen Receptor Activity (COMPARA); these models provide information for tens of thousands of chemical structures, well beyond the scope of high-throughput screening (HTS) in vitro. HTS data from the ToxCast program have been used to inform models of estrogen and androgen receptor activity and steroidogenesis disruption, and additional HTS assay data are available for thyroid-related bioactivity. HTS bioactivity data and models should be considered in concert with other available information on cytotoxicity, often referred to as the cytotoxicity “burst” threshold that typically aligns with an increase in the number of non-specific assay responses in vitro. For transformation of bioactive in vitro concentrations to external doses for comparison to exposure doses, an R software package that operationalizes high-throughput toxicokinetic modeling using toxicokinetic data from in vivo, in vitro, and/or in silico experiments, HTTK, is available with iterative refinement. Finally, a new meta-model for aggregate population median exposure, ExpoCast, is now available. Much of this information is already viewable in the CompTox Chemicals Systematic Empirical Evaluation of Models (SEEM3), is now available. This abstract does not necessarily reflect

### 74 Predicting Endocrine Disruption with Estrogen Receptor Machine Learning Models

**K. Zorn, Collaborations Pharmaceuticals, Inc.; D.P. Russo, Rutgers University / Center for Computational and Integrative Biology; A.M. Clark, Molecular Materials Informatics; W.E. Hillwalker, D. Feijferek, F.A. Jones, W.D. Klaren, A.M. Brinkman, SC Johnson / GSARA; S. Ekins, Collaborations Pharmaceuticals, Inc.**

Endocrine disruption is a major focus of toxicology research today, driven by government initiatives/responses for the evaluation of environmental risks to the population. The estrogen receptor is a major target of interest, but the downstream effects of activation are difficult to anticipate without expensive, time-consuming in vitro and in vivo testing. The Environmental Protection Agency (EPA) ToxCast program periodically releases high-throughput screening assay data across a wide variety of targets and biological processes. This data has been used by the EPA to construct mathematical models from early and intermediate molecular initiating event assays to predict and rank the likelihood of estrogen receptor activation. However, mathematical models require the in vitro data and lack the power of prospective prediction from molecular structure alone. Bayesian machine learning models (BMLMs) have shown applicability in using drug discovery and toxicology data. The current study describes several groups of BMLMs using either in vitro ToxCast estrogen receptor bioactivity data, the output data of EPA mathematical models, or data which incorporates cytotoxicity considerations. Performance of the BMLMs was evaluated by internal five-fold cross-validation statistics and cross-referencing output predictions with three sets of external in vitro and in vivo reference chemicals. These predictions were generated across all models and evaluated to produce an overall active/inactive classification of the potential for downstream effects of estrogen receptor agonism. These classifications were compared to the results reported by the previous mathematical model studies, notably those published by the EPA; BMLM predictions were equivalent to or exceeded benchmark results. The best performing datasets were selected for further comparison of alternative machine learning algorithms (e.g. support vector machines, deep neural networks). This study was limited to machine learning methods and yet demonstrated that prospective prediction is attainable from a suite of estrogen receptor activation models; this represents a starting point for incorporation of advanced models into the evaluation of endocrine disruption and activity potential on the basis of molecular structure alone. This methodology can be extended to other aspects of endocrine disruption such as the androgen pathway and steroidogenesis.

### 75 Effects-directed analysis of endocrine-active sediment samples from the Chesapeake Bay Watershed

The Chesapeake Bay Watershed contains agricultural, industrial, and commercial activities. These activities release complex chemical mixtures that may cause the high prevalence of intersex and immunosuppression observed in resident smallmouth bass (Micropterus dolomieu). To better understand the link between chemical mixtures in the watershed and smallmouth bass health, we utilized effects-directed analysis (EDA). Our EDA process combined in vitro tests for endocrine activity with analytical chemistry methods (ultra performance liquid chromatography-quadrupole time-of-flight-mass spectrometry [UPLC-QTOF-MS]) to characterize endocrine active compounds (EACs) from various locations in the Chesapeake Bay Watershed. Sediment and large-volume (30-50 L) water samples were collected in two different seasons in consecutive years from several sites in the Chesapeake Bay Watershed. Extracts of these samples were tested in two estrogen-responsive chemically-activated luciferase expression (CALUX) cell bioassays (the human VM7Luc4E2 and VM7LucERβc9 cell lines), two aryl-hydrocarbon-responsive CALUX cell bioassays (the human HG2L7.5c1 cell line and rat H4L7.5c2 cell line), and a glucocorticoid/androgen-responsive CALUX-type cell bioassay (the human MDA-kb2 cell line) to screen for EACs in the samples. Both anti-estrogenic and aryl-hydrocarbon activity were observed in sediment samples from one site, and potent estrogenic activity was observed in sediment from a second site (we observed low potency or no activity in sediment from the remaining sites and water at all sites). To facilitate identification of specific chemicals, sediment extracts from Sites 1 and 2 were fractionated and the fractions tested for activity in the CALUX cell lines. One broad peak of anti-estrogenic and aryl hydrocarbon activity was visualized in the “biogram” (the bioassay assessment) of the fractions from Site 1 sediment, and four distinct peaks of estrogenic activity were observed in the biogram of fractionated sediment extracts from Site 2. These bio-active fractions of Site 1 and 2 sediment extracts were evaluated using UPLC-QTOF-MS to further characterize EACs that may be associated with intersex and immunosuppression prevalence in Chesapeake Bay smallmouth bass.

### 76 Affinity Explains Estrogen Receptor Potency Impacts and Toxicity Prediction in Chemical Mixtures

**L. Burgoon, US Army Engineer Research and Development Center / Environmental Laboratory**

Humans, plants, and animals are a bag of chemical mixtures. These include endogenous as well as exogenous chemicals. Given that there are trillions of molecules of endogenous chemicals that have varying affinity for the estrogen receptor (and this is true for other receptors as well), a key question in biochemical pharmacology is how can the estrogen receptor still operate properly even when constantly being bombarded by all of these endogenous chemicals. Expand this same question to now include exogenous chemicals, and suddenly this becomes a biochemical mixtures toxicology question. In this presentation I will introduce the Chemical Affinity, Potency and Efficacy (CAPE) Theory of Mixtures, which demonstrates how multiple chemicals operating at the same receptor will actually function at environmentally relevant concentrations. Specifically, I will demonstrate how the endogenous estradiol actually functions in the presence of lots of competing chemicals, including the exogenous chemical, bisphenol A (BPA). This work will also demonstrate why BPA does not exert estrogenic activity in humans or animal models in vivo, and at what blood and exogenous levels BPA would need to reach in order to exert an estrogenic effect in humans. This presentation will also demonstrate what happens when there are thousands or millions of competing chemicals at very low doses with varying levels of affinity for the estrogen receptor, and how they may or may not disrupt estrogen signaling. This work builds further support for the idea of the
human-relevant potency threshold. The US Army Chief of Engineers has approved this paper for release. The views presented in this article do not necessarily reflect current or future opinion or policy of the U.S. Army Corps of Engineers.

77 Screening for Chemical Inhibition of the Iodide Recycling Enzyme, a Novel Molecular Target for Thyroid Axis Disruption

Environmental contaminants can disrupt thyroid function through a variety of molecular mechanisms, however some putative molecular targets have little known of their toxicological relevance, including susceptibility to chemical perturbation and resulting adverse organismal effects. The iodide recycling enzyme, iodotyrosine deiodinase (IYD), is one conserved putative molecular target that plays an essential role in maintaining adequate levels of free iodide in the thyroid gland for hormone synthesis. Thyroid disruption has recently been demonstrated in a model amphibian (Xenopus laevis) following in vivo IYD inhibition. These effects, along with previously documented effects in mammals, support the biological importance of IYD for proper thyroid function. Here we present development and application of screening assays to assess susceptibility of IYD to chemical perturbation and cross-species concordance between two IYD orthologues. With recombinant human IYD (hIYD) enzyme and Xenopus laevis liver microsomal fractions (xIYD), 96-well plate in vitro assays were developed to screen chemicals for inhibition of mammalian and amphibian IYD enzyme activity. The ToxCast phase 1, v2, phase 2, and e1k chemical libraries were screened using the hIYD assay. Of the over 1,800 unique chemicals tested, less than 200 (~11%) inhibited hIYD activity by 20% or greater at a single, high concentration (target of 200 µM). Further testing of 155 chemicals in concentration-response was conducted to determine IC50s and rank-order potency; this set of chemicals included 83 that produced inhibition of 50% or greater, 22 that produced low to moderate inhibition (20-50%), and 50 non-inhibitors. These same 155 chemicals were tested in concentration-response using the xIYD assay. There was strong cross-species agreement between inhibition of hIYD and xIYD (similar maximum inhibition and potency across most chemicals), with a few notable exceptions. These results greatly expand the number of compounds tested for inhibition of IYD and suggest that, in general, response of IYD activity to potential chemical inhibitors is conserved across these vertebrate species. Combining in vitro screening results, such as presented here, with targeted in vivo testing lends an iterative approach for characterizing the causal linkages between chemical inhibition of a specific molecular target and thyroid-related adverse outcomes. This abstract does not necessarily reflect USEPA policy.

78 Human-Relevant Potency Threshold for ER alpha Agonism

C. Borgert, Applied Pharmacology & Toxicology, Inc.; J.C. Matthews, University of Mississippi School of Pharmacy; S.P. Baker, Department of Pharmacology and Therapeutics, University of Florida College of Medicine / Department of Pharmacology and Therapeutics; S. Levine, Bayer AG - Crop Science Division / Regulatory; A. Bone, Bayer Crop Science / Environmental Toxicology & Risk Assessment

The ability of chemicals to produce physiological effects depends on pharmacokinetics and potency via the modes of action (MoAs) underlying the effects. Besides pharmacokinetics, a chemical’s ability to produce a physiological effect via a particular MoA depends on its affinity for the functional components (receptors, enzymes, transporters, etc.) that comprise the MoA and the ability to alter their functional state (activity). We tested the hypothesis that a minimum level of mechanistic potency is required for chemicals to produce physiological effects by a particular MoA in humans by comparing their potencies for the ERα-agonist MoA to data from clinical trials of estrogenic effects. Systematic literature searches identified potency data for transcriptional activation of human ERα (ERTA) and for rodent uterotrophic activity (RUA) for chemicals with consistently observable, possible, and no physiological estrogenic effects. Mean relative potencies (17β-estradiol reference) in the ERTA ranged from 3.5E-02 to 1.00 for endogenous estrogens (11 data points), 2.6E-02 to 2.0E+00 for pharmaceutical estrogens (19), 3.3E-05 to 7.0E-02 for botanical estrogens (109), and 2.5E-06 to 7.1E-06 for synthetic and endogenous androgens (5). ERTA potencies were corroborated by RUA data which showed similar rank orders at 0.5 to 1E-01 the ERTA potency. Physiological estrogenic effects in clinical trials are clear for endogenous hormones and pharmaceuticals, absent for androgens, and were equivocally observed for botanical estrogens with relative ERα-agonist potencies in the range of 1.0E-03, but not lower. Based on this approach and analysis, we conservatively propose a human-relevant potency threshold (HRPT) for ERα agonism of 1E-04 relative to the potency of the endogenous estrogenic hormone 17β-estradiol or the pharmaceutical estrogen, 17α-ethinylestradiol. This approach provides a practical means for addressing hazard identification based on MoAs, for defining common assessment groups for mixtures risk assessment, and for determining candidate chemicals for AOPs. Preliminary analysis suggests future work could extend the approach to ecological species by de-novo evaluations or possibly by species-extrapolation of potency data for conserved homologous molecular targets.

79 Mechanistic Potency is an Important Tool in Hazard Identification

E.M. Mihalch, ER2; C. Borgert, Applied Pharmacology & Toxicology, Inc.

Regulatory initiatives for identifying and managing chemical endocrine disruptors (EDs) are being developed and implemented in several jurisdictions in response to concerns that exogenous chemicals may interfere with the endocrine systems of humans and environmental organisms. According to the World Health Organization’s International Programme on Chemical Safety, an ED must (1) alter the function of the endocrine system; and (2) as a consequence of that alteration, cause an adverse health effect in humans or wildlife. This definition requires a causal link between the endocrine mode of action (MoA) and the adverse effect. However, with the publication of the ECHA/EFSA guidance for the identification of EDs, this requirement for a causal association appears to have shifted to one that is “biologically plausible.” This is a very different criterion, especially when the guiding regulatory approach is one of hazard and not risk. Pathway models are being established that provide plausible links between molecular initiating events, key events and ultimately adverse effects. However, when several potential pathways or MoA converge on the same adverse effect in an intact organism it becomes challenging to identify the biologically plausible causal link between the MoA and the environmental or health effect of concern. To minimize the risk of misidentification of an endocrine MoA, an objective and transparent weight of evidence (WoE) procedure based on biological plausibility, essentiality, and empirical evidence is recommended. In order to determine whether it is biologically plausible that a chemical produces an adverse effect via an endocrine MoA, i.e., that it might fit the definition of an ED, the mechanistic potency must be evaluated to measure the strength of a chemical’s activity via a specific endocrine MoA. We present a case study that applies a recently published potency threshold methodology to two chemicals identified on various lists of Endocrine Disrupters, a cyclic siloxane and bisphenol A. Mechanistic potency was evaluated along with other relevant information in a WoE framework to determine the potential for the chemical to meet the definition of an ED.
Natural and Ambient Soil Background Studies and Their Utility in Risk Assessment

80 Establishing Soil Background for Use in Risk Assessment Using USGS’s Data
B. Brooks, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes

The amount of metal present in soil due to natural background is important to consider when conducting risk assessments. Health-based soil values, derived using toxicity data along with exposure and metal specific parameters, are used to estimate risks to people and ecological species. For some metals, health-based soil values are below natural background levels. In these cases, most regulatory agencies will replace the metal specific health-based soil value with a soil background value when conducting risk assessments. The preferred method of establishing a soil background value is to conduct a soil study in the area being assessed, but this is not always possible as these studies are often costly and require significant effort. As an alternative method, we consulted with the United States Geological Survey (USGS) regarding their 2007 to 2010 Soil Survey of the Conterminous United States, to establish soil background values for some inorganics. USGS and EPA use different soil preparation and analytical methods; EPA’s method is typically used to evaluate soil in risk assessment. For some chemicals, there may be significant differences in the results from these two methods. We compared the results of USGS and EPA’s methods by reanalyzing a subset of USGS’s soil samples collected in the state of Minnesota using EPA’s methods. Results between the two methods varied from no significant difference in the analysis of arsenic to a significant difference in the analysis of aluminum and barium. We used this information and EPA’s ProUCL statistical software to establish soil background threshold values (BTV) applicable to the state of Minnesota.

81 The Development of Regional Background Concentrations with the Consideration of Naturally Elevated Areas
S. Fernandes, H. Phillips, C. Lucas, N. Thackeray, CanNorth

Establishing background soil concentrations is an important part of risk assessment, and provides context to the data and results. A robust estimate of background concentrations will help strengthen the risk assessment and can be used to inform risk management decisions. Guidance from the Canadian contaminated site program (FCSAP 2015) indicates that background soil should be representative of the true range of concentrations associated with the geographic area of the site. In addition, the CCME (2006) guidance document “A Protocol for the Derivation of Environmental and Human Health Soil Quality Guidelines” provides a definition of a background concentration as a representative ambient level for a contaminant in soil or water. They note that “ambient concentrations may reflect natural geological variations in relatively undeveloped areas or the influence of generalized industrial or urban activity in a region.” Thus, background concentrations can represent natural conditions based on geological formations or ambient conditions representing the sum of natural background concentrations and large-scale regional anthropogenic contamination (CCME 2016). In some areas in Canada there are natural geologic formations, such as volcanic rock areas which contain ore deposits of gold, silver, copper, zinc and lead making it a prime location for mining activities. These may not be representative of the surrounding areas that do not have these geological conditions and thus have lower concentrations. This presentation discusses an approach for development of background concentrations within an area of natural geological conditions as well as more regional conditions and how various considerations of background can be used in risk assessment. The discussion will use arsenic as an example and will touch on different statistics to describe background as well as the handling of method detection limits.

82 Contrasting Methods for Relative Human Health Risks Based on Background Soil Contribution
C. Peterson, T.M. Biksey, EHS Support / Risk Assessment

To evaluate potential cancer risks and non-cancer hazards in soils from anthropogenic sources and inform risk managers on the need for remediation, a human health risk assessment was conducted using the results of soil sampling conducted at a site to estimate potential excess lifetime cancer risks (ELCR) and hazard quotient/hazard indices (HQ/HI). Chemical concentrations occurring naturally in the soil exceeded human health risk-based screening levels. As a result of these elevated naturally occurring levels, cancer risks and non-cancer hazards calculated for the site also exceeded target cancer risks and target non-cancer hazards. To provide context around the contribution of naturally occurring risk in soils to the cumulative ELCR and HI, a background risk characterization was conducted. To quantify background concentrations, site-specific soil samples were collected from an area not affected by the anthropogenic activities of the site. These samples were submitted for comparable chemical analysis as soil samples analyzed during site investigation activities. Using the site-specific background soil results, two methods to evaluate the contribution of background risks relative to site risks were conducted to inform the risk managers on sources of anthropogenic risk drivers. Method 1 calculated the ELCR and HI from background data for all receptors across all exposure pathways; Method 2 calculated the ELCR and HI from background data specifically for risk drivers identified during the risk characterization of site data. For Method 1, an exposure point concentration (EPC) was determined for each chemical and input into intake equations. The ELCR and HQ were then calculated for each chemical and summed across each pathway to identify a cumulative ELCR/HI for each receptor to provide the contribution to risks from background soils. In Method 2, the EPC for each risk driver was calculated as well as the individual ELCR/HQ for the chemical and the percent contribution of the ELCR/HQ of background to the overall ELCR/HQ for the chemical. Both methods provided insight into the contribution of background concentrations to cumulative risk and hazards and focus remediation efforts. The differences in costs and time spent conducting the two methods was summarized.

83 Role of Arsenic Background Soil Concentrations in Risk Assessment: Hanford Site Case Study
D.A. Delistraty, E.A. Rochette, Washington State Department of Ecology

Several studies have evaluated background soil metal concentrations in Washington state, including the U.S. Dept. of Energy (USDOE) Hanford Site. Arsenic (As) is notable, since it is often a risk driver. The purpose of this study was to evaluate the relationship between As background soil concentrations and soil cleanup levels in order to frame As background risk. Arsenic background soil concentrations were compiled from relevant studies (both statewide and at Hanford) and compared against As soil cleanup levels (for human and ecological receptors, obtained from EPA and state sources). Risk-based As soil cleanup levels for human health (e.g., 0.0015-0.77 mg/kg, 1E-6 cancer risk) are typically 1-3 orders of magnitude below background (7.0 mg/kg statewide, 6.5 mg/kg at Hanford, 90th percentile) and sometimes below the practical quantitation limit (0.1-1 mg/kg). Consequently, risk-based As soil cleanup levels for human health often default to background. In contrast, ecological screening levels for As (e.g., 7-132 mg/kg) are similar to or exceed soil background concentration. Soil waste sites at Hanford may contain As from both naturally occurring and anthropogenic sources (e.g., former orchard lands). USDOE has previously presented risk with and without As to highlight its contribution to total site risk at Hanford and to more clearly show risk from other contaminants, respectively. Subsequently, a 2013 policy decision by the Washington State Dept. of Ecology allows soil background concentration of As at Hanford to be set at 20 mg/kg (~3-fold increase over measured background). This policy effectively establishes a soil cleanup level for As at 20 mg/kg at Hanford to reduce remedial cost and to promote consistency with area-wide cleanups associated
with anthropogenic sources in Washington (e.g., smelter plumes, orchard lands). A soil concentration of 20 mg/kg for As may correspond to human cancer risk levels, ranging from 3E-5 (soil direct contact) to 1E-2 (soil to protect groundwater ingestion), using exposure scenarios employed in EPA's Regional Screening Levels (RSLs) for soil. These observations clearly demonstrate that As is a risk driver at background levels. To illustrate components of risk at Hanford, and for consistency with EPA guidance that encourages retaining hazardous substances with concentrations that exceed risk-based screening levels, risk assessments should present results with and without As.

84 Characterizing Urban Background: A Collaborative Study in the Southeastern United States

T. Frederick, G. Adams, B. Alfano, S. Chan, USEPA / Region 4; F. Barnett, R. Ford, B. Schumacher, USEPA / Office of Research and Development

Soils in urban settings are likely to contain elevated levels of certain metals and/or polynuclear aromatic hydrocarbons (PAHs), due to human activity, non-point source industrial operations, and infrastructure materials. Because these increased contaminant concentrations are due to anthropogenic urban activity and not site-related point source releases, they can be considered to represent urban background soil concentrations. Whether certain soil contaminant concentrations are site-related or are part of natural or anthropogenic background is a question that frequently arises during environmental site investigations in urban settings. Robust data on urban background concentrations on a large scale is lacking, which can complicate decision making. To address these issues, EPA Region 4 (Atlanta) partnered with EPA's Office of Research and Development and all eight Region 4 States to conduct an urban background study. Project goals include the creation of a Region-wide urban background database that can be used to inform decision making across the Region and the creation of standardized procedures that can be used in other cities and Regions where the collection of robust and defensible background data is a priority. The project team has collaboratively collected data from eight cities in the Southeastern United States. This presentation will address the project methods and findings to date.

85 Background Concentrations of Polychlorinated Biphenyls, Polychlorinated Dibenzo-p-dioxins, and Polychlorinated Dibenzofurans at Superfund Sites

M.K. Lambert, US Environmental Protection Agency / Office of Superfund Remediation and Technology Innovation; K. Palaia, P. Sinski, K. Lamb, ICF

A robust background data set may be important for a variety of risk assessment and management purposes. Where risk-based Preliminary Remediation Goals (PRGs) are below background, it may be used to set the Cleanup Level (CUL). Often, this is true of PRGs for polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans (D/Fs), and polychlorinated biphenyls (PCBs). To understand how background levels are likely to affect Superfund remedy decisions, the Office of Superfund Remediation and Technology Innovation reviewed sites with D/Fs or PCBs in either soils or sediments for background datasets. The goal was to compile background concentrations near Superfund sites (including urban, rural, industrial, and residential areas) to understand the common challenges with developing and using background data. The study also sought to compare background values observed at Superfund sites to other published background studies for D/Fs and PCBs. The Superfund Program database was queried for site Records of Decision that were signed after 2002 and had D/Fs or PCBs as contaminants of concern in either soils or sediments. The administrative records of these sites were searched for information on background concentrations. The reported background concentrations and important meta-data, such as the number of samples collected and analytical methods, were collated, summarized, and compared to the final CULs for the site. There has been a steady increase over time in the number of background studies being conducted, although background sampling is more common at PCB sites than D/F sites. Ranges of background PCB and D/F concentrations in soil and sediment span several orders of magnitude. Reported background concentrations for PCBs and D/Fs in sediment span a similar, but lower, range than that of the final CULs. Reported background concentrations for PCBs and D/Fs in soil span a smaller range than that of final CULs. While background concentrations in the past tended to be lower than the CULs, recent changes in toxicity values, the consideration of additional exposure pathways, and incorporation of higher fish consumption values have lowered more recent CULs. Most sites surveyed used background concentrations in the development of the conceptual site model and as part of a risk assessment. Recently, several sites also formally incorporated background concentrations into the PRG and CUL selection process and a few sites have set the CUL to background.

86 Per- and Polyfluoroalkyl Substances (PFAS) Regulatory Values for Soil in the Context of Background Concentrations

C. Faith, K. Hathaway, Barr Engineering Co.

PFAS regulatory values for soil are being set below one part per billion (ppb) in several jurisdictions. At the same time, recent regional and global background studies have detected PFAS in soils at background levels exceeding one ppb. The methods used and considerations given to set the PFAS regulatory values for soil vary greatly between agencies including recent regulatory directives from certain agencies to evaluate the potential for PFAS to leach from soils using Synthetic Precipitation Leaching Procedure (SPLP). The presentation will compare and contrast established or proposed PFAS regulatory values for soils, how these values have been developed, causes for variability in these values and how these values relate to background levels. A compilation of hypothetical groundwater protection values, based on the methods used by various regulatory agencies, will be also be presented. The information presented will illustrate the relevance of background PFAS levels in the investigation and risk assessment at PFAS-impacted sites.

87 Establishing Soil Background Concentrations of Polynuclear Aromatic Hydrocarbons from Wildfire Sources

K. Patel-Coleman, AECOM

There are various sources of polycyclic aromatic hydrocarbons (PAHs) in the environment, both natural and anthropogenic. Anthropogenic sources of PAHs are often associated with environmental pollutant cleanup programs to protect human and environmental health. These sources typically come from crude oil related releases or industrial processes involving organic matter combustion, such as petroleum refining, coal gasification, chemical production, or incineration. Human exposures to PAHs may result in carcinogenic, mutagenic and immunosuppressive effects. Ecotoxic effects include tumors and adverse reproductive, developmental and immunological outcomes. However, because there are also natural sources of PAHs, such as wildfires, petroleum or coal seeps, and volcanic activity, it becomes imperative that cleanup programs for potential PAH releases consider the contribution of PAH concentrations from these natural sources as background levels. Various published studies report soil background PAH concentrations from both natural and anthropogenic sources. For certain geographies, such as the western United States, wildfires are commonplace and sometimes encroach upon urban areas, representing a potentially significant source of natural soil background PAHs for cleanup sites located in the vicinity of the wildfires. This presentation will review available literature on natural soil PAH concentrations with a particular emphasis on wildfire sources. In addition, wildfire air quality data as indicators of potential background soil PAH concentrations through aerial deposition will be considered.
Monday Platform Abstracts

Breaking Down Barriers in Science Communication: Methods, Language and Tools - Let’s Get Everyone Engaged

88 Science outreach through your local SETAC NA Chapter: Laurentian SETAC engages with its membership and the local community

E.A. Gilroy, Environment and Climate Change Canada / Aquatic Contaminants Research Division; O. Bireceanu, Wilfrid Laurier University / Biology; Y. Gopalapillai, Environment and Climate Change Canada / Department of Earth & Atmospheric Sciences; N.C. Feisthauer, Agriculture and Agri-Food Canada (AAFC) / Science and Technology Branch; R. Frank, Environment and Climate Change Canada / Water Science and Technology Directorate; L. Chibwe, Environment and Climate Change Canada / University of Guelph / School of Environmental Sciences; S. Roberts, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R.K. Giles, University of Toronto / Department of Ecology and Evolutionary Biology

In 2016, in light of increasing awareness of the importance of equity, diversity and inclusion (EDI) in science, the Laurentian Chapter of SETAC (L-SETAC - the Ontario, Canada Chapter of SETAC) created the Diversity in Science Committee (DISC). The DISC’s mandate is: implementing EDI practices within all of our Chapter activities; highlighting the achievements of women and members of other underrepresented groups; raising awareness of disparity in science (e.g., disparity in representation and opportunities); and creating mentorship opportunities for up-and-coming scientists. The establishment of the International Day of Girls and Women in Science, first celebrated in 2017, has been an unparalleled opportunity to communicate science to a diverse audience, while addressing questions and issues related to of diversity and equity. L-SETAC has been celebrating this event since 2017, by engaging its members and the community in discussions and activities relevant to science and EDI. Such events included photo-research exhibits by Dr. Eden Hennessey (2017) that uniquely communicated issues of sexism and gender discrimination in science, a tripartite panel (2018) discussion entitled We are Here: Constructive Actions Towards Achieving Equity in Science,” and a “Science on the Road” event (2019) to engage local high-school students in science. The 2019 event was themed “The Many Faces of Environmental Science,” where government, consulting and academic groups shared their love for science with high-school students, highlighted the diversity of career paths that are available in the field, and provided discussion points on how everyone has a voice in working towards equity. In this presentation, we will describe the various activities that the L-SETAC Chapter has done to promote EDI while also engaging with its community and member in science outreach and communication. We will discuss how we approached our different partners to promote and organize our events and will touch on future directions. Although regional chapters are small by comparison to the parent organization, SETAC North America, we strongly believe that each chapter has a powerful voice that can make a difference in their respective communities.

89 Science Education and Public Outreach- lessons from the IISD Experimental Lakes Area

S. Warrack, IISD-Experimental Lakes Area / Department of Environment and Geography; P. Gerrard, IISA-ELA

The International Institute for Sustainable Development Experimental Lakes Area (IISD-ELA) is an exceptional natural laboratory comprised of 58 small lakes and their watersheds in a sparsely populated region of Northwestern Ontario, Canada set aside for scientific research. Through whole ecosystem research on these small freshwater systems, scientists can examine how all aspects of the ecosystem respond. This unique research approach has influenced billion-dollar decisions of governments and industries and has generated more cost-effective environmental policies, regulations and management of large lakes and freshwater systems around the world. This presentation will use IISD-ELA’s 50 years of experience to examine the connections between science education, and public outreach. We will explore our current strategies for both our science programming, and public outreach as well as lessons learned through our successes and failures. Through our educational programming efforts we hope to build legitimacy in our freshwater science.

90 AquaSONG: An Interactive Field Trip Program to Inspire Future Scientists

G. Bruun, Wilfrid Laurier University / Center for Cold Regions and Water Science

Scientific research and discovery underlay many of the primary needs and daily activities within a community; from food and agriculture, to transportation, to communication and leisure. Despite this reliance on scientific endeavors, an understanding of basic science and an appreciation for the role science plays within society is often limited, ignored, or considered elitist. To foster a change in this trend, young people need to be inspired and excited about science revived. Hands-on experience with science in a local setting is one method for achieving this goal; however, current school budgets often leave little room for innovative activities. Too connect with the local community, share scientific knowledge, and inspire high school students, Wilfrid Laurier University initiated the Aquatic Science Outreach Network for the Grand (AquaSONG). AquaSONG is a full day field trip that engages and inspires high school students in the field of water science through field sampling and laboratory analyses. In addition, students may apply their own creativity to the challenge of water treatment. As a participant in AquaSONG, each student collects samples from a waterbody near a wastewater treatment plant or builds filters to replicate wastewater treatment processes. Under the direction of experienced Laurier staff, they assess these samples using sophisticated laboratory equipment and use microscopy to investigate the aquatic environment. AquaSONG began in 2016 and has grown dramatically. With continued Laurier funding and additional NSERC support, this project aims to reach approximately 500 students each year. This presentation will provide details on how AquaSONG began, how funding is obtained, the daily structure of the program, and advertising and media strategies. Challenges and successes will be included in the discussion.

91 Mama Aki Camp: Challenges, Successes, and Lessons in Indigenous Science Outreach

J. Duke, Wilfrid Laurier University / Indigenous Initiatives and Services; A. Strauss, S.M. Ramsay, F.C. Guinel, Wilfrid Laurier University / Biology

Indigenous youth are under-represented in the Science, Technology, Engineering and Mathematics (STEM) fields. In 2018, Wilfrid Laurier University launched the week-long Mama Aki / Mother Earth Camp to help address this issue. The goals of the camp are to engage Indigenous youth in the sciences and link science with Indigenous knowledge. The 2018 pilot camp targeted students in grade 7, with the initial challenge being recruitment for the camp itself. To increase attendance, it was essential to gain both the trust of the parents and that of the community. To resolve this challenge we included the involvement of respected community members, provided information sessions for parents and children, and conducted in-class visits. The trust of the parents was important as many of the children were experiencing the freedom of on-campus residence for the first time. Once the participants arrived in Waterloo, the challenge shifted to keeping activities entertaining and engaging while considering and expanding on the grade 7 Science curriculum. We presented relevant topics including biodiversity, ecosystem health, sustainability, diet, and waste management in fun and relatable ways. Throughout the week, elders and knowledge keepers helped link and incorporate traditional Indigenous knowledge. The campers loved the opportunity to explore the microscopic world they had learned about in school. At the end of the week, the campers left wanting more. The overall feedback was positive, expressed as a desire to return with friends for the 2019 camp. As a result, Mami Aki expanded and improved. We have two separate camps scheduled for the summer 2019: the revised grade 7 camp and a second advanced camp for grade 8 students. The advanced camp
aims to build on concepts in the grade 8 Science curriculum, includes more experiments, and revisits topics and locations from 2018 in new ways. The new camp experiments include documenting the development of Artemia salina, live observations of various protists and plant cells, and an introduction to paleoecology. We see this program as a successful model to share with other institutions looking to build offerings in support of under-served communities.

92 Going from scientist to science writer
B. Borowiec, McMaster University / Biology
The difficulties of accessing and digesting peer-reviewed research papers lead most members of the general public to rely on popular science articles, often written by non-specialist journalists, to stay informed about contemporary scientific research. By participating in popular science writing, scientists can reach new audiences, become more aware of public interests, and even correct the narrative around their work. Moreover, scientists can leverage their specialized knowledge and skills to increase the accuracy, quality, and diversity of writing about science. Unfortunately, getting into popular science writing as a scientist is difficult due to lack of formal training opportunities, different styles of writing, and strong cultural differences between the academic and popular press. I will use my experiences as a scientist, freelance popular science writer, and assistant editor at a popular science media outlet to discuss how scientists can get started with science writing, avoid some common pitfalls and barriers especially relevant to scientist-science writers, and how the inclusion of more scientist-science writers could improve the popular science landscape.

93 Do Scientific Publications in Environmental Toxicology and Chemistry (And Other Journals) Make A Difference?
G.A. Burton, University of Michigan / School for Environment and Sustainability; J. Lynch, SETAC
The high-quality science published in Environmental Toxicology & Chemistry (and elsewhere) supports SETAC’s motto of “Environmental Quality through Science.” But, does our science improve environmental quality? It appears the answer is yes: As we have learned about the ecological fate and risks of some chemicals their uses have been restricted; approaches to site assessments have been improved and guided restoration and remediations; and regulatory guidance and criteria have been improved. Nevertheless, we are failing in many ways to improve ecological risk assessments (covering different regions, agencies, and client-types) and discuss how to write and communicate more effectively for specific audiences. This presentation will also cover an example of on-the-job communication training for scientists and risk assessors.

95 The Duke Furniture Foam Testing Project: A Case Study in Citizen Science, Research Translation, and Science Communication
The National Institute of Environmental Health Sciences promotes environmental health science communication by requiring each of the funded Superfund Research Program Centers to have a Research Translation Core (RTC). Along with analytical chemistry support, the RTC at the Duke University Superfund Research program administers the Duke Furniture Foam Testing Project (http://foam.pratt.duke.edu). This free service screens samples of polyurethane foam submitted by the public for the presence of nine common flame retardants. Chemical flame retardants have been detected in household items such as couches, mattresses, car seats, and some baby products. Scientific evidence suggests that exposure to these chemicals occurs in the home and may elicit adverse health effects. Because manufacturers are not required to disclose the specific flame retardant used in a product, public access to and awareness of such information is limited without laboratory testing. The RTC interprets and disseminates the results for each submitted foam sample, and answers questions from individuals about their test results. In addition, the RTC has developed research-based educational materials for participants. The RTC recently evaluated the effectiveness of these materials in a survey of all past participants from the last 4 years. Survey questions assessed knowledge of potential exposure and health risks, flame retardant regulations, and behavior change. The response rate of the pilot survey was 45% (n=100). The full survey (n=1,000) will be distributed in June of 2019. In the pilot survey, more than 70% of participants had flame retardants detected in their samples. Almost 90% of survey respondents reported sharing the results with family or friends, suggesting the importance of this type of education. In order to invite the public, the Foam Testing Project aims to serve as an ideal platform to monitor trends in commercial flame retardant use, and helps direct future scientific research. This case study demonstrates the public’s interest in engaging with science, guides development of other RTC initiatives, and furthers RTC goals of increasing environmental health literacy and cultivating skilled science communicators.
applications is a hallmark of our society and is manifested throughout SETAC workshops, publications, and topical initiatives. It is inherently connected with bringing a multi-sector view to problem solving.

**97 The evolution of ecological risk assessment**

**A. Fairbrother**, Exponent / EcoSciences

Ecological risk (ecorisk) assessment is the art and science of predicting the probability of an adverse outcome to the environment as the result of a specified human activity, generally related to release of chemicals to the environment. This practice, initiated primarily as an assessment art, began in the late 1960s in response to the publication of Silent Spring by Rachel Carson when the US Department of Agriculture began considering the potential for adverse effects from birds from the use of pesticides. This was a simplistic analysis that compared known levels of toxicity to estimated environmental concentrations, i.e., what has become known as a hazard quotient. When the USEPA took over pesticide registration in 1972 and began similar assessments for industrial chemicals in 1976, they continued the same approach, developing standardized toxicity test protocols for a long list of species/endpoints and upgrading the sophistication of exposure models. The Framework for Ecological Risk Assessment, published by USEPA in 1992, was a major step forward as it emphasized the importance of the Problem Formulation step and explicit descriptions of assessment endpoints. The science of ecorisk has advanced to include uncertainty and reporting of results as probabilities (the true definition of risk) instead of deterministic hazard quotients. Expressing risks in ecological terms such as changes in population growth rates or community biodiversity metrics also has proven scientifically feasible. Similarly, techniques have evolved for assessing risks on ecologically relevant scales, such as watershed assessments that include nonpoint pollution sources. It is unfortunate that the science of ecorisk, developed by SETAC scientists through research, publications, and multisectoral SETAC workshops, has evolved at a much faster rate than regulatory applications. The art of the possible is truly exciting; scientists now need to partner with educators and communication specialists to bring the best available tools and strategies to managing the risks of chemicals that are integral to our modern lifestyle and provide useful and meaningful information to the decision makers charged with protection of our overall societal interest.

**98 Landscape scale ecological risk assessment and the development and use of the Bayesian network relative risk model**

**W.G. Landis**, Western Washington University / Institute of Environmental Toxicology

In 1997 it had become apparent that the original formulation of ecological risk assessment was not applicable for our project on the fjord of Port Valdez, AK. In this case study there were multiple stressors operating on multiple endpoints over a diverse marine and freshwater landscape. Janice Wiegers proposed the alternative approach of using ranks and filters to describe the interactions in the sources-stressors-habitats-effects-impacts pathway. Methods were developed to incorporate uncertainty and the risk assessment for the fjord of Port Valdez in 1998 demonstrated the applicability of the approach. In the early 2000s the relative risk model (RRM) incorporated Monte Carlo to better describe uncertainty. By 2010 the RRM had been applied to sites in Tasmania, Brazil, Australia, China, the United States, and Chile. The development of the Bayesian network derivative of the RRM (BN-RRM), published in 2012 by Ayres and Landis, broadened the applicability of the approach to better describe uncertainty, sensitivity, and incorporate data from a number of sources. Since the development of the BN-RRM the method has been applied to invasive species, forestry management, a CRCA contaminated site, large scale risk assessments in Australia, emergent parasitic disease in the American Southwest and to develop quantitative AOPs and QSARs, synthetic biology and water flows. The latest development is the incorporation of the BN-RRM into adaptive management for the South River and the Upper San Francisco Estuary.

**99 Quantification of Risks, the Evolution of the Risk Characterization in Ecotoxicology**

**K.R. Solomon**, University of Guelph / School of Environmental Sciences

One can only pity the ancient Romans who threw dice with no concept of the risk (probability) of winning. In the thousands of years since the teachings of the ancient Romans and Greeks, we have advance in many ways but not so much in the understanding or risk and the probability of harm. Risk assessment was focused on humans and was empirical from the time of Hippocrates to 1600s when the word probability was first used to describe risk. In 1854, James Snow tested a hypothesis on the risk and origins of cholera in London and in 1965, Sir Austin Bradford Hill published his eponymous guidelines for causality. Since then human-health risk assessment (HHRA) flourished in the area of human epidemiology. It was only in the 1980 that probability theory was used to determine environmental quality criteria (EQCs) in the work of Stephan and several others, including members of SETAC. At about the time the concepts of risk of harm in the environment were being picked up in the Netherlands and this transatlantic connection resulted in further evolution of the ecorisk concept. Refinements were added over the years and probabilistic environmental risk assessments (PERA) started to appear in journals, including ET&C. The use of species sensitivity distributions has become widespread for setting EQCs, the joint probability distribution (JPC) has become to display tool in risk assessment but full probabilistic risk assessment still eludes or is avoided by regulators. PERA is now ahead of HHRA in the sense that variation in response of ecological receptors is explicitly considered. Cycling back to the some of the guidelines of Bradford Hill, concepts such as weight of evidence and adverse outcome pathways are increasingly being used to better understand responses and their propagation to apical endpoints.

**100 The best of all worlds: Integrating decision analysis and causal modeling with ecological risk assessments**

**J.E. Carriger Jr., US Environmental Protection Agency / National Risk Management Research Laboratory**

For the past several decades, the ecological risk assessment (ERA) process has been an instrumental tool for government agencies to protect and evaluate risks to environmental resources. Predicting the future of ERA is difficult because of the many methodological improvements currently under development. One direction that has the potential to be especially useful for managing risks is the integration of ERA with decision analysis frameworks and tools. The primary goal of an ERA process is to provide information for decision making; consequently, better correspondence between risk assessment and decision making has been a topic of ongoing research and discussion. For example, integrating risk with decision making was a focus of a National Academy of Sciences charge by the United States Environmental Protection Agency in 2009. This was echoed in a 2011 journal special issue article and rejoinder discussions on moving towards a “solution-focused risk assessment” that integrates the decisions under consideration with the design and output of the risk assessment. Decision analysis frameworks and analytic structures can be especially useful for solution-focused ERAs by augmenting the problem formulation stage, the characterization of risks, and the identification of the value of ERA information for risk management decisions. Decision analytic tools that would be useful for an integrative approach for decision modeling in ERAs are graphical modeling approaches as exemplified by Bayesian networks and influence diagrams. Recent advances in causal modeling and inferences with graphical modeling approaches have opened a pathway towards better integration of decision making, risk management, and risk assessment. Graphical models, such as results chains and Bayesian decision networks, are powerful tools for capturing and evaluating the information needed for managing risks. Moreover, incorporating ERAs into the steps of a formal decision analysis approach, one that examines the consequences and quality of candidate decisions, will help ensure that the technical data and analyses are focused on what is needed for examining trade-offs and making more informed decisions.
Behind each ERA is a decision problem. Better correspondence between
decision analysis and ERA will lead to improved risk assessments and
information for managing environmental stressors.

101 SETAC’s role in establishing the science foundation behind life
cycle assessment
J.A. Fava, Anthesis

In 1990, the Society of Environmental Toxicology and Chemistry
(SETAC) sponsored an international Pellston workshop (in Smugglers
Notch, Vermont, USA) where the term ‘Life cycle assessment’ was
coinined. SETAC (NA and Europe) and its global members played key on-
going and global roles in the continued advancement of the understanding
and use of the LCA framework, methodology, and data through effort
through a) SETAC’s own LCA advisory groups, b) establishment and
development of the International Organization for Standardization (ISO)
- life cycle assessment standards, TC-207 - SC5 on Life cycle assessment,
and c) co-founded the UNEP/SETAC Life cycle Initiative. As SETAC
grew and expanded on its own and with its supporters and partners, it
continues to advance the understanding and use of LCA while ensuring
that science is kept at the forefront of LCA development. The presenta-
tion will outline the key roles that SETAC has played in establishing the
scientific foundation for LCA.

102 Life Cycle Assessment: Development and Evolution of Methods
for Addressing Heath and Environmental Life-Cycle Impacts
O. Jolliet, University of Michigan; T.E. McKone, University of California
/School of Public Health; P. Fantke, Technical University of Denmark
/Quantitative Sustainability Assessment Division; B.W. Vigon, Breveja
Environmental Consulting, LLC

Life Cycle Assessment (LCA) aims to compare environmental impacts of
products and services on a functional basis. With life-cycle invento-
ries established, LCA must provide in its Life Cycle Impact Assessment
(LCIA) phase impact factors per kg of chemical emission/extracted
resources, expressed in term of impacts on human health, ecosystem
quality, or resources depletion. In this presentation, we track the development
and evolution of LCIA methods over three decades and focus on the role
of SETAC in collaboration with the United Nations Environment Program
in forming the Life-Cycle Initiative to establish, interpret, and dissemi-
nate a globally harmonized LCIA approach. The Initiative has hosted a
series of complementary efforts for LCIA consensus building, striving for
recommendations and guidance on LCIA methods and factors. SETAC
conferences and Pellston Workshops have provided important venues
for the Initiative process. Three rounds of SETAC working groups have
resulted in category-specific recommendations for developing LCIA
impact indicators, taking advantage of broader consensus efforts, such as
the World Health Organization, USEPA, and EU health risk assessment
efforts. A combination of academic, government, and industry experts
have participated in these efforts. As an informative example we will
review the development and dissemination of the USEtox global scien-
tific consensus model, which provides LCIA characterization factors for
human toxicity and ecotoxicity, and which is now used worldwide. It is the
default tool in both the European Union and North America. We conclude
by considering future needs and opportunities for LCIA with a focus on
the continuing role of SETAC.

103 Panel Discussion on Past Successes and Future Needs in Risk
and Life Cycle Assessment
B.W. Vigon, Breveja Environmental Consulting, LLC; E.J. Dorward-King,
Newmont Mining Corporation / Sustainability and External Relations
A spotlight session at the 40th Annual Meeting of the Society of
Environmental Toxicology and Chemistry (SETAC) represents an opportu-
nity to reflect on our progress, consider the current state of the science,
and look to the future. There will be two panel discussions during this
session: this one from the morning session and one from the afternoon
session reflecting talks in environmental fate and modeling, aquatic
toxicology, and terrestrial and wildlife toxicology. The six representative
speakers and several invited guests will participate in the panel discus-
sion to allow questions and interaction with the SETAC audience. The
speakers will address development of the science and application of risk
assessment and life cycle assessment, particularly highlighting SETAC
contributions over the past four decades, will evaluate and address the
current state of play and will give perspectives on future scientific needs
that could be encouraged through SETAC. This is an excellent opportu-
nity for coordinated discussions from the audience with key leaders in the
field that represent long-standing contributions to the science and applica-
tion development RA and LCA. We believe this session and the discussion
panel will be of historical significance since some of the participants in
this panel will represent expertise in RA and LCA and involvement in
SETAC in these areas for decades. We welcome SETAC members and
guests to join us for this anticipated and very interesting panel discussion
where they will have the opportunity to ask questions and interact with
significant leaders in our fields of science.

Mollusca Toxicology: An Ecological Important and
Imperiled Phyla but Often Left Out

104 Assessing the efficacy of EarthTec QZ for controlling Bithynia
tentaculata populations in the Upper Mississippi River
A. Galbraith, N. Carmosini, University of Wisconsin, La Crosse / Chemistry & Biochemistry; G. Sandland, University of Wisconsin, La Crosse / Biology

The invasive freshwater snail species, Bithynia tentaculata, has become a
growing concern to the Great Lakes and Mississippi River Regions since
its introduction from Europe in the late 1800s. Bithynia tentaculata is a
carrier of multiple parasites that have caused the death of over 200,000
waterfowl since 2002. Because of this, and due to the fact that the species
may be outcompeting native species, there has been great interest in iden-
tifying strategies that mitigate the spread of this snail and its associated
parasites. For this project, we conducted two separate laboratory studies
that assessed the effectiveness of a novel copper-based molluscsicide,
EarthTec QZ, on our target species, B. tentaculata. In the first study we
compared the effects of two concentrations of EarthTec QZ on the adult
life stage of B. tentaculata and a coexisting native snail species, Physa
gyrina. Upon completion of this study, we observed that B. tentaculata
adults were better able to persist at higher concentrations of Cu^{2+} (the
active ingredient of EarthTec QZ) than their native counterparts. We also
found that female B. tentaculata experienced higher mortality than males
after exposure to the compound, which may generate consequences for
local populations of this species. In the second study, we conducted LC50
experiments on the adult life stage of the two snail species in which we
identified the EarthTec QZ concentrations required to eradicate 50% of
a population of exposed adult B. tentaculata and 50% of a population of
exposed adult Physa gyrina. Together, our results demonstrate that
EarthTec QZ holds potential for B. tentaculata control, but further work
needs to be conducted in order to minimize the negative effects of this
compound on non-target, native species.

105 Ecotoxicological Consequences of the Invasive Apple Snail
Pomacea maculata in Louisiana wetlands
S. Banerjee, P.L. Klerks, University of Louisiana, Lafayette / Department of Biology

The apple snail Pomacea maculata is an invasive species that has recently
been introduced and is now present in several marsh areas in the southern
United States. The introduction and range expansion of this species are
bound to have a variety of ecotoxicological consequences, including
possible changes in the biogeochemical cycling of metals. Such changes
can result from diverse activities of the snail including feeding by pedal
surface collecting from the water column, benthic grazing and sedi-
ment resuspension, and herbivory. In addition, fecal matter deposition on
the sediment surface can enhance metal flux from water column to the

Monday Platform Abstracts
sediment. The apple snail invasion may also have a favorable aspect by providing us with a species that may be well suited for biomonitoring of environmental contaminants. Our ongoing research will provide insights into both aspects of the snail’s introduction, using two approaches. A field approach investigates the presence of correlations between snail tissue burdens and environmental concentrations of metals, by quantifying copper levels in sediment, water, vegetation and snails at sites that differ in physicochemical parameters and biological characteristics. The other approach uses laboratory mesocosms set up with sediment, water and aquatic vegetation collected from one of our field sites. This approach will determine whether the presence of apple snails affects the distribution of copper in these mesocosms. Copper levels will be determined in snail tissues, plants, sediment and water at the end of a 1-month period, and the environmental distribution compared between mesocosms with and without apple snails. The research is ongoing; results will be presented at the meeting. The study connects two environmental issues - biological invasions and metal pollution, both of which can have significant impacts in freshwater ecosystems. It is critical to understand whether invasive species affect contaminant dynamics in their environment and whether they can be used as contaminant biomonitor.

106 eDNA metabarcoding supporting community assessment of environmental stressor in a field-based sediment microcosm study

Y. Jianghua, Nanjing University / School of Environment

Conventional ecological risk assessment on toxic stressors in sediment is limited to a small and select fraction of benthic communities. Ecogenomic approaches provide unprecedented capacity to monitor the changes of biodiversity and community composition in the field, but how to utilize it to assess ecological impact by contaminants remains largely unexplored. Here, an environmental DNA (eDNA) metabarcoding approach was used to assess the effect of copper on changes in biodiversity and community composition across the Tree of Life (including bacteria, protist, algae, fungi and metazoa) in a field-based microcosm. Many micro-organisms across a broad range of taxa groups changed their relative abundance in response to increased copper concentrations in sediments. Changes in community structure of microbiota appeared to be more sensitive to copper than survival of laboratory-bred organisms and indigenous macroinvertebrates. Copper caused a significant shift in prokaryotic community composition via substitution of dominant species. Network heterogeneity and Shannon diversity of the bacterial community decreased in the copper contaminated sediment with less effort than manually processing samples. Our study highlighted the value of community profiling by eDNA based approach in prospective and retrospective risk assessment of environmental stressors.

107 Antioxidant defense, metabolism and morphological changes in Octopus maya during embryo development: Does mommy history matter?

K.M. Ortega-Ramirez, National Autonomous University of Mexico / Posgrado en Ciencias del Mar y Limnología; G. Rodríguez-Fuentes, National Autonomous University of Mexico / Unidad de Química Sisal; F. Díaz, CICESE / Departamento de Biotecnología; C. Caamal-Monsreal, National Autonomous University of Mexico / Facultad de Ciencias; L. Mendez-Can, National Autonomous University of Mexico / Posgrado en Ciencias del Mar y Limnología; S. Ramos-Rodriguez, M. Mascareño-Miquelajuarregui, C. Rosas, National Autonomous University of Mexico / Facultad de Ciencias

Octopus maya is an endemic species from the Yucatan Peninsula, Mexico, which presents holobenthic embryonic development. Characterizing the biology and biochemistry of embryonic forms provides information on how organs develop and activates the physiological mechanisms that will prevail for the rest of their lives. The importance of aerobic respiration lies in the efficiency and production of energy, translated into ATP which is traditionally measured as oxygen consumption (MO2). During respiration, reactive oxygen species (ROS) are produced, which react with biological macromolecules, producing structural cellular damage. Its effects are counteracted by the antioxidant defense system (ANTIOX). The objective of this work was to establish a solid baseline of the ANTIOX, morphological changes and MO2 throughout the embryonic development of O. maya using embryos from mothers captured at different seasons. Three females were captured at Sisal, Yucatan, Mexico during dry and rainy season and were kept at similar conditions until spawning. Embryos were maintained for development in 40 L tanks at 24°C, 36 UPS and 5 mg/L OD for approximately 50 days. Every 5 days, 15 embryos were sampled from each female. It was observed that there is a very close relationship between organogenosis and the metabolism of embryos: at the end of stage XV enzymatic activity, the consumption of vitellus, and the MO2 showed an evident increase, just when the activity of the systemic heart started. Results of morphological changes indicated that there were statistical differences between developmental stages, but no significant differences were detected between embryos from mothers captured at different seasons. Oxygen and vitellus consumption indicated significant differences at stages closer to hatching with respect to early stages. In addition, there was a higher consumption in oxygen and vitellus in embryos from mothers captured during the dry season. With respect to antioxidant defense, activities of CAT, SOD and GST indicated that there were differences between developmental stages, increasing with the growth of the embryo, but no significant differences were detected between seasons. On the contrary, oxidative damage, measured as lipid hydroperoxides and oxidized proteins presented higher values at early development stages, especially in embryos from mothers captured during the dry season.

108 Alterations in the Gonads of Blue Mussels Mytilus edulis Exposed to Paracetamol

W. Koogow, University of Brighton; C. Ciocan, University of Brighton / School of Pharmacy and Biomolecular Sciences

Paracetamol or acetaminophen is the most widely used pharmaceutical in the world and recent studies have reported its progressively increasing concentrations in aquatic compartments. Meanwhile, scientific evidence suggests that pharmaceuticals can exert some important toxic effects to non-target aquatic species, due to their chemical and biological properties. The present study aims to assess the biological responses induced by paracetamol, at environmentally relevant levels, in the blue mussel Mytilus edulis, namely focusing on reproductive parameters. After 24 days laboratory exposure, seven potential target genes were selected to investigate toxicological effects in mussel gonads, and potential disturbances of the reproductive cycle. Results show the modulation of some important reproduction-related genes: estrogen receptor 2 (ER2), vitelline envelope zona pellucida domain 9 (V9), and vitellogenin (VTG). The variation in mRNA expression of four other genes involved in apoptosis (CASP8, HSP70, BCL2 and FAS) was also investigated. Histopathological alterations caused by paracetamol, together with its potential to act as a non-traditional endocrine disruptor are discussed.

109 But first, let me take a shelf-fie: Standardizing embryo development for novel ecotoxicological endpoints in freshwater snails using macrophotography

R.K. Osborne, R.S. Prosser, University of Guelph / School of Environmental Sciences

Despite being the most diverse class of the Molluscan phylum, very little is known about Gastropods (snails and slugs), especially those that live in freshwater. Embryonic development in freshwater gastropods has yet to be characterized thoroughly and as a result, developmental milestones are not common as ecotoxicological endpoints. Throughout embryonic development, numerous complex changes occur on timescales ranging from seconds to days and improvements in technology allow us to accurately measure these changes on increasingly finer scales. As these developmental changes reveal important underlying evolutionary and ecological processes, it is especially important now to improve our understanding of them in light of the unprecedented local
and global change that many populations are experiencing. Using novel macrophotography and image processing techniques, we identified and measured embryonic growth patterns and the timing of developmental milestones in the freshwater snail Planorbella pilsbryi. Variations in abiotic factors (temperature and light) were tested to assess the natural variability of embryonic development within and between egg masses, as well as the influence of culturing conditions on development. There was very little variability within and between egg masses cultured under the same conditions, which allowed us to develop a standardized growth and development curve for this species. Our previous multi-generational work has shown that embryonic milestones may reveal the influence of past parental contaminant exposure, provide insight into the complex biological responses to environmental stress, and predict the health of juveniles later in life. To explore these concepts further, testing of the influence of contaminants on embryonic development and their use in multi-generation studies is ongoing.

110 Exploring the effects of bisphenols in the freshwater snail Planorbella pilsbryi using traditional apical endpoints and metabolomic approaches

E.A. Gilroy, K.B. Robichaud, M. Villega, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R. Brua, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division

Bisphenol A is a precursor to plastic polymers used in consumer products, including some food containers and/or packaging, adhesives and paper coatings. Increasing concerns about its endocrine activity and leaching from plastics have led to its ban from the production of baby bottles. However, BPA remains in use in other applications; alternate products are being developed and/or are in use, many of which are similar in structure and could pose comparable health hazards. These concerns are being addressed by the Chemicals Management Plan, a government initiative aiming to reduce the risks posed by chemicals to Canadians and their environment. Endocrine disrupting chemicals (EDCs) interfere with hormone systems and can change the normal functioning of a variety of processes, including, sexual development, reproduction, and growth. These compounds are often not overtly toxic, but cause effects at low concentrations after prolonged exposure. Hence, these chemicals with endocrine disrupting potential are of concern at concentrations detected in the environment. Freshwater snails have been identified as sensitive biota to BPA, however, there is a lack of information on the effects of alternative bisphenols (e.g., BPF and BPS). Until recently, the bulk of toxicology studies have overlooked freshwater mussels, even though early stages of some species have been reported as particularly sensitive to contamination (e.g., metals, road salts). Recent efforts to develop internationally standardized toxicity testing procedures have been fruitful, with the development of guidelines for life-cycle toxicity testing with freshwater snail species for the assessment of endocrine disruption. In the present study, we assessed the acute and chronic toxicity of BPA in the freshwater snail Planorbella pilsbryi in a 96 h assay examining survival and egg production, and a 28 d assay modelled on the OECD 2016 Lymnea stagnalis Reproduction Test, extended to evaluate effects on juvenile stages. The metabolomic response of snails after a 96 h exposure to BPA will also be assessed by nuclear magnetic resonance spectrometry using a non-targeted approach, to gain a better understanding of potential mechanisms of action. This study will evaluate the acute and chronic toxicity of BPA in different life stages of freshwater snails, as well as its endocrine effects, if any. Further research underway will also assess the toxicity of alternative bisphenols BPF and BPS.

111 Refining Standard Methods for Conducting Chronic Toxicity Tests with Juvenile Freshwater Mussels

N. Wang, J.L. Kunz, J.A. Steevens, US Geological Survey / Columbia Environmental Research Center; E. Hammer, USEPA; C. Barnhart, Missouri State University / Biology

The ASTM International standard for chronic toxicity tests with freshwater mussels was published in 2005 and needs refinement to optimize survival and growth of juvenile mussels in standard (4-week) and longer-term (12-week) exposures. We conducted multiple studies with juvenile fatmucket (Lampsilis siliqua), a commonly tested mussel, to refine test conditions and use refined methods to evaluate the influence of test duration (4 to 12 weeks) and starting age of organisms (1-week to 2-month-old juveniles) on mussel sensitivity to chemicals. Results of a feeding study indicated that (1) an addition of silica sand substrate limited the accumulation of debris and biofilm on mussel shells; (2) replacement of sand and test chambers every 2 weeks reduced debris and biofilm on test chamber surface; (3) raising water temperature from 20°C recommended in ASTM standard to 23°C increased growth of juvenile fatmucket; and (4) increased feeding rate and frequency of algal mixture from traditional twice daily (i.e., manual feeding 2 mL of algal mixture in the morning and afternoon) to 6 times daily (automatic feeding 2 mL once every 4 h) increased more stable food in water column and substantially improved growth. Several 12-week toxicity tests were successfully completed with 95 to 100% control survival under refined test conditions. Younger (1-week-old) juveniles were more sensitive to NaCl than older (2-month-old) juveniles. Chronic effect concentrations of NaCl and Ni to fatmucket did not substantially change from 4- to 12-week exposures whereas effect concentrations of Zn observed in 4-week exposure decreased more than 2-fold at the end of 12-week exposure, indicating that chronic toxicity remained the same or increased (depending on chemicals tested) with extended periods from 4 to 12 weeks. An additional 4- to 12-week test with juvenile fatmucket in KCl exposures is ongoing, along with a partial life cycle KCl test starting with gravid female fatmucket. The effects on the juvenile growth in the 4- and 12-week exposure will be compared to the effects based on reproduction endpoints (e.g., glochidia viability and metamorphosis success) from the partial life cycle study.

Environmental Considerations for the Risk Assessment of Polymers, Rubber and Macropolymers: State of the Science

112 Overview of aquatic risk assessment polymers - evidence from cationic polymers

H. Sanderson, A. Brun, Aarhus University / Environmental Science; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; J. Brill, J.M. Rawlings, Procter & Gamble Company / Environmental Stewardship and Sustainability; M. Lam, Procter & Gamble / Global Product Stewardship; K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability

Polymers including macropolymers and rubbers are large macromolecules consisting of repeating monomer units. Polymers are an exceptionally diverse group of compounds with varying properties and uses. They can both be synthetic, such as plastics and rubbers (e.g. polystyrene; PET; PE; etc.) or natural, (e.g. DNA; starch; polyamides; polysaccharides). - hence, while all plastics are polymers - not all polymers are plastic. They have a wide and growing global use and represent a multi-billion US$ global market value with uses in the millions of tons per year. According to REACH legislation, polymers are defined as molecules that have at least three covalently bonded monomer units. These repeating monomers must represent the majority of the molecule’s weight. Polymers are currently exempt in REACH and generally not reviewed in some regulatory programs - this exemption is due to the assumption that there would be little toxicological concern due to their significant molecular weight and low water solubility. The big question now is how to assess and model these
113 Towards a Robust Quantitative Analytical Method for Aquatic Effects Testing of Cationic Polymers

M. Lam, Procter & Gamble / Global Product Stewardship; Y. Sun, K. Wehmeier, M.J. Karb, Procter & Gamble Company / Trace Analytical Core; J.M. Rawlings, Procter & Gamble Company / Environmental Stewardship and Sustainability; J. Brill, K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship

There is growing regulatory attention and increased use of water-soluble polymers in consumer cleaning products which requires robust environmental risk assessment methods. Analytical characterization is key step to provide an accurate measure of test chemical concentration in exposure solutions. With advances in mass spectrometric instrumentation, robust approaches are possible with many simple organic chemistries. However, historically polymers were a challenge due to their complexity of varying repeating subunits, and non-specific methodology such as total organic carbon was often applied for exposure solution analysis. The scope of analytical methods used in the past several decades have been to characterize polymers for molecular weight and structure, number of repeat subunits, with the aim to evaluate performance, measure rheological properties, and thermal mechanical properties (for solid polymers used in packaging). Several regulatory agencies have already identified cationic polymers as higher priority for registration due to their expected higher ecotoxicity potential, and this has led to the selection of several variants of polyquaternium-10 as candidate cationic polymers to case study the development of a high throughput, high sensitivity Flow Injection-High Resolution QTOF mass spectrometry method for exposure solution analysis in the testing of algae, aquatic invertebrate and fish embryo as part of the CEFIC “Improved Aquatic Testing and Assessment of Cationic Polymers (iTAP)” research program. To the best of our knowledge, this work represents the first known mass spectral attempt to quantitate high Mw cationic polymer exposures in aquatic ecotoxicity tests. Attempts have been made by others using wet chemistry methods or selective membrane methods for polyquaternium-10, but these were limited and generally not used in support of environmental effects testing. This presentation will cover polymer characterization methods to measure physical-chemical properties expected to be relevant for environmental risk assessment, and the strategy for detection and quantitation in exposure solutions and field studies. Insights into method reproducibility, specificity and sensitivity with mass spectrometric based methods are covered, and an evaluation of other analytical approaches like Capillary GPC-Mass Spectrometry for cationic polymers will be presented.

114 Progress in understanding the ecotoxicology of cationic polymers - evidence with Polyquat 10s

J. Brill, J.M. Rawlings, Procter & Gamble Company / Environmental Stewardship and Sustainability; A. Brun, Aarhus University / Environmental Science; Y. Sun, Procter & Gamble Company / Trace Analytical Core; M. Lam, S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability; H. Sanderson, Aarhus University / Environmental Science

Research has been undertaken to support the development of methods to improve the accuracy and precision of the aquatic environmental risk assessment of cationic polymers. The project aims to lay the foundation for regulatory acceptance based on improved methods for regulatory assessment and compliance testing of polymers and address significant gaps in the knowledge base. Cationic polymers are used in a wide range of personal care and fabric care products and present challenges to traditional hazard assessment. Cationic polymers combine two contrasting elements - a positive charge and a long hydrophobic chain - and the resulting dichotomy typically provides unusual behaviors in water, particularly in interfacial regions. One of the challenges is that the polymers are typically large and not expected to pass biological membranes, making toxicity testing problematic as they still exert demonstrable effects. Another is that they are expected to interact with the outer membranes of aquatic organisms and thereby affect their functionalities. This behavior makes it hard to describe the dose-response relationship as responses likely confound external physical effects and internal uptake. We are assessing a group of related but “understudied” model cationic polymers widely used in industry - polyquaterniums 6, 7, 10, and 16. The proposed polyquaterniums vary in molecular weight, %N, #C-N bonds, and charge density that we assessed for a correlation with effects. Initial investigations have focused on the polyquaternium 10 group. Due to widespread usage and lack of biodegradability the potential for environmental exposure is high. We conducted algal inhibition, acute invertebrate and fish embryo toxicity studies to understand potency within the class and assess toxicity mitigation factors such as humic acid. In parallel, analytical methods were developed and used to measure freely dissolved concentrations of cationic polymer. Experimental data to date suggests unique toxicity patterns to cationic polymers with issues concerning bioavailability, mitigation and physical impairment versus conventional organic compounds. This presentation will emphasize learnings on polymer/humic acid interactions and their effect on cationic polymer toxicity. We summarize by identifying informational needs for future environmental risk assessments of cationic polymers.

115 Application of standard tests to non-standard compounds - the aquatic toxicity of cationic polymers

A. Brun, Aarhus University / Environmental Science; J.M. Rawlings, J. Brill, Procter & Gamble Company / Environmental Stewardship and Sustainability; M. Lam, Procter & Gamble / Global Product Stewardship; M. Hansen, Aarhus University / Department of Environmental Science; K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; H. Sanderson, Aarhus University

Risk assessment of chemicals used in the environment rely to a large degree on data gained through standard toxicity test guidelines. The guidelines are designed to ensure comparability between chemicals and laboratories. But what if we want to test a chemical that is not comparable to our “usual suspects”? Polymers are widely used globally, but they differ from well-investigated compounds like pesticides or pharmaceuticals on a number of parameters, e.g. their size and structure or the way they interact with a non-target organism. Not a lot is known on polymers’ effect on aquatic organisms. This is mainly due to the assumption that polymers because of their large size will not be able to cross the cell membrane and therefore not be toxic. This assumption has made them exempt from the REACH-framework, leading to low requirements for acquiring data on polymers. Though, it is known that cationic polymers (CP) bind to
negatively charged surfaces, including the surface of an organism or some aquatic organic substances. Early polymer work showed that CPs may not cause direct toxicity but actually can indirectly harm or impair aquatic organisms. The limited data on CPs combined with the known effect CPs can have, underlines the need for further exploring of the effects on aquatic organisms. Scientific knowledge should add to a better understanding of environmental effects of polymers and to lay the scientific foundation for a possible inclusion in regulatory frameworks. The unusual mode of“toxicity” and how we describe, test and model environmental interactions of CPs is a challenge that needs to be met. The known effect-predictors like hydrophobicity may not describe physical-chemical impacts on toxicity caused by a CP. Instead, other properties as charge-density, average molecular weight or viscosity may be more appropriate effect-predictors. This research is the early foundation of a science-based approach of testing CPs. As a starting point different tradenames of the cationic polymers Polyquaternium-6, -7, -10 and -16 have been tested by applying standard toxicity guidelines, namely ISO 11348-3, OECD 201, OECD 202, OECD 211 and OECD 236. We will present these findings to give an overview of the aquatic toxicity and cast light upon which properties could be drives for toxicity. In addition, we will present what challenges arise when applying standard test guidelines to non-standard compounds, and possible solutions on how to overcome them.

116 A proposed approach for assessing cationic polymers bioavailability in the environment

D.J. Cros, Laboratoire PAREVA / R&D and Regulatory; C. Durou, CEHTRA SAS

PolyHexaMethylene Biguanide, hydrochloride (PHMB) is a cationic polymer used as a biocide in a wide range of end-use products. One of its properties is to combine very quickly and very strongly to most of solids leading to formation of non-extractible residues. This property is an advantage for its biocide effect however this makes environmental studies difficult to carry out and to interpret results for conducting an Environmental Risk Assessment (ERA). No consensus is (yet) available to well define how Non-Extractible Residues (NER) should be addressed in an ERA. Ideally, it should be tested in a standard system but soils, sediments and waters sources are so diverse around the world. We tried to address this question by using HPLC to study the overall behaviour of PHMB towards easily available stationary phases (5um), selected for their similarity to components of environmental soils : bare silica to assess its behaviour with polar suspended solids or sediments with low electronic charge, cation exchange bonded silica to assess its behaviour on soluble or suspended matter carrying a strong anionic function (such as humic, fulvic and similar acids) and C18-grafted silica to evaluate its behaviour on apolar un-charged soluble or suspended organic matter (or other plant debris). To increase the environmental relevance of study, empty HPLC columns were filled-in with natural sand grades. PHMB behaviour was evaluated with a 2-step protocol: - A percolation step to measure its combination ratio towards environmental substrates. - A washing step with severe conditions to assess PHMB combination strength with various carriers by measuring its maximum extractable portion. In all cases, 100% PHMB was retained on the tested stationary phases during the percolation step. After the washing step, the recovery rates were 55%, <14% and 71% for the 3 tested columns respectively. PHMB towards natural sands showed the same behaviour, but with no recovery during the washing step. This was probably due to the presence of organic matter in these natural matrices (not measured) as inorganic and high size organic compounds create cavities able to strongly entrap organic substances. This approach, easily reproducible inter-lab, is proposed to assess limited bioavailability after binding (mainly cationic polymers), and taken into consideration in ERA.

117 Quantitative determination of microplastics in environmental water samples using Pyrolysis-Gas Chromatography - Mass Spectrometry

H. Nvoni, University of South Africa / Nanotechnology and Water Sustainability (NanoWS) Research Unit; B. Vilakati, B.B. Mamba, T.A. Msagati, University of South Africa / Nanotechnology and Water Sustainability Research Unit (NanoWS)

In the recent past, microplastics have been recognized as emerging pollutants and their measurements in environmental waters have emerged as challenging to the analytical scientist. The pyrolysis - gas chromatography/ mass spectrometry (Pyr-GC/MS) has been used for simultaneous determination of the microplastics and polymer additives. The technique is based on the combustion of the sample and subsequent detection of the thermal degradation products of the polymers. The identification of thermal degradation products then serves as markers specific for each polymer. Sadly, results obtained through Pyr-GC/MS analysis have been the limited determination of the mass concentration of plastic and have not been used to provided information on the number of particles in the aquatic sample. In this work, we report a new approach of using Pyr-GC/MS method to provide particle counts of common consumer microplastics (polypropylene, polycarbonate, polystyrene terephthalate, polyvinyl chloride, polystyrene, poly (methyl methacrylate), polystyrene and polyamide 6) in environmental water samples. To obtain external calibration curves, the stock solution of certified reference microplastics suspension were diluted with an appropriate solvent. Quantification of individual microplastics was based on a five-point matrix-matched using integration results of mass chromatograms for preselected indicator compounds. The concentration ranges to which the method can be applied were determined and reported. Further, the Pyr-GC/MS-based method was successfully applied to the microplastic standard mixtures and typical environmental water samples.

118 Short-Term Effects of Plastic Consumption on Anemones

N. Sawickij, Hawaii Pacific University; Z. Diana, Duke University / Marine Science and Conservation; N. Rivera, Duke University / Department of Civil Environmental Engineering; M. Chernick, Duke University Nicholas School of the Environment; H. Hsu-Kim, Duke University / Department of Civil Environmental Engineering; D.E. Hinton, Duke University / Nicholas School of the Environment; D. Rittschof, Duke University Marine Lab / Nicholas School of Environment

Ubiquitous plastic pollution raises pertinent questions of the impacts of plastic pollution on organisms. Plastic consumption by organisms is documented though impacts of the complex mixtures that are plastic leachates are poorly understood. This study aims to quantify metals in anemones, Aiptasia pallida, after individuals consumed one pellet per day of level II high-density polyethylene (HDPEII) and level III high-density polyethylene (HDPEIII) for 12 days. The pellets were fresh preproduction pellets from the National Institute of Standards and Technology (NIST). Anemones consumed all NIST pellets as if they were food. On average, pellets were retained for 5.5 to 6 hours. In a separate experiment, pellets egested by the first anemones were fed to other anemones until they were no longer consumed. For some plastics, the flavor appears to decline over time. HDPE III pellets were retained for shorter periods of time and not eaten after 4 egestions. Inductively coupled plasma mass spectrometry results show that depending on the plastic type, consumption alters the amount of metals in anemones. Some plastics delivered metals to anemones, others removed them. Anemones consume plastic, plastic loses flavor, and plastic changes metal concentrations in anemones. Our results have environmental health and food safety implications.
119 Towards the Development and Application of an Environmental Risk Assessment Framework for Microplastic

T. Gouin, TG Environmental Research / Safety and Environmental Assurance Centre

Plastic waste emissions to the environment and subsequent degradation into microplastic particles (MPs) represents a global concern given their potential to interact with biota. Current understanding of the potential impacts from MPs on aquatic and terrestrial population stability and ecosystem structure and function, however, is insufficient to fully assess these environmental risks. To address these issues, we held a multi-stakeholder discussion to identify and prioritize key knowledge gaps in assessing potential risks. This discussion took place during a one-day, International Council of Chemical Associations (ICCA) sponsored symposium, which involved 39 scientists from 8 countries with representatives from academia, industry, and government. We asked participants to consider the following: Discuss the scientific merits and limitations of i) applying a proposed conceptual environmental risk assessment (ERA) framework for MPs and 2) identify and prioritize major research needs in applying ERA tools for MPs. Multi-stakeholder consensus was obtained with respect to the interpretation of the current state-of-the-science related to effects and exposure to MPs, whereby it was suggested that environmental MPs are unlikely to represent a high risk. It should be noted, however, that participants also agreed that the quality and quantity of data requires substantial improvement before conclusions regarding the potential risks and impacts of MPs can be fully assessed. This presentation will summarize conclusions on research needs and outline a framework for an environmental risk assessment on MPs.

121 Response to Edwardsiella piscicida infection in estrogen exposed juvenile largemouth bass (Micropterus salmoides)

Disease outbreaks, skin lesions, fish kill events, and reproductive abnormalities have been observed in wild populations of Centrarchids in the Chesapeake Bay watershed (CBW). Occurrence of estrogenic endocrine disrupting compounds (EEDCs) such as synthetic and natural hormones from wastewater treatment plants and livestock operations as well as pesticides and phytoestrogens from agricultural lands have been implicated as potential causes of these adverse effects. Fish health is currently monitored in the CBW; however, direct associations between altered disease susceptibility and EEDC exposure have not been confirmed. Host-pathogen interactions and outcomes following EEDC exposure depend on a number of factors including the host fish life stage and physiological condition, environmental conditions (e.g. water temperature), and specific attributes of the disease organism. This study was designed as an initial investigation to evaluate the effects of estrogen exposure on disease susceptibility in a fish species relevant to the CBW using a laboratory disease challenge model. We examined the effects of exposure to a potent synthetic estrogen (17alpha-ethinylestradiol, EE2) on disease susceptibility in juvenile (6 months old) largemouth bass (Micropterus salmoides) infected with Edwardsiella piscicida. Fish were exposed to EE2 treatments for 4 weeks, then moved to EE2-free water and infected with E. piscicida through intraperitoneal injection within 48 h post-treatment. The average measured EE2 concentrations in each treatment were: < 0.4 ng/L EE2 (control); 0.9 ng/L EE2; and 9.1 ng/L EE2. Endpoints included: survival, histopathology, hepatosomatic index (HSI), alternative complement pathway analysis, and transcriptomic changes in liver and spleen tissue. Increased survival was observed with increasing EE2 concentration, resulting in significantly greater survival in the 9.1 ng/L EE2 treatment compared to control. HSI was significantly greater in the high EE2 treatment compared to control, both immediately after EE2 treatment and following the disease challenge. The observed effects may result from stimulation of immune pathways in response to the estrogen exposure. These pathways are being further examined through RNAseq. Our results demonstrate that exposure to a model EEDC can induce changes in disease susceptibility in this economically important fish species.

Addressing Existing Challenges in Immuno-ecotoxiconology: From Tool Development to Risk Assessment - Part 2

120 The fish immune system under the impact of stressor combinations: are estrogenic endocrine disruptors enhancing or attenuating the susceptibility towards pathogens?

K. Rehberger, C. Bailey, A. Casanova-Nakayama, S. Butzier, E. Herzog, L. Kernen, E. Wernicke von Siebenthal, University of Bern / FiWi; H. Segner, University of Bern / Centre for Fish and Wildlife Health

Freshwater fish are threatened by the cumulative impact of multiple stressors. Exposure to environmental contaminants can alter immune responses, potentially putting fish at risk of disease and death. Here, we investigate if exposure of rainbow trout, Oncorhynchus mykiss, to environmentally relevant concentrations of ethinylestradiol (EE2) modulates the response of the fish to infection with the myxozoan parasite, Tetracapsuloides bryosalmonae, which causes proliferative kidney disease (PKD). The experiment was designed as a long-term, chronic study. Three key findings were generated by the experiment: (i) the EE2 exposure had an immunomodulating effect in rainbow trout and this effect occurred in the same concentration range as the EE2 effect on the reproductive system. (ii) the EE2 exposure altered immune parameters of rainbow trout. RNAseq analysis revealed a greater number of differentially expressed genes (DEGs) across major physiological and immunological processes in the PKD x EE2 group. These DEGs were observed neither in the PKD-only group nor in the EE2-only group. (iii) the infected EE2-exposed fishes showed a decreased parasite load and reduced pathological alterations in comparison to the PKD-only condition, suggesting an attenuating effect of the EE2 treatment. This finding is in contrast to published studies of other groups as well as our own group, which show immunosuppressive effects and increased pathogen susceptibility of estrogen-exposed fish. It may indicate that the immunological action of estrogens in fish, as in mammals, can be paradoxical, i.e. exerting both immunosuppressive and immune-enhancing actions, depending on the estrogen concentration and the physiological condition of the organism.

122 The impact of various oiled sediments on immune-related transcriptional responses in Southern flounder (Paralichthys lethostigma)

M.L. Rodgers, R.J. Griffitt, University of Southern Mississippi / Coastal Sciences

Previous work in our lab indicates that Southern flounder (Paralichthys lethostigma) exposed to oil-contaminated sediments experience reduced growth and survival, increased occurrence of gill abnormalities, and shifts in the gill and gut microbiomes. We believe that some of these changes can be attributed to suppression of the immune system following oil exposure. In order to elucidate the full suite of immune effects that an event such as the Deepwater Horizon oil spill elicits, we performed RNAseq on livers from Southern flounder collected at an oiled field site post-spill and compared them to livers from lab-exposed flounders to determine transcriptomic differences in wild vs. lab exposures. Overall, only 3 immune-related pathways were significantly dysregulated in the lab-exposed group compared to 26 in the wild-caught group. In order to obtain a clearer understanding of factors that contribute to immune dysregulation following oil exposure, we then exposed flounder to oiled sediment at two different concentrations (13.5 g/kg and 27 g/kg) for 7 days. On the seventh day, half of the control group and half of the...
oil-exposed group were subjected to a one-hour challenge with the pathogen *Vibrio anguillarum*. 24 hours later, fish were harvested, and spleens were taken for RNAseq. For both concentrations, the oil alone, pathogen alone, and oil + pathogen groups showed distinct canonical pathway profiles with relatively few pathways overlapping between all three treatment groups. In comparing dysregulated immune pathways between the oil alone groups, the higher dose exhibited twice as many dysregulated immune pathways than the lower dose (44 vs. 22). Interestingly, both oil doses shared dysregulation of immune pathways relating to acute phase response and various interleukin signaling, but the higher oil dose exhibited unique dysregulation of pathways related to T and B cell processes. While there was nearly universal suppression of immune pathways at the higher oil dose, the lower oil dose exhibited a mosaic pattern of expression with some immune pathways activated and other suppressed. In the oil + pathogen groups, the higher oil dose also led to an increased number of dysregulated immune pathways (31 vs. 16), however, there was a unique and interesting pattern of dysregulation: in the higher oil dose, there was a clear pattern of immune pathway suppression, but in the lower oil dose there was a strong pattern of immune pathway activation.

123 Assessing the effects of microcystin LR ingestion on innate immunity and the gut microbiome of zebrafish

The endangered Lost River sucker (*Deltistes luxatus*) of Upper Klamath Lake (OR) is threatened by a lack of substantial recruitment into older age classes. Despite successful spawning of resident adult fish each spring, juvenile fish do not survive to sexual maturity. Several environmental factors are thought to contribute to juvenile mortality including poor water quality, infectious disease and exposure to the cyanobacterial toxin microcystin. Our group has observed the presence of *Microcystis* cells in the digestive tract of juvenile fish during summer *Microcystis aeruginosa* blooms leading to the hypothesis that ingestion of microcystin contributes to low juvenile survival. However, histopathology consistent with microcystin toxicity is rarely observed for wild caught suckers. In 2017, we conducted a pilot study that revealed dysregulation of the hepatic transcriptome of lost river suckers 24 hours after microcystin ingestion including genes involved in metabolism and reproduction. Based upon these initial findings, we used zebrafish to model the potential effects of microcystin ingestion on immunity owing to the utility of this species. Innate immunity represents the first line of defense against pathogens largely through the response to pathogen associated molecular patterns (PAMPs) that are recognized by pattern recognition receptors on or within leukocytes. This process results in inflammatory and interferon-based responses and is partially regulated by the host microbiome. To address the hypothesis that microcystin LR ingestion affects innate immunity, adult zebrafish were fed a microcystin diet for 7 days—a time span that correlates with average, summer *Microcystis* blooms in Klamath Lake. On the 8th day, fish were injected with microbial PAMPs (peptido-glycan or Poly:IC) to mimic infection. Livers and intestines were sampled from fish on days 3 and 7 post PAMP stimulation to assess both hepatoxic and immunotoxic effects of microcystin ingestion by transcriptome analysis. In addition, microbial community structure was assessed post microcystin consumption to address toxin mediated dysbiosis. Current investigations include assessing differential gene expression and identifying innate immune pathways modulated by microcystin ingestion. Together, this study will provide insight into the interactive or synergistic effects of factors that are implicated in the lack of recruitment of the Lost River suckers of Upper Klamath Lake.

124 The impacts of developmental thyroid disruption on immune function and the immune response in the fathead minnow

L. Thornton Hampton, University of North Texas / Biology; M.G. Finch, Texas Christian University / Department of Biology; B.J. Venables, University of North Texas / Biological Sciences; M.K. Sellin Jeffries, Texas Christian University / Department of Biology

Current evidence suggests that thyroid hormones (THs) may impact development of the immune system. However, studies that explore the role of THs in immune development are limited, and the mechanisms leading to alterations in immune function are poorly understood. It is important to elucidate the role of THs in immune development given that many environmental contaminants have been shown to disrupt TH homeostasis and may also have negative impacts on the immune system. As such, the main goal of this study was to determine the long-term consequences of early life stage (ELS) hypothyroidism on immune function. To achieve this goal, fathead minnows (FHM, Pimephales promelas), a newly developed model for immunotoxicity, were exposed to the model thyroid suppressant propylthiouracil (PTU) from < 1 to 30 days post hatch and reared under normal conditions until adulthood. FHM were infected with Yersinia ruckeri and monitored for 14 days to determine pathogen resistance. At eight hours post injection, the immune response was assessed via a suite of endpoints (i.e. bacterial load, hematocrit, spleen index, leukocyte counts). Respiratory burst and phagocytic cell activity were also assessed. No significant alterations were detected for most endpoints measured. However, phagocytic cell activity was significantly reduced in female fathead minnows exposed to PTU, suggesting that immune cell function or cellularity may have been impacted by ELS hypothyroidism in a sex-specific manner. The potential impact of ELS hypothyroidism will be further explored via the assessment of the renal transcriptomic response in female FHMs.

125 Chemical-induced changes in immune parameters following a lipopolysaccharide challenge in the amphibian Xenopus laevis

M. Gallant, N. Baldwin, University of Saskatchewan / Toxicology Centre; K. Hamonic, University of Saskatchewan / Department of Animal and Poultry Science; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre

Numerous contaminants present in the aquatic environment have the potential to disrupt immune defences and potentially increase disease susceptibility. Amphibians are known to inhabit contaminated environments, and there is growing concern that known immunotoxic chemicals may magnify the impacts of global emerging infectious diseases. We assessed two environmental chemicals of concern, benz(a)pyrene (BaP), a polycyclic aromatic hydrocarbon and chlorpyrifos (CPF), an organo-phosphate pesticide for their ability to alter immune parameters in juvenile *Xenopus laevis*, alone and following a challenge with simulated pathogen, lipopolysaccharide (LPS). Individuals were aqueous exposed to BaP (70 or 350 µg/L) or CPF (1 or 10 µg/L) for seven days followed by immune challenge. Assessment of differential leukocyte profiles (by flow cytometry) and expression of cytokines in the liver (by qPCR) was conducted in PBS-injected (immune-rested) and 10 µg/L LPS-injected (immune-stimulated) individuals. The highest concentration of BaP impaired the inflammatory response of juvenile *X. laevis* to LPS as indicated by an inability to increase the granulocyte:lymphocyte (G:L) ratio or IL-1β (interleukin-1beta) mRNA expression. Exposure to CPF resulted in an overall reduction in circulating lymphocytes, a decrease in basal circulating monocytes, and increased expression the cytokines TNF-α (tumour necrosis factor-alpha) and CSF-1 ( colony stimulating factor-1). This study demonstrates that chemicals can modulate the inflammatory immune response to a simulated pathogen, providing some of the first evidence of the immunotoxic potential of these compounds in amphibians. Given the fundamental role of inflammation in immune responses, these findings suggest that exposure to BaP and CPF may have consequences for amphibian susceptibility to ecologically relevant pathogens.
126 Immune responses of American kestrel hatchlings exposed to isopropyl triphenyl phosphate flame retardants

Disease dynamics in wildlife are commonly related to changes or increases in environmental stressors that are placed upon an animal. Environmental pollutants are known to evoke immunomodulatory effects that result in impaired resistance to infection and potential increases in disease outbreaks. Immunological effects of contaminants also have implications for animal fitness and reproduction due to the link between the immune and endocrine systems. Organophosphorus flame retardants (OPFRs) have been increasingly used as replacements for brominated flame retardants such as polybrominated diphenyl ethers and hexabromocyclododecane. Because OPFRs show structural similarity to organophosphorus insecticides, their potential toxicity and immunomodulatory effects may also be similar. Raptor species, such as the American kestrel (Falco sparverius), have been shown to be highly susceptible to avian influenza and other emerging infectious diseases caused by various microbial pathogens. We investigated the immunomodulatory effects of the emerging flame retardant isopropyl triphenyl phosphates (ITPs) on kestrel nestlings. ITPs are components of multiple flame retardant mixtures currently on the market (e.g. Firemaster(R) 550) and with their increasing use, both the U.S. Environmental Protection Agency and Environment and Climate Change Canada’s Chemicals Management Plan have prioritized ITPs for assessment. We determined the ability of the nestlings to respond to a novel disease threat (immune-challenge with a viral analogue) when exposed to ITPs and used multiple methods, including histology of immune organs, measurements of phagocytic activity, and examination of immune cell types (heterophils, monocytes, lymphocytes, and CD4+ cells) to assess immune system changes. We will present the results of these assays and discuss their utility for assessing immune responses in non-model birds.

127 Immunotoxicity evaluation as a tool for protecting public and environmental health from PFAS

T. Woodlief, S. Vance, East Carolina University / Department of Pharmacology & Toxicology; Q. Hu, J.C. DeWitt, East Carolina University / Pharmacology and Toxicology

One group of per- and polyfluoroalkyl substances (PFAS) that has emerged in the aquatic environment in the past five years are perfluoroalkyl ether acids (PFEAs). Although they are marketed as having a favorable toxicological profile, the reality is that very little is known about the toxicity of these emerging PFAS. Further, data gathered from PFAS that have been phased out of production in the United States demonstrate that these “legacy PFAS” are immunotoxicants in exposed humans and experimental animals. Deficits in immune function occur at doses that do not negatively impact lymphoid organ weight, histopathology, or cellularity. This is a point of concern for PFAS as while standard toxicity studies include assessments of lymphoid organ weight, histopathology, and cellularity, they do not include measures of immune function without a “trigger” such as a histopathological finding in the spleen, for example. Therefore, the weight-of-evidence supports immune function assessment for PFAS, especially for those that have become part of the aquatic environment and that enter drinking water systems as well as wildlife habitat. Our laboratory has applied the suite of immunotoxicological assays recommended for assessment of pesticides as well as environmental chemicals to several PFEAs of concern in the state of North Carolina using a C57BL/6 mouse model. One compound, 2,3,3,3-tetrafluoro-2-(heptafluoropropylo)-propionate (known by the trade name as “GenX”), produced an unbounded no observed adverse effect level (NOAEL) for suppression of the primary antibody response in female mice at an internal dose that was ~90% lower than the internal dose associated with the NOAEL for a legacy PFAS. Neither compound altered spleen weights, cellularity, or splenic lymphocyte subpopulations in a dose-dependent manner or in association with suppression of the antibody response. Work with other PFEAs that have fewer carbons than GenX demonstrates that when orally administered to male and female C57BL/6 mice for 30-days, standard markers of toxicity for PFAS, such as increases in liver weight and peroxisomal enzyme activity, are not observable. Therefore, PFEAs may affect the immune system without producing effects detectable in standard toxicity studies. Our work with PFAS of unknown toxicity and high relevance to the aquatic environment demonstrates that immunotoxicity is a relevant and sensitive endpoint for public and environmental health protection.

Assessing Contaminant Effects in Ecosystems with Multiple Stressors - Part 2

128 A pathway toward the adaptive management of multiple stressors for the Upper San Francisco Estuary region

W.G. Landis, S.R. Eikenbary, A.J. Markiewicz, Western Washington University / Institute of Environmental Toxicology

Landis et al., in a 2017 publication, describe a workable adaptive management scheme. We have begun to apply this scheme to a classic case study, the Upper San Francisco Estuary (USFE). The USFE, also known as the Bay/Delta, is a region characterized by extensive development, agricultural inputs and iconic species. The goal of our effort is to build an adaptive management process based on the Bayesian network relative risk model (BN-RRM) to ensure the sustainable and resilient region. As is typical for the approach, we catalog sources, endpoints, the habitats, effects and impacts and construct a conceptual model to capture the cause-effect relationships. Data are acquired from a variety of sources and GIS information used to provide context. The study area is then delineated in a series of risk regions constructed in regard to data availability and management goals. We define sustainable and resilient in a risk assessment modality; the boundaries of the sustainability box are defined by the endpoints derived in the risk assessment process. Risk is defined as the probability of exceeding the boundaries of the sustainability box along one of more axes. The resiliency of the system is defined by the change in probability of exceedance beyond the defined parameters of the model subjected to a variety of perturbations. A variety of management options can be examined to evaluate the efficacy in their abilities to affect the system. The analysis provides the framework so that the observation, orient, decide, act (OODA) loop can be employed. At the end of the process the adaptive management process will be available for testing and evaluation.

129 Multi-stressor effects on biological communities in contrasting regions of the USA

Multiple physical and chemical stressors can simultaneously affect the biological condition of streams. To evaluate such complex relations, the U.S. Geological Survey sampled from 75 to 98 streams in each of four regions of the United States from 2013 to 2016. Water and sediment chemistry, streamflow, and temperature were characterized for as many as 14 weeks prior to ecological surveys of habitat and of algal, macroinvertebrate, and fish communities in each stream. Boosted regression tree (BRT) models were developed for biological metrics of algal, macroinvertebrate and fish communities based on in-stream stressors. Results from the BRT models informed the development of structural equation models (SEM) for two of the regions that link landscape drivers, reach-based variables, instream stressors, and ecological responses. Multiple physical and chemical stressors were included in the models for all four regions but the mix of stressors varied by region and by dominant land-use setting. Generally, physical habitat variables explained more variance in the models of the agricultural Midwest Corn Belt whereas chemical contaminants...
explained more variance in the models of the Southeast Piedmont, Pacific Northwest, and Northeast, where urban land uses dominate development. The BRT models identify which specific stressors and stressor combinations have the strongest influence on biological condition and the SEM models provide support to conceptual models that link human activities on the landscape to specific stressors and biological responses.

130 The Role of Pesticide Mixtures as Stressors on Invertebrate Communities in Wadeable Streams

Pesticide mixtures were assessed in five regional multistressor studies done during 2013-2017 by the U.S. Geological Survey’s Regional Stream Quality Assessment. In each region, 225 pesticide compounds were analyzed in weekly water samples from 77-100 wadeable streams over 6-14 weeks, followed by ecological surveys and collection of bed sediment for analysis of 118 pesticide compounds. Potential for invertebrate toxicity in the sampled streams was predicted by comparing measured pesticide concentrations with aquatic-life benchmarks, sediment benchmarks, the Pesticide Toxicity Index, and species sensitivity distributions. Predictions were tested by evaluating relations between pesticides and field-surveyed macroinvertebrate community condition and by mesocosm experiments that assessed effects of key pesticides on natural aquatic communities under controlled conditions. A total of 208 pesticide compounds were detected in water and 44 in bed sediment. Pesticide mixture complexity varied by region and land use. In water, the most pesticides were measured at agricultural sites in the Pacific Northwest and Midwest (median of 37 and 26 compounds per sample, respectively). For basins with minimal agriculture, the number of pesticides detected per water sample increased with urban land in the basin. Potential effects on invertebrates were predicted in all five regions—either from dissolved pesticides (at 18 to 77% of sites, in Pacific Northwest and Midwest regions, respectively), and/or from pesticides in bed sediment (at 2 to 18% of sites, in Pacific Northwest and Northeast, respectively). For dissolved pesticides (all regions combined), 14% of sites exceeded acute thresholds, 46% of sites exceeded chronic thresholds (by 21-d average concentrations) for at least one pesticide, and 14% of sites exceeded chronic thresholds for multiple pesticides. Acute thresholds were exceeded most frequently by imidacloprid and organophosphate insecticides in water and by bifenthrin in sediment. In the Midwest, predictions of pesticide toxicity were supported by quantile regression showing significant associations between concentrations of imidacloprid and bifenthrin and impaired invertebrate communities in the field, and by mesocosm studies demonstrating effects of imidacloprid and bifenthrin on natural aquatic communities under controlled conditions. Multiple lines of evidence suggest pesticides affected invertebrate community condition in about half of the sampled streams.

131 Reproductive Effects of a Multi-Chemical, Multi-Stressor Exposure Across Several Generations of Fathead Minnows (Pimephales promelas)

C King, St. Cloud State University / Aquatic Toxicology Laboratory

More than one third of the Earth’s freshwater is used for agricultural, industrial, and domestic purposes leading to the frequent co-occurrence of nitrate and contaminants of emerging concerns in aquatic ecosystems. However, little is understood about the consequences of long-term exposure of fishes to these complex mixtures. This project examined changes in physiology, behavior and reproduction in fathead minnows across three generations of exposure to these mixtures at environmentally relevant concentrations. Exposure of adult fathead minnows in the first generation to high nitrate concentrations (50mg/L) resulted in a two-fold increase in egg production. In the second generation, only the agricultural mixture contained a stimulatory effect in fecundity (p<0.001; ANOVA). Contrary to prior studies, neither nitrate nor estrogenic agricultural mixtures stimulated vitellogenin production in male fishes. In contrast, feminization (presence of the egg-yolk protein vitellogenin) was found in first generation males following exposure to an urban chemical mixture independent of nitrate concentrations. Behavior does not appear to be affected regardless of treatment and generation. Using a multi-generational fathead minnow exposure, we were able to improve our understanding of the consequences associated with long-term exposures to environmentally relevant chemical mixtures. The interactions between these pollutant stressors require further study for adequate assessment of environmental risk.

132 Developing normal ranges for fish health indicators from a 30-year study of impacts of bleached-kraft pulp mill effluent at Jackfish Bay, ON

K.R. Munkittrick, Wilfrid Laurier University / Biology; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate, Aquatic Contaminants Research Division; S. Williams, Wilfrid Laurier University / Biology; E. Ussery, Environment and Climate Change Canada / Aquatic Contaminant Research Division; T. Clark, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants and Research Division; A. Wynia, Environment and Climate Change Canada / Aquatic Contaminant Research Division

Jackfish Bay, located on the north shore of Lake Superior (48°50’N, 86°58’W), was identified as a Great Lakes Area of Concern in 1987 due to changes in its chemical, physical and biological integrity associated with the effluent from a bleached kraft pulp mill in Terrace Bay, ON. Extensive studies on white sucker (Catostomus commersoni) populations documented reduced gonadal sizes, delayed sexual maturation, and altered levels of circulating sex steroid hormones in the late 1980s. Studies have monitored the impacts following installation of secondary waste treatment (1989), changes in the bleaching process (1990s) and a series of closures associated with changing ownership (2000s). The mill changed ownership again in 2012 with the intention of switching the mill to dissolving pulp, but it has remained operating as a bleached kraft mill. Collections in 2018 and 2019 extended the time series (previous collections stopped in 2013) of spring and fall collections. Differences in body size, liver size, gonad size and condition persist, although changes in liver and gonad are much smaller than in the early years. Reference site variability over the 31 year time period approaches 2 SD, and the long term data has been used to develop normal ranges for Jackfish Bay and the reference site. There have been few studies on the impacts of dissolving pulp mill effluent on wild fish, and the normal ranges for Jackfish Bay will enable future studies to follow responses when the mill changes pulping process.

133 Assessing effects of salmon life treatment (hydrogen peroxide) on shrimp populations in a multi-stressor environment

J. Møg, Norwegian Institute for Water Research (NIVA) / Section for Ecotoxicology and Risk Assessment; T. Jager, DEBtox Research / Dept of Theoretical Biology; D. Hjermann, Norwegian Institute for Water Research (NIVA); E. Ravagnan, R.K. Bechmann, NORCE Norwegian Research Centre AS / IRIS

Hydrogen peroxide (H2O2) is used as anti-parasitic biocide in salmon farms worldwide. Since the treatment water is discharged to the sea, there are concerns about effects of H2O2 on the coastal ecosystems. Our study focuses on the effects of this biocide on populations of the Northern shrimp (Pandalus borealis), which is an economically and ecologically important species in Norwegian fjords. Shrimp may be exposed to multiple stressors including repeated exposure to salmon lice biocides from surrounding aquaculture farms, commercial harvest, and climate change. Laboratory experiments have demonstrated that even short pulses (3 x 2 h) of exposure to H2O2 in concentrations well below the prescribed treatment concentrations result in mortality of shrimp. Moreover, sublethal effects such as gill damage and reduced feeding
have been observed after a recovery period. The aim of this study is to make the information on these effects more relevant for risk assessment and management of Northern shrimp populations. We apply a mechanistic effect model for individual survival (GUTS) in combination with an age-structured population model to project the effects of H2O2 exposure on population decline under different scenarios of H2O2 treatment and environmental stressors. The GUTS model is calibrated to the experimental data from H2O2 exposure, and used to predict survival probabilities under different scenarios of H2O2 exposure profiles in the field. The population model accounts for additional stressors in the environment: variation in adult survival due to harvest and predation, and variation in larval survival due to fluctuating food availability. Since we have little information on the distribution of H2O2 at different distances from aquaculture farms, we use a set of model scenarios representing different medicine application schemes and different degrees of exposure for the shrimp populations. The purpose of this modelling study is to predict effects of H2O2 exposure in combination with other stressors on population-level endpoints such as long-term abundance and age structure, and to assess the risk of population decline below threshold abundances. Potential future development of this modelling approach include: (1) address more types of commonly used salmon lice medicine by including mixture toxicity in the GUTS model; (2) address additional stressors such as harvest in more detail, to make the results more relevant for coastal ecosystem management.

134 From microbes to fish tumours and their linkages to contaminated sediments in a Great Lakes Area of Concern

K.G. Drouillard, A. Grgicak-Mannion, N. Falk, C.G. Weisener, J. Li, University of Windsor / Great Lakes Institute for Environmental Research; M. MacDougal, River Institute; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate, Aquatic Contaminants Research Division; D. Haffner, University of Windsor / Great Lakes Institute for Environmental Research

The Detroit River was designated a Great Lakes Area of Concern in 1987 owing to impaired status of several beneficial use impairments (BUIs), many of which were linked to toxic contaminants. In 1999 a comprehensive sediment survey was completed covering the entire connecting channel using a stratified random sampling design. The survey was repeated multiple times up to 2013 providing detailed spatial and temporal perspectives of the system-wide contamination for metals, PCBs, OC-pesticides and PAHs. These sediment surveys were pivotal for generating cause effect linkages between in-place toxic contaminants and several beneficial use impairments in the system. Here, we describe a series of case studies demonstrating disruption of microbial and invertebrate communities, fish tumours and bioaccumulation risks to sport fish that incorporate statistical assessment and mechanistic models. We demonstrate that the major spatial patterns of metals, PCBs and PAHs contamination in Detroit River sediments are associated with significant changes to sediment microbial structure and function, produce limited invertebrate toxicity at the highest contamination sites, are associated with elevated incidence of hepatic neoplasms in brown bullheads and generate spatially distinct chemical bioaccumulation patterns in fish. We discuss the merits of implementing high resolution system-wide monitoring programs used to address multiple stressors and guide remediation priorities that go beyond assessment of BUI impairment status.

135 Assessing changes in the fish community composition in tributaries of the Lower Athabasca River Basin in relation to the Athabasca Oil Sands formation

A.G. Wynia, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate, Aquatic Contaminants Research Division; E. Ussery, Environment and Climate Change Canada / Aquatic Contaminant Research Division; J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants and Research Division; T. Clark, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; G. Tetreault, Environment and Climate Change Canada / Water Science and Technology Directorate

The lower Athabasca River watershed geographically overlaps with the Athabasca Oil Sands deposit in northeastern Alberta, Canada. The main stem Athabasca River and several of its tributaries run through the heart of many of the oil sands surface mining operations north of Fort McMurray. Rising concerns about the impacts of industrial activities on ecosystems, particularly in the Athabasca Oil Sands formation, initiated a collaborative relationship between the Government of Canada and the province of Alberta resulting in the Joint Oil Sands Monitoring Plan (JOSM). As part of this project, the present study evaluates aquatic ecosystem health in the watershed through examinations of the fish community composition at 19 tributary locations within the Athabasca Oil Sands deposit. These sites have varying degrees of connectivity to the main stem Athabasca River and proximity to industry. In September 2018, fish community data was collected from six 25-meter transects at each site using backpack electrofishing. For each site, fish community endpoints including species richness, diversity, and abundance were quantified. Habitat variables including wetted/rooted width (m), discharge (m$^3$/sec), substrate composition and water depth (m) among others were recorded for each site. Additionally, water quality readings of temperature ($^\circ$C), dissolved oxygen (mg/L), pH and conductivity ($\mu$S/cm) were recorded as ancillary environmental data to help account for any observed trends in community composition. The preliminary results suggest a trend of decreasing species richness with distance from confluence with the main stem Athabasca River, as well as a shift in the dominant species. Through multivariate statistical techniques relationships among biotic and abiotic endpoints will be developed. The results from this study will help to inform future directions of the current Oil Sands Monitoring (OSM) and associated environmental effects monitoring of wild fish health in the lower Athabasca River watershed.

Advances in Ecotoxicology and Risk Assessment of Reptiles and Amphibians

136 Development of a Standardized Toxicity Test Method Using a Native Amphibian Species

L.A. Van der Vliet, Environment and Climate Change Canada / Science and Technology Branch; B. Lo, Nautilus Environmental; P.M. Jackman, Environment and Climate Change Canada / Atlantic Laboratory for Environmental Testing; R.P. Scroggins, Environment and Climate Change Canada / Biological Methods

Although there is growing evidence of the sensitivity of amphibians to contaminants, and thus a growing demand for their use in regulatory frameworks, amphibian toxicity data are currently under-represented in risk assessments. Few standardized methods are available, which in part contributes to this under-representation. In addition, none of the available aquatic methods pair whole-organism chronic endpoints with species that are relevant to Canadian environments. To address this gap, Environment and Climate Change Canada has invested in developing a standardized test method for assessing contaminants with a native amphibian species (*Lithobates pipiens*, Northern leopard frog). We will discuss some lessons learned from laboratory research and data from recent inter-laboratory
testing rounds to validate the new test method. For the inter-lab project, we used sodium chloride, thyroxine and perchlorate as model compounds in this multi-laboratory experiment. The inter-lab is a critical step in the standardization process, and we will present data which demonstrates the reproducibility of the test method. With feedback from participating labs, the inter-lab is also used to develop quality control criteria for the test method. The final steps in standardized test method development will include refinement of methodology text, and peer review. The result will be the first Canadian standardized toxicity test method using a native amphibian species.

137 Dermal Fungicide Exposure at Realistic Field Rates Induces Lethal and Sublethal Effects on Juvenile Rana temporaria

E. Adams, V. Gerstle, C. Bruehl, University of Koblenz-Landau / Institute for Environmental Sciences

Amphibians are declining worldwide at alarming rates. Pesticides have been identified as one of the major drivers for these declines. Most ecotoxicological studies examining the effects of pesticides on amphibians are conducted in simplified aquatic laboratory set-ups. Adverse effects on terrestrial life stages of amphibians are probable since their skin is highly permeable and thus, the dermal uptake of pesticides represents a likely exposure route. However, terrestrial stages are mostly neglected in ecotoxicological amphibian studies. The aim of the present study was to investigate the effects of a realistic exposure to the most common German viticultural fungicide folpet on juvenile Rana temporaria in a laboratory study. In addition, a potential effect of the aquatic pesticide history was examined. In spring 2018, R. temporaria tadpoles of an uncontaminated pond were placed in enclosures in eight ponds of different pesticide contamination in the viticultural area around Landau (Rhineland-Palatinate) in southwest Germany to mimic different aquatic pesticide history. After metamorphosis, the juveniles were dermally exposed to soil contaminated with realistic field rates of the viticultural fungicides Folpan(R) 80 WDG and Folpan(R) 500 SC with folpet as active ingredient. After 48 hours, effects on the survival as well as the behavior such as distance moved and foraging on Drosophila melanogaster were investigated. No effect of the aquatic pesticide exposure background on the terrestrial sensitivity could be detected. However, the terrestrial exposure lead to mortality rates of 17-100% and had effects on the foraging behavior. Exposed juveniles fed less drosophila and needed longer to catch the first one. In addition, the results indicated that the toxicity differed between the two tested fungicides, suggesting that the toxicity highly depends on additive ingredients in the formulation. The results of this study suggest that a realistic worst-case exposure of commonly used viticultural fungicides can have detrimental effects on early terrestrial life stages of amphibians. These effects can result in an increasing population decline leading to a possible extinction of the population. Since pesticide exposure was conducted at a realistic field rate, the findings of this study can help to estimate the risk of pesticide applications in agricultural landscapes dominated by viticulture for German Anura.

138 Integrating early-life stage transcriptome analysis with apical outcomes of chronic chlorpyrifos exposure in the amphibian, Xenopus laevis

N. Baldwin, A. Alcaraz, A.J. Masse, University of Saskatchewan / Toxicology; D. Cramp, Environment and Climate Change Canada / National Wildlife Research Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; N. Baldwin, A. Alcaraz, A.J. Masse, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

Chlorpyrifos (CPF) is one of the most widely used organophosphate pesticides worldwide with extensive occurrence in aquatic ecosystems. Exposure to CPF is associated with adverse effects across a wide range of physiological parameters in fish, most notably neurotoxicity through inhibition of the enzyme acetylcholinesterase (AChE). However, effects of exposure to CPF in amphibians are relatively poorly studied. In particular, little information is available on the underlying molecular mechanisms that drive adverse outcomes. The main objective of this study was to identify key molecular response patterns in a model amphibian, Xenopus laevis, following early-life stage exposure to CPF, which may enable prediction of apical outcomes of ecological relevance. Xenopus laevis were exposed to CPF (0.4, 2, 10 µg/L, nominal) from 24 h post-hatch through to metamorphosis (50-55 d post hatch). A subset of exposed individuals were sampled at 96 h and whole-body transcriptome profiles were assessed using high throughput sequencing (RNASeq). Transcript quantification, differential expression analysis and enrichment analysis were performed using ht-seq count on the Galaxy server (galaxy.ecotoxexplorer.ca), the EdgeR tool in EcoToxXplorer (www.ecotoxxplorer.ca), and ClueGo on Cytoscape, respectively. Pathway analysis revealed a number of significantly dysregulated pathways including those associated with “classic” outcomes of CPF exposure, such as serine hydrolase activity (e.g. AChE) and immune pathways, including immune function, inflammatory response, and cytokine receptor activity. Other affected pathways, not typically linked to CPF exposure, included vasculature development, sensory perception of light stimulus, and blood coagulation. Tadpoles exposed to CPF through to metamorphosis exhibited increased relative liver weight (30% increase in 10 µg/L treatment) and a dose-dependent decreased in brain AChE activity. Disruption of pathways associated with serine hydrolase following CPF exposure during early-life stages is in agreement with decreased AChE activity at metamorphosis. Transcriptomic analysis also revealed a number of novel dysregulated pathways that were not directly linked to apical outcomes measured in this study suggesting that CPF impacts a wide range of biological pathways in amphibians that warrant further study. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

139 Effects of the herbicide triclopyr on the behavior and physiology of juvenile frogs

A.J. McFall, Savannah River Ecology Laboratory / Department of Biology & Geology; J. Ziemba, University of Georgia / Savannah River Ecology Laboratory; G. Rodriguez, K. Ramstad, University of South Carolina Aiken / Department of Biology & Geology; S.L. Lance, University of Georgia / Savannah River Ecology Laboratory

Amphibians are highly susceptible to anthropogenic stressors. The application of herbicides to amphibian habitat has been shown to cause mortality and sublethal effects on the behavior and physiology of many amphibian species. Most ecotoxicology studies of amphibians focus on aquatic contaminants encountered by larvae. Few studies have examined the effects of contaminants on juveniles though juvenile amphibians are sensitive to anthropogenic stressors and the survival rate of the juvenile life stage is linked to population persistence. Triclopyr is an herbicide used in forestry to control woody plants and broadleaf weeds via ground and aerial spray. Although triclopyr is commonly applied to upland habitat used by amphibians and can persist in the soil for up to 90 days, no studies have examined the effects of triclopyr on terrestrial amphibians. In this study, we examined the behavioral and physiological effects of triclopyr on juvenile Cuban tree frogs, (Osteopilus septentrionalis). Juvenile frogs were exposed to an ecologically relevant concentration of triclopyr (60 ul of Garlon® 4 Ultra, based on manufacturer-recommended 6 qt/acre concentration) applied to a soil substrate for 48 hours. To evaluate the effects of triclopyr exposure on juvenile performance, we conducted feeding and hopping trials. Additionally, we used a non-invasive water-borne assay to compare stress hormone (corticosterone) levels before and after exposure to triclopyr. We found no evidence that exposure to triclopyr affected feeding performance. However, we did find that triclopyr-exposed individuals had significantly shorter average sprint distances than control individuals. We are currently in the process of analyzing the corticosterone data. For many vulnerable amphibians, impaired juvenile hopping performance following triclopyr exposure could translate to a reduced ability to avoid predators and migrate to suitable overwintering habitat, which may have negative population-level consequences.
140 Effects of Marcellus shale petroleum production water on the survival and development of a common North American amphibian (Lithobates sylvaticus)
E. Green, Towson University / Environmental Science and Studies; P.F. Henry, US Geological Survey / Patuxent Wildlife Research Center; C.J. Salice, Towson University / Environmental Science & Studies Biology

Salinization of freshwater systems is a well-recognized and documented issue. The largest contributors to this worsening issue are anthropogenic. Two specific examples are the application of road de-icing salts and waters produced as part of oil and gas production activities both of which drastically elevate salinity in freshwater systems. For example, a single well at one shale gas development site over 8 years can generate nearly one million liters of high conductivity water potentially contaminated with hydrocarbons and other toxic compounds. We conducted acute and chronic toxicity tests using *L. sylvaticus* (wood frog) larvae to estimate the toxicity of produced water retrieved from a site involved in Marcellus Shale gas development (collected by the USGS and transported to the Applied Ecological and Ecotoxicology Laboratory at Towson University, Towson, MD). In the acute toxicity test, larvae were exposed to a range of concentrations (0.0, 0.1, 0.2, 0.375, 0.75, and 1.5 mL/L) for 96 hours. We estimated an LC50 (± 1 SE) of 1.95 ±0.39 mL/L. To examine chronic effects of the produced water on the survival of *L. sylvaticus*, we exposed larvae to concentrations of 0.0, 0.5, 1.0, 2.5, 5.0, and 10.0 mL/L for 30 days. We then conducted a time-to-event analysis to determine the relative hazard (likelihood of mortality) compared to control animals (0.0 mL/L). We found significantly higher hazard to larvae in the 2.5, 5.0, and 10.0 mL/L treatments. To evaluate the chronic effects of produced water on the development and metamorphosis of *L. sylvaticus*, we are exposing larvae to concentrations of 0.0, 0.125, 0.25, and 0.5 mL/L. Preliminary data suggest that elevated salinity may contribute to an increase in time-to-metamorphosis. Our data suggest that even small amounts of produced water, if allowed to enter amphibian breeding habitats, can exert harmful effects on developing individuals. Relatively low concentrations (2.5 mL/L) can cause significant increases in likelihood of mortality of *L. sylvaticus* larvae. Characterization of produced water and ongoing amphibian research will help to better understand the potential impacts on amphibian communities that may be in proximity to similar oil and gas production activities.

141 Marbled salamander (Ambystoma opacum) metabolomic profiling across an agriculturally intensive landscape gradient
R. Van Meter, Washington College / Biology & Environmental Science; J. Portmann, Washington College / Environmental Science and Studies Department; M. Henderson, US Environmental Protection Agency / Office of Research and Development

Throughout the US, many forested areas with ephemeral wetlands have been converted for agricultural use. The conversion process has fragmented critical habitats that provide essential landscapes for obligate vernal pool breeding amphibians. Thus, these amphibians are often restricted to smaller forested patches or must transit long distances through agricultural areas to breeding ponds. Although remnant forest patches can vary substantially in size and abundance of ephemeral pools, in an agriculturally intensive landscape all are subject to impacts from nearby operations. In particular, application of fertilizers and pesticides on crops has emerged as a concern for amphibian populations. In September 2018, marbled salamander adults were collected during fall migration to breeding pools in Queen Anne’s, Caroline and Calvert Counties in Maryland. GPS points were taken at all locations where individual salamanders were collected. Using GIS, a 200m buffer was placed around each GPS point and percent agriculture within the buffer quantified. Agriculturally intensive sites were classified as those with >30% agriculture within the buffer zone, intermediate sites ranged from 5-30% agriculture, and forested sites were those with <5% agriculture. Individuals were sexed, snout-vent length was measured, photographed for identification and then swabbed for chytrid fungus and metabolomics analysis. Swabs were analyzed for presence/absence of chytrid fungus using DNAeasy kits followed by PCR. The remaining ethanol was used for GC/MS-based metabolomic analysis. In total, 34 adult marbled salamanders were collected with a minimum of 11 salamanders for each land use classification. Salamanders were significantly larger (ANOVA p< 0.001) at the forested sites. None of the salamanders collected tested positive for chytrid fungus. Although the sample size is small, this preliminary data suggests that salamanders in more agriculturally developed landscapes are not more likely to serve as vectors for chytrid. With respect to metabolomic analysis, there were distinct differences in the biochemical profile of salamanders collected between agriculturally intensive (>30% ag) and forested (<5% ag) vernal pool habitats. However, salamanders collected from intermediate (5-30% ag) landscapes were metabolically indistinguishable from both the intensive agriculture and forested sites. Further data collection is warranted to better inform risk assessment of the effects of agrichemicals and their impacts in vernal pool breeding amphibians.

142 Primary and Immortalized Gonad and Liver Fibroblast Cell Cultures Derived From Laparoscopic Biopsies and Cytotoxicity of Key Organic Contaminants
C.A. Godard, Texas Tech University / Environmental Toxicology/The Institute of Environmental and Human Health; J.D. Pierro, Texas Tech University / Environmental Toxicology; C. Wittmaack, Texas Tech University / Environmental Toxicology/The Institute of Environmental and Human Health; J. Flanagan, Houston Zoo; B.M. Higgins, NOAA National Marine Fisheries Service

Internal organ biopsies from live, healthy endangered animals are rarely acquired. Here, we report on the successful collection of liver and ovary biopsies, via laparoscopy, in loggerhead sea turtles with subsequent cell culture establishment, immortalization, and cytotoxicity testing. Cell cultures were established from one liver, one testis, and five ovary biopsies. One liver and one ovary culture were exposed to either of two immobilization agents: Simian Virus 40 Tt (SV40Tt) and Human papilloma virus 16 E6/E7 (HPV 16 E6/E7). The result was one SV40Tt liver line, one HPV liver cell line, and one HPV ovary cell line. These are the first experimentally immortalized sea turtle cell lines and the first immortalized cell lines derived from healthy sea turtles. The establishment of these immortalized cultures provides for the expansion of in vitro sea turtle research at a more rapid pace and for organs that are underrepresented. Cytotoxicity assays were conducted using one primary ovary, one HPV Ovary, and one HPV liver immortalized cultures via the MTT mitochondrial integrity and Lactate Dehydrogenase (LDH) leakage experiments after exposure to three ubiquitous contaminants—Benzo[a]pyrene (B[a]P), Polychlorinated Biphenyl 77 (PCB 77), and Perfluorooctanoic Acid (PFOA). Cells were exposed to each contaminant for the toxicologically standard 24, 48, 72, and 96 hours. Concentrations of each contaminant applied are those that have been established as scientifically relevant for cell cultures. MTT data indicate PFOA had statistically significant adverse effects on primary and immortalized liver and ovary cells at the highest concentration of 500 uM, while 10 uM B[a]P negatively affected the immortalized ovary fibroblasts compared to the control but had little effect on HPV liver cells. MTT data indicate adverse effects on HPV transformed ovary and liver fibroblasts at all time points following exposure to 10 uM of PCB 77. LDH assays showed far less effect on cell viability than MTT results in general. These findings provide a critically needed understanding of relative toxicity of known contaminants in these endangered species and highlight the difference in sensitivity between MTT and LDH in detecting cell viability. This study advances the field of sea turtle toxicology through the provision of immortalized cell lines derived from key internal organs, introduction of new cytotoxicity data, and the use of laparoscopy for obtaining biopsies from live animals.
143 A stochastic Sceloporus population model to investigate extinction risk from toxicant-induced reductions in demographic parameters

S.M. Weir, Queens University of Charlotte / Biology; C.J. Salice, Towson University / Environmental Science & Studies Biology

There is a growing interest in population-level risk assessment, with some authors suggesting that population growth rate is an important endpoint to consider in ecotoxicology. We previously reported a generalized deterministic population model for Sceloporus sp that could be used as a screening-level tool for risk assessment. Our model is a simple 2 stage model with a juvenile stage (1 year) and an adult stage. We expand on this model by adding parameters stochasticity to provide an additional layer of realism to the model. We performed theoretical simulations of 0 to 100% toxicity to each stage of the model (clutch size, juvenile survival, adult survival). We assessed effects of demographic reductions on quasi-extinction risk (defined as an adult population < 10 individuals). Results indicated that the baseline stochastic model had approximately 30% of the adult population size that was affected. Our model suggests that reptile populations may be more susceptible to reductions in demographic parameters than would be suggested by the results of deterministic models. This susceptibility seems to be the result of relatively low abundance and multiple years in a row with lower demographic parameters. Given the cryptic nature of most reptiles, more investigations of toxic effects along and/or the likelihood of demographic parameter reductions in contaminated areas is warranted. Next steps for the model would be incorporating landscape-level considerations of multiple populations and movement between populations.

Stockholm Convention on POPs: Progress in Monitoring, Research and Risk Assessment of Legacy and Emerging Chemicals - Part 2

144 UN Environment Biennial Global Interlaboratory Assessment On Persistent Organic Pollutants - Fourth Round 2018/2019, Non-Dioxin-Like POPs

I.V. Veen, Vrije University Amsterdam / Department Environment and Health; H. Fiedler, Örebro University / MTM Research Centre School of Science and Technology; I.I. de Boer, VU University / Environment & Health

In 2018 the United Nations (UN) Environment Biennial Global Interlaboratory Assessment on Persistent Organic Pollutants (POPs) was organized for the fourth time as part of the UN Environment Programme’s capacity building project. Participants were requested to submit results of organochlorine pesticides (OCPs), indicator polychlorinated biphenyls (PCBs), polybrominated diphenylethers (PBDE), toxaphenes, and hexabromocyclododecane (HBCD) in test solutions, sediment, air extract, fish and human milk. 117 laboratories submitted results which were statistically analysed, after which assigned values and z-scores were calculated, allowing laboratories to evaluate their own methods and performance. Statistical analyses of the data was performed as described by Cofino et al. (2017)I. The z-scores were calculated for each participant’s data for each matrix/analyte combination, which is given an assigned value. The performance for OCPs and PCBs in the test solution was less good than in previous rounds, even though the concentrations were comparable. Participation of new labs may have caused this result. The performance on the fish matrix was rather poor for all compound classes, which most likely is caused by the low concentrations, 1-30-fold lower compared to the those in the third round for OCPs, 20-50-fold lower for PCBs and 20-200-fold lower for PBDEs. For sediment the performance was better, and the performance on human milk was equal to last round. Plotting the results of the different detection methods used for CB 52 in the test solution showed that for high resolution mass spectrometry the majority of the results were within |z|<2, while results obtained with other detection techniques were more scattered. Results show that laboratories in developing countries are on average still far away from the required measurement quality for POPs. Acknowledgements This work was developed under agreement with UN Environment, Division of Technology, Industry and Economics (DTIE), Chemicals and Waste Branch. Funds have been provided by the Global Environment Facility (GEF) through four regional projects “(Continuing) Support for the implementation of the Global Monitoring Plan under the Stockholm Convention in the African/Asian/GRULAC/Pacific Islands Region. 145 Towards mechanistic and comprehensive quantification of emissions of persistent organic pollutants into the global environment

L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

Accurate and complete information on the sources and emissions of persistent organic pollutants (POPs) worldwide is critical for understanding their environmental fate and behavior, and implementing the Stockholm Convention to minimize their adverse environmental and health effects. To this end, there is a need for temporally- and spatially-resolved estimates of global emissions of POPs, in particular those intentionally produced for industrial and consumer uses (e.g., flame retardants), from various lifecycle stages (e.g., production and industrial processes, use, and/or waste disposal) to multiple environmental media (e.g., the atmosphere, water, and/or soils). For many intentionally produced POPs, however, such comprehensive emission estimates are currently unavailable; there is often a lack of a mechanistic understanding of their accumulation and transformation in the human socio-economic system (the “anthroposphere”) and emissions therefrom. In this presentation, we will present a historical overview of existing efforts aimed at elucidating the global emissions of POPs. We will propose substance flow analysis as a powerful tool for facilitating the development of comprehensive emission estimates of POPs. For illustration, we will introduce a mechanistic, dynamic model named Chemicals in Products - Comprehensive Anthropospherical Fate Estimation (CIP-CAFE), and apply it to derive lifecycle-based, temporally- and spatially-resolved, multimedia emission estimates of polychlorinated biphenyls (PCBs) and hexabromocyclododecane (HBCD). The CIP-CAFE model successfully captures the long-term temporal trend of the two POPs and the hotspots of their geographic distribution; it helps explain the observed transport and transformation phenomena of the two POPs in the global environment. These case studies demonstrate how global anthropospheric and environmental fate modeling complements the global monitoring activities and addresses international risk assessment and management under the Stockholm Convention.
146 How Does Modeling of the Global Environmental Fate of Short-Chain Chlorinated Paraffins Complement the Global Environmental Monitoring?

C. Chen, Peking University / College of Environmental Sciences and Engineering; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; J. Liu, Peking University / College of Environmental Sciences and Engineering; J. Liu, Peking University

Models serve as a powerful tool to complement global environmental monitoring and enable our understanding of the fate and risk of short-chain chlorinated paraffins (SCCPs). However, a gap still exists between modeled and monitored SCCP concentrations in the global environment, likely resulting from the uncertainties associated with (i) the global emission estimates, and (ii) modeling using a single set of physicochemical properties of the commercial SCCP mixture as a collective approximation of tens of complex SCCP homologues with extremely diverse properties. Here, we investigate whether a discrepancy exists between the modeling global environmental fate of SCCPs based on the single set or multiple homologue-specific physicochemical properties, and if so, the conditions (i.e., proximity to the emission source region, and regional temperature) that bring about the most pronounced discrepancy. We applied a mechanistic fugacity-based multimedia BETR-Global model to simulate the environmental concentrations and compartmental distribution of SCCPs. Our modeling results suggest that the discrepancy in modeled air concentrations based on single vs. multiple sets of physicochemical properties is most remarkable in regions with a low temperature and negligible emissions, e.g., the remote and cold background Arctic region. By contrast, in regions with a relatively high temperature and emissions, e.g., South China, the discrepancy is less noticeable due to the influence of local emissions. Lumpng tens of SCCP homologues as a whole and characterizing them using a single set of properties in models, minimize the information required for modeling, but also result in a bias in evaluating the environmental occurrence of SCCPs in cold, remote background areas. In other words, the quality of emission estimates is more relevant than physicochemical properties if we aim to accurately appraise the occurrence and risk of SCCP for warm regions with high emissions, whereas accurate physicochemical properties are more important in the appraisal for cold, remote background regions. Presently, we cannot tell whether using a single set of physicochemical properties in modeling is acceptable in terms of the global risk assessment, because most of existing available measurements are conducted in warm regions with high emissions, where the discrepancy between different sets of modeling is marginal. As such, we argue that future monitoring efforts, in particular those under the Global Monitoring Plan, should be directed to cold, remote background regions.

147 Targeted analysis of organophosphorus and brominated flame retardants in human adipose tissue from Colombia

A.C. Torres Moreno, University of Cartagena / Facultad de Ciencias Exactas y Naturales; B. Johnson-Restrepo, University of Cartagena / School of Exact and Natural Sciences; G.P. Codling, RECETOX, Masaryk University

Torres- Moreno, Carolina; Johnson-Restrepo, Borisl; Codling Garry. 2 IChemistry and the Environment Group, University of Cartagena, Cartagena, Colombia. 2Research Centre for Toxic Compounds in the Environment (RECETOX), Masaryk University, Kotlarska 267/2, 611 37 Brno. Czech Republic Flame retardant compounds were detected in 45 human adipose tissue samples collected during 2017 and 2018 from Cartagena and Cucuta cities in Colombia. Flame retardants (FRs) including twelve brominated (ATE, BATE, TBPE, and nine PBDEs), twenty one novel brominated, two chlorinated flame retardants (a-DP and s-DP), and sixteen organophosphorus were measured using a GC-Q-Exactive MS instrument. The highest concentrations of brominated flame retardants (BFRs) were found for TBP, BDE-47, and BDE-66 on average value of 10.82, 4.20 and 4.01 ng/g lw., respectively. Those concentrations were higher in the Cartagena, located on the Caribbean coast, than Cucuta located at east of the Colombia. T21PPP (mean concentration of 402.12 ng/g lw) TBP (mean concentration of 261.37 ng/g lw), EHP (mean concentration of 215.55 ng/g lw), TCEP (mean concentration of 169.23 ng/g lw), TCPP (mean concentration of 297.07 ng/g lw), TDCPP (mean concentration of 16813.73 ng/g lw) were the highest values of the OPFR compounds. The great finding of this study is the change in the FRs profile for our country, revealing a major presence of OPFRs compounds than PBDEs as it was expected.

148 Polychlorinated biphenyls and chlorinated paraffins in home-produced eggs from an e-waste area in South China: Occurrence and human dietary exposure

Y. Zeng, C. Huang, X. Luo, B. Mai, Guangzhou Institute of Geochemistry / State Key Lab. Organic Geochem

Polychlorinated biphenyls (PCBs) and chlorinated paraffins (CPs) are among the most well-known and studied families of organic pollutants. Rudimentary e-waste recycling activities can result in severe PCB and CP contamination and their hydrophobicity and lipophilicity lead to their bio-accumulation in fatty tissues of animals. However, data on human dietary exposure to PCBs and CPs associated with e-waste recycling are still limited, or in the case of M/LCCPs, are almost non-existent. Therefore, the levels of PCBs and short/median-chain chlorinated paraffins (S/MCCPs) in home-produced eggs collected from an e-waste site in South China were measured and the human dietary exposure to these two classes of contaminants via egg consumption was calculated. The levels of PCBs, SCCPs, and MCCPs varied from 236 to 8870 ng/g lipid weight (lw), 477 to 111,000 ng/g lw, and 125 to 91,100 ng/g lw, respectively. Concentrations of IICES-6 PCBs and TEQs of DL-PCBs strongly exceeded current European maximum limits. Consuming these eggs implicates a serious health risk for local residents, especially for children. There were no significant changes in the PCB, SCCP, and MCCP levels between 2013 and 2016, indicating that these compounds remain at relatively high levels in environmental and biological systems for a long period of time. Therefore, it is necessary to raise awareness among the local population and take appropriate measures to reduce the intake of contaminants by home-produced eggs.

149 PFAS research within the US Environmental Protection Agency: Science to support the Stockholm Convention

A. Gillespie, US Environmental Protection Agency / Atlantic Ecology Division

Per- and polyfluoroalkyl substances (PFASs) are a growing concern among many communities in the US due to increasing reports of potential human exposures. In response, the USEPA is implementing a PFAS Action Plan which advances many of the goals of the Stockholm Convention with respect to understanding, managing and mitigating risk from this class of chemicals. The USEPA’s PFAS Action Plan includes a robust program of research which is already generating results for advancing our understanding of PFAS. This includes an integrated set of research activities aimed at filling gaps in our current ability to conduct scientifically rigorous risk assessment and risk management activities. This research program is designed to address these data gaps and enable stakeholders to begin making effective decisions for identifying and mitigating risk from PFAS in the environment. This information will also be of benefit to the global community working in support of the Stockholm Convention; The science required to protect public health and the environment from PFAS exposure cuts across many applications and disciplines. The risk assessment/risk management paradigm provides a useful means to assess the state of the science available for informing decisions, and to identify gaps in knowledge needed to support risk management. USEPA’s initial scoping of information available for assessing and managing PFAS risks revealed deficiencies in all key areas of the risk paradigm including hazard and toxicity (there are likely hundreds of PFAS in the US environment, and most lack sufficient suitable toxicity information for informing understanding of the potential for human or ecological effects); exposure (information about different PFAS sources, fate and transport, and human and ecological exposure is sparse, both spatially and temporally); and
suitable treatment and remediation approaches (there is little information on effective methods and costs for treating or removing different PFAS from drinking water, groundwater, wastewater, air, soils, and sediments). The purpose of this presentation is (1) to provide an overview of USEPA’s overarching PFAS research program, with a focus on recent advances and ongoing activities, and (2) to highlight the relevance and utility of this science to the Stockholm Convention.

150 Triclosan and methyl triclosan in small fish in estuary waters influenced by wastewater effluent

D. Lin, San Francisco Estuary Institute / Department of Civil and Environmental Engineering; R. Sutton, San Francisco Estuary Institute; C. Hamilton, SGS AXTS / Client Services; J. Hobbs, UC Davis
San Francisco Bay is an estuary of hemispheric ecological importance that receives significant stormwater and wastewater loads from surrounding urban areas. Triclosan is an antimicrobial used in a wide variety of personal care products such as soaps, toothpastes, detergents, as well as other plastic consumer products. Ubiquitous use of triclosan in consumer products has led to widespread detections of triclosan in wastewater, surface waters, sediment, aquatic life, and humans, and there are significant concerns about its persistence and toxic impacts to humans and aquatic life. Methyl triclosan is a major metabolite of triclosan that forms in wastewater treatment plants, and is more persistent than the parent compound. Triclosan and methyl triclosan were analyzed in small fish in Bay waters near a wastewater outfall location to evaluate bioaccumulation and potential impacts to aquatic organisms. A novel analytical method for extraction and analysis of both triclosan and methyl triclosan in tissue was developed and used to quantify triclosan and methyl triclosan. Combined concentrations of triclosan and methyl triclosan were measured up to 240 ppb wet weight. Triclosan and methyl triclosan in fish tissue were related to degrees of wastewater influence at the sampling locations, and calculations suggested bioaccumulation from diet in addition to direct uptake from water. Potential impacts to fish were evaluated by comparing to other toxicity studies. Field sampling occurred in 2016 when the US Food and Drug Administration announced its ban on triclosan and 18 other active ingredients in liquid hand soaps for consumers, which took effect in 2017. Results indicate prey fish are a useful monitoring matrix for triclosan and its metabolites and that ongoing monitoring is needed to ensure management actions are sufficient to mitigate ecological risks.

151 Legacy and Emerging PFAS in Australian WWTPs

B. Clarke, University of Melbourne / School of Chemistry

The Australian environmental community are fast recognising per- and polyfluoroalkyl substances (PFAS) as a contaminant of emerging concern. Traditionally regulators have focussed on a small range of legacy perfluoro carboxylic acids and sulfonates measuring them in environmental matrices. However, to date over 3000 PFAS have been produced and distributed internationally. It is becoming apparent that unidentified PFAS are present in environmental matrices having unknown effect. Worldwide wastewater treatment plants (WWTP) have been recognised as a source of PFAS to the environment. Few studies on newer fluorinated compounds in WWTPs have been produced with only limited data available on PFAS in Australian WWTPs. Influent and Effluent at three Australian WWTPs were extracted and analysed utilising unique workflows to identify anionic PFAS. Targeted analysis was performed using LC MS/MS to quantify a range of PFCAs, PFSAs and FTSs. The samples were then screened for unknown PFAS on LC-QTOF using a custom database with various levels of verification. Finally, software tools such as MassHunter molecular feature extractor (MFE), mass profile professional (MPP) and molecular structure correlator (MSC) were used to propose and identify fluorinated compounds in the wastewater samples not present in the database. This study provides further insight into PFAS cycling and emissions in Australian WWTPs for use by environmental regulators.

Mercury Fate, Biogeochemistry and Risk in a Changing Environment

152 National view of temporal atmospheric anthropogenic mercury deposition across Canada using lake sediments

S. Roberts, J.L. Kirk, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Wiklund, University of Waterloo; A. Gleason, G. Lawson, F. Yang, Environment and Climate Change Canada; J. Keating, Environment and Climate Change Canada / Water and Science Technology Directorate; M. Evans, Environment and Climate Change Canada / Water, Science and Technology Directorate; M. Pilote, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Mercury (Hg) is a pollutant of concern globally which is emitted into the atmosphere from largely coal combustion, gold mining and metal smelting, and can be transported over large distances due to its long residence time before it is deposited. Atmospheric Hg is dominated by anthropogenic contributions, and this study provides a national view of spatial temporal trends, from 1850 to 2018 CE, in atmospheric anthropogenic Hg deposition across Canada, using $^{210}$Pb dated lake sediment cores. Over 60 small headwater lakes have been sampled at sites nearby known pollution sources, such as Flin Flon and Thompson Manitoba smelters, Trail British Columbia (BC) smelter and urban centres, as well as within remote locations such as Kejimkujik National Park (NP) in Nova Scotia and Experimental Lakes Area (ELA) in Ontario. This study examines whether atmospheric anthropogenic Hg fluxes (corrected for sediment focussing and catchment effect) decline with increasing latitude and longitude away from known emission sources, and whether anthropogenic Hg fluxes match predictions of the global mercury model for each geographical location. Thus, testing whether anthropogenic Hg fluxes can be used to validate model predictions where Hg wet deposition measurements are limited. Since the 1990’s, anthropogenic Hg fluxes have declined by 4-fold at sites nearby the Flin Flon Manitoba smelter and Trail smelter in British Columbia, whereas at remote sites such as Kejimkujik NP and ELA, anthropogenic Hg fluxes are ongoing. Sedimentary Hg profiles across Canada can therefore be used to assess the effectiveness of national and international mitigation efforts and controls on industrial Hg emissions.

153 Insights into surface water methylmercury patterns in a complex freshwater estuary - production zones and transport mechanisms

M. Castruita, University of Minnesota, Duluth; N.W. Johnson, University of Minnesota, Duluth / Civil Engineering

Mercury cycling in freshwater ecosystems involves a complex set of interrelated physical, chemical, and biological processes, many of which remain poorly understood. Our study investigates methylmercury (MeHg) concentrations in the surface water of an ecologically complex freshwater estuary to provide insight into conditions that promote net MeHg production and transport mechanisms that determine its fate in the larger ecosystem. Using the spatial distribution of MeHg in the estuary as a basis, we provide insights into the magnitude of loads introduced into the rest of the system. Predator fish that inhabit the St. Louis River estuary (SLRE) have higher levels of MeHg than those recorded in other parts of the watershed. Bioaccumulation of MeHg in these fish threatens human and ecosystem health and compromises the recreational value of recreational resources. Over the course of 3 years, surface water data was collected from several characteristic ecosystem types. Within each of these ecosystems, replicate plots were chosen along a transect that included near shore environments, the main river channel and locations in between. Our observations show that surface water MeHg concentrations increase from the main channel of the river towards nearshore areas in isolated embayments, which suggests that there are “hotspots,” or net MeHg production zones within the estuary. We use this spatial information with transport parameters derived from hydrologic models and conservative ion tracers to constrain the parameters of a reduced-order-complexity model describing the relationship between MeHg production...
154 Salinity influences on mercury photochemistry in estuarine rivers in Minas Basin, Canada

R. Clarke, Acadia University / Biology; S. Klapstein, Acadia University / Earth & Environmental Science; R. Keenan, Government of Canada / Environment and Climate Change Canada; N.J. O’Driscoll, Acadia University / Department of Earth and Environmental Science

Mercury (Hg) loss from natural waters can occur through photoreduction that is controlled primarily by ultraviolet (UV) radiation. The retention of Hg in aquatic systems is largely affected by its reduction-oxidation photochemistry, and the chemical characteristics of estuarine water may significantly affect the photochemistry of Hg and its eventual accumulation in food webs as methylmercury, a potent neurotoxin. Currently, there are limited data on Hg photochemical cycling in estuarine ecosystems compared to freshwater ecosystems. To address these knowledge gaps, the photochemical kinetics of mercury speciation with respect to salinity and dissolved organic matter (DOM) were quantified. It was hypothesized that the rate and absolute amount of photochemical Hg reduction in estuarine waters is facilitated by DOM and inhibited by salinity. Water samples from the Cornwallis tidal river estuary in the Minas Basin, Nova Scotia, Canada were taken in July of 2018. Using tangential ultrafiltration, an array of salinity and DOM conditions were attained and then irradiated over an environmentally-relevant range of five UV intensities between 300-400 nm. Gaseous elemental mercury (Hg(0)) was analyzed every five minutes over a period of 24 hours using a Tekran 2573BS CVAFS automated mercury analyzer. Gross photoreduction and photooxidation reversible pseudo-first order reaction rate constants and total photoreducible Hg in each treatment were determined using curve-fitting software. These data and the correlations with DOM and salinity change will and be presented.

155 Assessing land use impacts in mussels in the Saint John River with mercury and stable isotopes

E. Weir, McMaster University / Biology; E. Lippert, University of New Brunswick / Biology; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute; A. Curry, University of New Brunswick / Biology

The Saint John River (SJR) in New Brunswick, Canada, supports diverse aquatic communities, a population of over 500,000 people, and many different industries. In recent years, the impacts of point and non-point sources of contamination have garnered increased attention in the SJR. Elevated mercury concentrations are of particular concern since mercury is known to bioaccumulate in tissues, biomagnify across trophic levels, and cause adverse health effects in fish and their consumers. The present study used mussels as bioindicators for mercury and stable carbon and nitrogen isotopes to evaluate nutrient inputs at 23 sites across 4 physiographic regions to assess spatial variability in contaminants and to identify specific sites which may pose a risk to wildlife. Foot tissue from Eastern elliptio and Eastern lampmussels was collected at each site in summer 2018, dissected, freeze dried and homogenized. Samples from similarly-sized individuals were analyzed for total mercury on a DMA-80 and were sent to the University of New Brunswick for determination of stable isotopes. Significant differences in mercury were observed across physiographic regions (ANOVA, p = 0.0131), with sites downstream of the Mactaquac dam having notably high concentrations. At 7 sites, mercury levels exceeded the tissue residue guidelines for mink, a predator of freshwater mussels. δ13C decreases and δ15N increases occurred in mussels from upstream to downstream along the SJR, with significant differences between regions for both δ13C and δ15N (ANOVA, p < 0.0001). Overall, the spatial trends in both mercury and stable isotopes of the mussels likely reflected greater inputs from agricultural and urban land use in lower reaches of the river.

156 Assessing variability of atmospheric mercury (Hg 0) trends using tree-rings in Northern Canada

K. Eccles, I. Lehnertz, T. Porter, S. Clackett, A. Ghota, H. Majeed, University of Toronto Mississauga / Department of Geography

Atmospheric mercury (Hg), primarily in the form of Hg0 plays an important role in the global Hg cycle and is a significant input of Hg to many ecosystems. An improved quantitative understanding of atmospheric Hg concentrations and historical anthropogenic emissions is key to be able to evaluate the efficacy of regulatory action, such as the Minamata Convention, on Hg concentrations in environmental compartments, food webs, and exposure risks in human and wildlife. Emerging research suggests that annually resolved tree-rings have the potential to be a powerful biomonitoring tool for reconstructing temporal and spatial atmospheric Hg concentrations as previous research demonstrates that atmospheric Hg is reliably incorporated into new trunk growth solely via deposition on the foliage. However, this biomonitoring tool still requires further development to better understand both small and large spatial scale variability. We use tree-rings from white spruce (Picea glauca) to reconstruct spatial and temporal trends in atmospheric Hg spanning from 1600 AD to present-day, across a large geographic region in northern Canada, including continental sites (central and northern Yukon) and coastal sites (Mackenzie River Delta, Northwest Territories). To assess local scale influences in Hg, tree rings are analyzed from Little Fox Lake, Yukon, the site of a historic forest fire (1998), to determine if a signal of local forest fire activity can be detected. Results show regional differences in the timing of the initial increase attributed to anthropogenic emissions and the timing of maximum Hg, the fastest rate of increase in Hg concentrations occurs between 1850 and the mid 20th century at all sites. The enrichment factor in modern Hg relative to the pre-industrial baseline estimated from tree rings appears to be lower compared to enrichment factors calculated from other paleo records such as sediment and peat cores. Comparing samples with known local inputs such as a forest fire provide a better understanding of how local influences can augment tree-ring Hg concentration. Overall, these methods can be used to address gaps and discrepancies in the Hg literature and will help to develop more precise estimates of atmospheric Hg concentration which, will be useful for validating emission inventories and refining atmospheric Hg models.

157 A Case Study of Long-term Risk Management of a Complex Mercury Site

J. Collins, AECOM / DCS Remediation; C. Mancini, AECOM / Remediation Practice; T. Bingman, Corteva Agriscience / Environmental Remediation

Complex sites that extend beyond the property boundaries of the primary constituent source often require a long-term strategy to manage risk as exposure paradigms and property ownership change over time and space. This is particularly true for sites for constituents such as mercury, that are persistent in the environment. The risk-based approach to addressing undefined exposure scenarios needs to be collaborative, consensus-based, consistent with regulatory program strategies and efficient to keep pace with often competing program schedules and objectives. A case study will be presented that discusses a long-term risk management strategy being implemented on the South River program in Virginia, that has proven effective in addressing potential exposure scenarios as they arise. Historical mercury (Hg) releases occurred at a textile manufacturing facility on the South River, Virginia, which led to increased Hg concentrations above background for approximately twenty-five miles of floodplain and bank soils downstream of the source. Although the ecological and human health risk assessments have been approved as part
of the site’s RCRA corrective action permit, a framework was needed to address exposure scenarios and outside stakeholder projects (e.g. parks and recreation improvements, dam removals, etc.). Two risk management frameworks will be presented that address these concerns. First a surficial soil strategy that evaluates exposure to mercury impacted floodplain and bank soils at properties identified in the HHRA to be carried forward to the corrective measures study, as well as properties where Interim Remedial Measures focusing on bank stabilization are not necessary based on remedial action objectives. The second approach addresses beneficial reuse and material management concerns associated with mercury impacted soils as part of non-RCRA related projects. An overview will be presented that discusses the data inputs, exposure parameters and the collaborative approach required to achieve regulatory approval. Project examples will also be discussed where each framework has been successfully implemented to achieve mutually beneficial outcomes that are protective of human health and the environment.

158 Diffusive Gradient in Thin Film (DGT) samplers as a biomonitoring tool for Hg bioaccumulation in freshwater wetlands

N. Neal-Walthall, U. Ndu, Duke University / CEE; H. Hsu-Kim, Duke University / Department of Civil Environmental Engineering; D. Elias, Oak Ridge National Laboratory; B.G. Perrotta, Baylor University / Biology

Mercury (Hg) is a well-known neurotoxin and common environmental contaminant. After entry into the environment, Hg may form a wide variety of compounds including the bioaccumulative form methylmercury (MeHg). High concentrations of MeHg are often found in upper-trophic level aquatic macrofauna which poses a risk to human health if consumed. Traditionally, bioaccumulative Hg in the environment has been estimated by MeHg measurements in water and soil samples. In reality, though, this sampling strategy may not be effective as the compound may bind to organic matter or sorb to particulates, rendering it unavailable for uptake. These processes are highly site specific and thus sites with similar sediment and/or water concentrations may have very different impacts on human and environmental health. Here, we assess the viability of using diffusive gradient in thin film (DGT) samplers deployed in the water column to estimate bioavailable Hg in the water column and subsequent accumulation in freshwater wetland biota. Mesocosm freshwater wetlands were dosed with four isotopically labeled inorganic Hg endmembers known to span a range of bioavailability and methylation potentials(204Hg2+, 196Hg-humic acid, 199Hg-sorbed to FeS, 200HgS nanoparticles). DGTs were then deployed in the water column at regular time intervals for a three-month period and accumulation of MeHg and Total Hg (TotHg) over a one-week period were measured. During this time period plants, biofilms, snails, and mosquito fish were retrieved from the mesocosms and assessed for MeHg accumulation. As expected, net production of MeHg (as a % of the total) was generally greater for the dissolved endmembers than the particulate endmembers resulting in greater bioaccumulation of MeHg originating from those species. Moreover, accumulation of both TotHg and MeHg on the DGTs correlated with MeHg concentrations in macrofauna, plants, and periphyton biofilms, indicating that they may be useful in predicting bioaccumulation in freshwater wetland organisms. Surprisingly, TotHg accumulated by DGTs correlated more strongly than MeHg. We attribute this to MeHg production in periphyton biofilms entering the food web through grazers, indicating that biofilms may play an important and previously unrecognized role in Hg cycling and bioaccumulation in freshwater wetlands.

159 Mercury in aquatic food webs impacted by two run-of-the-river hydroelectric plants, forest fires, logging and constructed wetlands

D. Ponton, University of Montreal / Biology; R. Lavoie, M. Leclerc, University of Montreal / Biological Sciences; F. Bilodeau, Hydro-Québec; D. Planus, UQAM / Biological Sciences; M. Amyot, University of Montreal / Biological Sciences

Methylmercury concentrations ([MeHg]) were unexpectedly high in fish from low-impoundment run-of-river reservoirs located in the St-Maurice River (Quebec, Canada). Apart from the flooded zones of few kilometers square, other perturbations occurred in the watershed that could have led to conditions that favored mercury methylation by microorganisms. Among those were: constructed wetland channels, forest wildfire, and current and past logging activities. To observe the dynamic of mercury transfer through food webs in sectors differentially affected by these disturbances, we collected 332 invertebrate samples and 432 fish of different sizes and species. We analyzed [MeHg], isotopic signatures of carbon (δ13C) and nitrogen (δ15N) as well as Esox lucius and Sander vitreus growth rate (using bone structure for age determination). We calculated the trophic magnification slopes (TMS) for each sector using regressions of [MeHg] as a function of adjusted δ13N of all organisms of each food web. TMS were significantly different between sectors and were function of the intercept of the regressions (Log[MeHg] at δ13N = 0) which were significantly correlated to the [MeHg] in primary consumers. Those results gave new insights on the uses of TMS in Hg bioaccumulation studies. In comparison to top predatory fish, low trophic level fish (TL < 3.5) had higher [MeHg] than expected from their δ13N values. Analysis of their δ13C showed that [MeHg] were not function of trophic status but rather of their source of carbon. Indeed, we observed that for those fish as well as for invertebrates, [MeHg] were higher at lower δ13C (depleted in 13C). On the other hand, top predators [MeHg] were negatively correlated with growth rate, indicating that fish in impacted areas grew more slowly and accumulated more MeHg than fish from other sectors. A dynamic model of bioaccumulation taking into account water and food uptakes, growth and physiological loss successfully predicted measured [MeHg] in Northern Pike and Walleye. In conclusion, variation in MeHg in top predators in this river system affected by multiple disturbances was affected by changes in growth rates as well as by changes in methylation rates at the base of the food web that could have been traced with carbon isotopes.

Recent Advances on the Analytical Chemistry, Fate and Mitigation of PFAS from Aqueous Film-Forming Foam (AFFF) Contamination

160 In-Depth Characterization of AFFFs and PFAS Dispersions by High Resolution MS

J. McCord, US Environmental Protection Agency / ORD; K. Mauge-Lewis, NIEHS / Division of the National Toxicology Program; M.J. Strynar, US Environmental Protection Agency / ORD/NERL/EMMD; S. Fenton, NIEHS / Division of the National Toxicology Program

Per- and polyfluoroalkyl substances (PFAS) are a class of chemicals of significant interest due to their environmental persistence and unknown ecotoxicological effects. The historical long-chain perfluoroalkyl acids (PFAAs) garnered international regulatory and/or health advisory levels due to their known bioaccumulation and toxicity, and an explosion of novel chemistries has appeared to fill the role of these PFAAs. One of the most common uses for non-polymeric PFAS materials is for their useful surfactant properties, including in aqueous film forming foams (AFFFs), and as dispersants in polymer processing. These mixtures are highly complex and frequently exhibit non-fluorinated materials as major components, including ionic and non-ionic hydrocarbon surfactants. Characterizing the PFAS portion of the mixture by non-targeted analysis can be challenging due to substantial matrix effects and ion suppression, and some knowledge of the non-fluorinated components is extremely useful for toxicological evaluation of the complex mixture (e.g., mixture toxicology). High resolution mass spectrometry offers a solution for screening due to its ability to separate species via mass resolution, determine accurate molecular formula from isotopic information, and perform multiple MS fragmentation to resolve structural information. We applied a repeated injection scheme with iterative inclusion/exclusion lists to fully characterize AFFF and PFAS dispersions samples in industrial use. An initial list of potential masses was collected in a full scan, and inclusion lists were generated for subsequent data dependent MS/MS.
injections until the entire list was collected, allow us to “dig deeply” into less abundant species. Data processing scripts were written to prioritize features for classification and examination, including filtering for (fluoro- and hydrocarbon) homologous series and major diagnostic fragments. MSn fragmentation was used to characterize unknowns and MS data was stored in local MS libraries. The compilation of PFAS mixtures was used as a screening library for waste stream outputs (air and water emissions) for PFAS uses, to identify components of the mixture that were environmentally relevant, and non-targeted analysis was used to identify potential transformation products of processing and/or waste treatment.

161 The Enrichment PFASs and the Discovery of Hydrocarbon Surfactants in Foaming on Surface Waters Impacted by AFFF

T. Schwichtenberg, Oregon State University; R.A. Garcia, University of San Diego; C.C. Carignan, Michigan State University / Department of Food Science and Human Nutrition; D. Bogdan, AECOM; J. Field, Oregon State University / Environmental and Molecular Toxicology

Foaming surface waters near sites where aqueous film forming foams (AFFFs) and other sources of per- and polyfluoroalkyl substances (PFASs) were released have raised public concern. Accumulation of PFASs at the air-water interface is due to the surface active nature of PFASs yet few measurements of PFASs in foam are reported. Foam arises upon agitation of the surface microlayer of surface water bodies (e.g., wind action) that may be enriched in surface active PFASs. After a foaming event in 2018, pairs of foam and the bulk water immediately under the foam were collected. Samples were analyzed by liquid chromatography quadrupole time of flight mass spectrometry for 400+ suspect individual PFASs and 12+ suspect classes of hydrocarbon surfactants. Concentrations in foam and underlying bulk water were ratioed to generate an enrichment factor for PFASs and hydrocarbon surfactants in each pair of samples. Foams were enriched in long-chain PFASs, including PFNA, PFDA, and PFMnDa, and hydrocarbon surfactants such as linear alkylbenzene sulfonate relative to bulk water. These long-chain PFASs were near detection levels (ng/L) in bulk surface water but were in the mg/L level in foam (when collapsed to a liquid). The implications of the concentrations and enrichment factors for public and fresh water organism health will be discussed.

162 Characterization of Per- and Polyfluoroalkyl Substances (PFAS) in Firefighting Training Areas across Eastern Canada

M. Liu, McGill University / Civil Engineering; G. Munoz, S. Vo Duy, S. Sauvé, University of Montreal / Chemistry; J. Liu, McGill University / Civil Engineering

The extent of PFAS contamination as well as the identity of PFASs at aqueous film-forming foam (AFFF)-impacted sites are not fully understood, which impedes the risk assessment and proper management of such contamination sites. To fill this knowledge gap, the PFAS profiles and levels in soil samples collected from four firefighting training areas (FTA) close to airport across Eastern Canada were characterized by analytical techniques encompassing targeted, suspect-screening, non-targeted, and non-specific methods, e.g. Total Oxidizable Precursor (TOP) assay. This is the first time that a comprehensive PFAS profiling was performed at federal Canadian AFFF-impacted sites. Results showed that a large variety of PFAS species (52 target and 236 suspect PFAS) contributed to the PFAS contamination in these AFFF-impacted soils, with the concentration of known PFASs amounting to 103.2-11093.8 ng g⁻¹ dw. The dominant PFAS included anionic perfluoroalkyl sulfonates, n₂ fluoroelomer sulfonates, neutral perfluoroalkyl sulfonamide, and cationic perfluoroalkyl sulfonamide quaternary ammonium salt. Persistent transformation intermediates (such as 6.2 fluoroelomer trihydroxyxymethyl sulfoxide (6.2 FTSAs-SO), 8.2 fluoroelomer mercaptopalkamidol sulfonate fluoride (8.2 FTSAs-SO2) were also prevalent in these contaminated soils. Clear differences in PFAS profiles at these sites were observed, such as a high concentration of 6.2 fluoroelomer sulfonamide betaine (FTAB) and n:3 and n:1.2 fluoroelomer betaines (n=5, 7, 9 and 11 FTBs) in soils from one FTA site whereas rather low concentrations in the other three sites. The differences in PFAS profiles and levels among these FTA sites may be associated with AFFF use volume and history, variations in sorption and bioavailability of PFASs depending on soil and PFAS properties, different transport potential of PFASs related to varied hydrogeological conditions, etc. Furthermore, comparison between the concentrations of known PFAS and total PFAS revealed the presence of a large fraction of unknown PFAS in these soil samples. Finally, the use of non-target analysis method enabled the discovery of several new classes of PFASs among these unknowns. The comprehensive PFAS profiling for soil samples impacted by either historical or current use of AFFFs is helpful for in-depth understanding of their environmental behavior, fate, and their impacts after release into the soil environment.

163 Detection and Transformations of Poly- and Perfluoroalkyl Acids Downstream from Fire Training Areas in Groundwater-fed Coastal Watersheds

Poly- and perfluoroalkyl substances (PFAS) are a class of more than 4,700 aliphatic fluorinated compounds manufactured for use in commercial and industrial applications. Adverse human health effects including dyslipidemia and immunosuppression in children have been associated with PFAS exposures. Aqueous film forming foam (AFFF) for firefighting and training activities near military bases and airports is a major point source of PFAS contamination. Prior work has shown many PFAS in AFFF are highly mobile in groundwater. However, the spatial extent of PFAS transport and precursor transformations during transport away from contaminated source zones are uncertain. Here we present new surface water and groundwater discharge data of 24 PFAS, bulk precursors determined by the Total Oxidizable Precursor (TOP) assay, and extractable organofluorine collected between 2016-2019 in six coastal watersheds (three with known AFFF point sources and three without AFFF point sources) on Cape Cod, Massachusetts. Levels of PFAS in the watersheds contaminated by AFFF point sources were one to two orders of magnitude higher than levels in non-AFFF impacted watersheds. Principal component analysis confirmed by hierarchical clustering indicates that the AFFF fingerprint is distinct from the non-AFFF fingerprint and is characterized by PFAS with less than nine perfluorinated carbons. The fingerprint is persistent throughout the AFFF-contaminated watersheds. This result is supported by mass budgets for a river that originates from an AFFF-contaminated lake. The budgets, developed by paired flowrate and concentration measurements, indicate conservative transport in the river of PFAS with less than nine perfluorinated carbons. At the discharge point of the river to a saltwater bay, bulk precursors represent 16-26% of the total PFAS signal, indicating that precursors persist in the river and are transported more than 6 kilometers under oxic conditions. These findings suggest that PFAS from AFFF with less than nine perfluorinated carbons propagate far downstream from the source and serve as an ongoing source to the marine environment.

164 The Use of PFAS onboard marine vessels: Impacts to Halifax Harbour

L. Hodgkins, Department of National Defence; R. Mulligan, Queen’s University / Department of Civil Engineering; K.P. Weber, Royal Military College / Chemistry and Chemical Engineering

PFAS are presently essential ingredients in aqueous film forming foam (AFFF) used for fire-fighting, but are also persistent and pervasive environmental contaminants. For example, AFFF used onboard a marine vessel can wash overboard resulting in addition of PFAS to the surrounding ocean environment. A hydrodynamic model (Delft3D) was used to predict the transport of PFAS released into Halifax Harbour at different locations over differing environmental conditions. The initial AFFF input was relatively conservative representing 10 minutes of firefighting using one standard hose. Results indicate that PFAS released in the presence
of strong winds and waves during a storm will travel up to 31 km in 2 days, approximately 40% farther than PFAS released during a time period dominated by tidal currents with calm wind and no waves. When PFAS was released from inner harbor locations, during environmentally calm periods, PFAS concentrations reached 500 ng/L after 12 hours, but dissipated to 300 ng/L after 48 hours, and 60 ng/L after 10 days. These levels are close to some international guidance values for recreational water use. Given the relatively conservative AFFF input used here, some risk is identified. The methods used here could be further refined and used to develop best practices for fire fighting near shorelines while aboard marine vessels. These results also indicate that PFAS use on marine vessels should be considered in further assumptions underlying long range PFAS transport.

165 Fingerprinting AFFF, Landfill, and Municipal Wastewater Sources of Per- and Polyfluoroalkyl Substances

_Stephen A. Roehl, Oregon State University / EMT; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering; J. Field, Oregon State University / Environmental and Molecular Toxicology; M. Barlaz, North Carolina State University / Civil Constr and Env Eng_

Per- and polyfluoroalkyl substances (PFAS) impart unique water and oil repellent properties. As such, they are applied to a number of consumer products and are used in aqueous film forming foams (AFFFs), which are used to suppress hydrocarbon fuel fires. Consequently, use and disposal of PFAS-containing products have the potential to contribute to environmental PFAS loading from sources including landfill leachates, wastewater treatment plant effluents, and AFFF releases. To date, attempts to differentiate PFAS sources rely on discerning differences between perfluoroalkyl carboxylates (PFCAs) and sulfonates (PFSAs) from various sources. However, because PFCAs and PFSAs are common to many sources, differentiation of sources is very challenging. To remedy this situation, groundwater collected from AFFF source zones, an archive of landfill leachates from a US national survey, and select wastewater effluents from around the US were fingerprinted by liquid-chromatography-quadrupole time-of-flight high-resolution mass spectrometry for 400+ individual PFASs. The number of individual PFASs, PFAS concentration and their ratios, and the ratio of branched to linear isomers were evaluated by hierarchical clustering and principal component analysis in order to differentiate PFAS fingerprints from landfill leachate, wastewater effluent, and AFFF source zones.

166 Effects of ‘Traditional’ and ‘Novel’ Perfluoroalkyl Substances on Early Life Stages of Salmonid Fishes

_S. Su, J.C. Raine, Y. Xie, Y. Gong, J. Tang, C. Wang, Z. Yang, University of Saskatchewan / Toxicology Center; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre_

Emerging substitutes for traditional perfluoroalkyl substances, purported to pose lower risks to humans and the environment, have been raising concerns over the past few years. There is a clear need for additional toxicological information on these ‘novel’ perfluoroalkyl substances to better describe their environmental impact profiles. As representative salmonid species, arctic char (_Salvelinus alpinus_) and rainbow trout (_Onchorhynchus mykiss_) were exposed to three typical substitutes, perfluorobutanesulfonic acid (PFBS), perfluorobutyric acid (PFBA), and undecafluoro-2-methyl-3-oxahexanoic acid (GenX) as well as the well-known perfluorooctanesulfonic acid (PFOS). Survival and development of these two species were both most affected by PFOS when compared with the other perfluoroalkyl substances. Exposure to the chemicals was done in early life stages, and the portion of chemicals delivered into the fishes showed different patterns among the different perfluoroalkyl substances. Additional experiments, including bioavailability studies and determination of affected metabolic pathways, need to be done to better explain the possible risks of these substitutes for traditional perfluoroalkyl substances.

167 Identification of genes involved in per- and poly-fluoroalkyl substance metabolism in the soil bacterium, _Gordonia sp._ NB4-Y

_E.M. Bottos, Thompson Rivers University / Biological Sciences; E. Alishabib, University of Regina; D. Shaw, Thomson Rivers University; B.M. McAmmond, Thompson Rivers University / Biological Sciences; D.M. Suchan, A. Sharma, A.D. Cameron, University of Regina; J. Van Hamme, Thompson Rivers University / Biological Sciences_

To date, perfluoroalkyl and polyfluoroalkyl substance (PFAS) biodegradation pathways have been inferred by studying mass loads in sewage treatment plants, or determined experimentally with in vitro studies examining PFAS biotransformations using mixed sewage inocula, sediment in microcosms, or in mammalian cell cultures, and extracts. While these studies are valuable, developing a deep understanding of the biochemical machinery driving biological PFAS biotransformations in the environment demands detailed examination of the specific genes and proteins involved. Building on pathways elucidated for fluorotelomer sulfonamidoalkyl betaine (6:2 FTAB) and 6:2 fluorotelomer sulfonate (6:2 FTSA) metabolism by the soil bacterium, _Gordonia sp._ NB4-1Y, the present study compared gene expression profiles of NB4-1Y exploiting either 6:2 FTAB, 6:2 FTSA, octane sulfonate and magnesium sulfate as the primary source of sulfur for growth. High-throughput sequencing of mRNA from exponentially growing NB4-1Y allowed for the identification of 2 nitriotriacetate monoxygenase genes (ntaA) as being differentially expressed on exposure to 6:2 FTSA, enzymes which are hypothesized to catalyze 6:2 FTSA desulfonation, a novel activity for this enzyme class. Other genes that were observed to be differentially expressed include: 4 genes putatively involved in C-N bond cleavage in 6:2 FTAB; 4 genes putatively involved in dehalogenation and acetyl-CoA addition to the fluorinated alkane backbones of 6:2 FTAB and FTSA; 17 stress response genes; and 8 genes related to sulfur starvation. Of 14 genes annotated as taurine dioxygenase (_taud), alkanesulfonate monoxygenase (ssud) or nitritotriacetate monoxygenase (_ntaA), 4 were upregulated on 6:2 FTSA, 6:2 FTAB and octanesulfonate, 6 were upregulated on 6:2 FTSA and 6:2 FTAB, 1 was upregulated on 6:2 FTSA, and 3 were not expressed under any condition. In combination with proteomic analyses, genes of interest are being cloned and expressed to allow for identification of structural features that allow the enzymes to interact with PFAS breakdown products. This work is improving understanding of the molecular mechanisms of PFAS metabolism and will allow for the development of site assessment tools to inform remediation practitioners of the biological potential for PFAS removal, thus guiding treatment decision making processes.

Environmental DNA (eDNA) Approaches to Enhance Biodiversity Monitoring and Risk Assessments - Part 2

_C.C. Helbing, University of Victoria / Biochemistry & Microbiology; J. Hobbs, J. Hobbs Ecological Consulting, Ltd_

Environmental risk assessments require accurate and timely information regarding occurrence and distribution of ‘at risk’ and invasive species. Conventional survey methods generally rely on direct observation that can be stressful to the target species and damaging to their habitat. For species that are cryptic or low density, the likelihood of detection is low. A new approach involves sampling DNA in sediments, soil, or water that is sloughed off target organisms. Environmental DNA (eDNA) detection is accomplished through the identification of unique sequence segments of genetic material without the necessity of coming into direct contact with the target organisms. The high sensitivity of eDNA methods can dramatically increase detection rates, particularly for species that occur at low densities, have secretive ecologies, feature discontinuous distributions, or share morphological traits that confound accurate identification. Furthermore eDNA methods are more cost-effective, non-invasive, and more accurate than conventional survey methods. eDNA methods...
require an effective synergy between field and DNA detection methodologies with several points of consideration that require attention during development, adoption, and implementation. Analytical techniques and technologies are rapidly evolving and the methods chosen depend upon the desired purpose to 1) detect taxa in a targeted fashion or 2) assess community biodiversity. Environmental samples are complex and the quality and quantity of DNA can vary substantially. As such, field and analytical components of eDNA methods face particular challenges that require a heightened awareness and attention to methodological requirements. Best practices strive to mitigate sources of false positive and false negatives, utilize eDNA methodology appropriate for study design objectives with appropriate regard to statistical power, include attention to quality control, and provide transparency in assessment of test performance. We present the highlights of a recent consensus-based synthesis of the current needs in eDNA practice in order to address specific issues to remove barriers to the adoption of eDNA methods for environmental risk assessment. These include addressing quality issues with accuracy and reliability, lack of accredited national standards for both sample collection and analysis, and the need for demonstrated competency and proficiency testing by practitioners.

169 Seasonal variation in detection of vertebrates at a uranium mine containment pond using environmental DNA (eDNA) metabarcoding
K. Klymus, C.A. Richter, N. Thompson, J. Hinck, US Geological Survey / Columbia Environmental Research Center

Development of new uranium mining in northern Arizona was halted in 2009 by the federal government until studies assessing the potential impact of radionuclide and other heavy metal contamination were conducted. In order to understand the possible toxicological effects on wildlife, a better understanding of the local food web and exposure pathways was needed. One potential source for exposure to heavy metals associated with mining activity are the containment ponds required at each mine site. We have previously shown that eDNA metabarcoding can detect vertebrates utilizing these water sources and identify taxa to species level. We have conducted quarterly water sampling at one, pre-production mine site to assess seasonal variation in vertebrate usage of the containment pond. By using a metabarcoding approach with 12S and 16S rDNA markers, we identified species and assessed temporal variation in detection rate and read number. We recovered large numbers of sequence reads from taxa expected to be in the area, as well as from less common or hard to observe taxa such as the Mexican free-tailed bat and the tiger salamander. Detection of the tiger salamander is of note because this species was not observed by the traditional biological survey techniques used. eDNA is quickly becoming a popular tool for wildlife surveys and has unique advantages and as well as limitations relative to traditional survey methods. Ultimately this tool will enable us to better understand the overall biodiversity of the area and potential movement of heavy metal contaminants through the food web.

170 Environmental DNA Survey in Lake Ontario to Assess Presence of Round Whitefish During Known Spawning Periods and General Fish Community Composition

Environmental DNA (eDNA) analysis is an emerging and non-intrusive tool to detect species in the environment. It is supplemental, or in some cases, may be an alternative to traditional methods for surveying biota. Industrial applications of eDNA approaches have primarily been in rivers, streams and small ponds, whereas studies in large water bodies such as the Great Lakes are scarce. In the current study, a winter field program was developed to survey eDNA from Round Whitefish in tandem with gillnetting in Lake Ontario. The objective was to evaluate the potential for eDNA analysis to be used as a tool for detecting Round Whitefish during spawning. In this study, size-selective gillnets were deployed in December to capture Round Whitefish in a known spawning location in Lake Ontario. Different volumes of water were collected along the nets before, during, and after fish capture, followed by on-site DNA extraction. Primers were developed to detect Round Whitefish DNA using quantitative polymerase chain reaction (qPCR) in a highly sensitive and specific manner. Metabarcoding was also investigated for assessing fish community composition. Results from qPCR and gillnetting were consistent, as both approaches demonstrated the presence of Round Whitefish in the spawning area, with no detections at the control site. Round Whitefish DNA was more frequently detected at sampling locations in close proximity to the nets. The most promising approach for detecting Round Whitefish DNA is collecting larger volumes of water along a transect within a spawning location. Metabarcoding of Lake Ontario water samples yielded results indicating a relatively small number of fish species including Round Whitefish, White Sucker, Rainbow Trout, while only Round Whitefish, White Sucker and American Eel were captured by nets. Limitations associated with metabarcoding were noted, including not being able to distinguish between closely related species (genetically), and not being able to detect American Eel that were caught in the nets. Overall, this study successfully demonstrates the potential for using eDNA to assess fish presence in the Great Lakes during winter spawning and the potential to provide additional information on fish community composition. It is the first study to use eDNA to demonstrate Round Whitefish presence in the Great Lakes and that transect sampling to collect large volumes of filtered water greatly improves eDNA detection sensitivity.

171 Environmental DNA (eDNA): Opportunities and Constraints for Advancing Ecological Risk Assessment and Environmental Effects Monitoring
D. Bright, Hemmera Envirochem, Inc.; C.C. Helbing, University of Victoria / Biochemistry & Microbiology; J. Hobbs, J Hobbs Ecological Consulting, Ltd.; A. Weir, Bureau Veritas Laboratories / Forensic & DNA Services; M.J. Allison, University of Victoria / Biochemistry & Microbiology

There are a large number of studies published over the last decade that support the use of eDNA surveys for aquatic ecosystems as a sensitive and highly efficient approach for evaluating the presence and distributions of biota of interest. The major portion of targeted species eDNA studies have focussed on at-risk or invasive species, while metagenomic approaches have focussed on biodiversity. There are merits, however, to the wider use of eDNA approaches in the types of eco-epidemiological approaches that underpin multi-species ecological risk assessments and environmental effects monitoring (including cumulative effects monitoring). This is based on (i) the increased complexity and especially geographic and temporal scales of the issues we seek to address, and (ii) the inherent potential of eDNA approaches for increasing our capacity per unit of effort to acquire both more extensive and intensive knowledge about biota distributions over space and time. Furthermore, to the extent that eDNA collection, analytical and interpretative data standards can be developed and implemented in not-too-distant future, eDNA results produced by different parties may exhibit a higher level of accuracy and reproducibility than is typically achieved through more traditional ecological monitoring methods. This is important to the extent that we wish to resolve the big environmental issues through greater access to crowdsourced environmental data and big data meta-analytical approaches (as is currently achievable for air quality and water quality data, for example). One substantial limitation of eDNA surveys in their current state of development is that they provide taxon presence-absence but not abundance data. Nonetheless, we discuss the potential applications of both targeted taxa eDNA and metagenomics methods for ecotoxicological / ecological risk assessment application, with a discussion of both the merits and limitations. The species sensitivity distribution (SSD) is an important precept in modern applied ecotoxicology and this is discussed in the context of new eDNA-based approaches for identifying where and when potentially sensitive species occur relative to the observed environmental conditions.
We also discuss challenges with reconciling existing ecological impact metrics (e.g., for stream invertebrate communities) with the data characteristics associated with eDNA methods.

172 Assessing freshwater mussel restoration efforts in the Clinch River with environmental DNA metabarcoding

The Clinch River is located in the Appalachian Valley of southwestern Virginia and northeastern Tennessee, USA and contains the highest concentration of extant federally listed aquatic species in the United States. The fauna includes a diverse mussel assemblage of 46 extant species, 20 of which are listed as endangered, and a diverse fish assemblage of 132 species, 3 of which are listed as either endangered or threatened. Habitat alterations and contaminants have led to major declines in the mussel fauna. In 1998 a chemical spill in Virginia killed 18,000 mussels of 16 species, and was followed by a Natural Resource Damage Assessment and Restoration (NRDAR) case to propagate and reintroduce mussels to depleted populations. Our objective was to test the utility of eDNA metabarcoding for monitoring mussel populations and restoration efforts. We developed and tested a metabarcoding assay to detect all freshwater mussel species with known mitochondrial COI gene sequences that occur in the Clinch River. The degenerate PfaCOI2 primers, with a 241 bp amplicon, amplified all tested Unionid mussel swab and tissue samples, and did not amplify tested outgroups, including human, emerald shiner, blue mussel, Dreissena spp., and silver carp. However, we found an unexpected non-target amplification product that interfered with sequencing depth. Removal of the non-target amplicon allowed a final sequencing depth of approximately 12 million reads, with approximately 6.5 million reads suitable for the analyses. We detected 18 freshwater mussel species. Trends in mussel diversity from site to site were in agreement with data from traditional mussel surveys. We concluded that robust sequence data for the target species and related species, as well as careful assay design, primer optimization, water sampling, lab practices, controls, and bioinformatics are critical for confident interpretation of eDNA metabarcoding results. The metabarcoding field has a need for consistent methods to avoid or remove sequencing errors, contamination, and tag jumping.

173 Application of environmental DNA methods for detecting species at risk fish

S. Tarof, Azimuth Environmental Consulting, Inc. / Ecology; M. Thomas, S. Crookes, K. Romanick, Precision Biomonitoring, Inc.

Environmental DNA (eDNA) is DNA released into an organism’s habitat that can be used to infer species presence/absence without sampling the organism. Application of eDNA as a rapid, indirect environmental monitoring technique is gaining traction in conservation and invasive species studies. Indeed, eDNA is emerging as a particularly powerful tool for detecting covert Species at Risk (SAR), but has not been applied to the environmental consulting sector. We applied eDNA methods to test for presence/absence of Redside Dace (Clinostomus elongatus) (Endangered) and Lake Sturgeon (Acipenser fulvescens) (Endangered) using mitochondrial DNA markers and occupancy analyses for populations in Southern Ontario, Canada. Traditional field survey data were used to identify positive and negative control sites a priori. Results from two years of discrete and continuous transect sampling indicated that positive control sites showed presence of the target species’ eDNA. Using environmental metadata as covariates, we calculated the probability of detection and occupancy to explain patterns of variance in eDNA presence/absence. This novel study is part of a four-year collaborative eDNA project to develop field-tested protocols to determine presence/absence of several SAR. Environmental DNA promises to revolutionize SAR assessments in the consulting sector by providing a faster, more efficient method of species detection compared with traditional field surveys.

174 The Critical Need to Assess the Variables Applied to Survey Design and Analysis of Environmental DNA

J. Cashubec, J. Ward, AECOM Environment / Water and Natural Resources

Environmental DNA (eDNA) detection technology has the potential to greatly contribute to the understanding of species distribution and to inform conservation efforts. This presentation builds on the previous research that has noted the particular benefit of eDNA analysis when attempting the detection of imperiled species, where conventional means of detection are intrusive, entail risk of harm, or have lower efficacy. Our presentation highlights multiple case studies that include the use of eDNA for the endangered and imperiled Redside Dace (Clinostomus elongatus) in Irvine Creek; the remediation of the Lower Seymour Conservation Reserve abandoned gun range, home to a number of endangered amphibian and mammals; identification of source microbial contamination in a municipal wellhead; and more. During the design and implementation phases of eDNA surveys, the many variables that factor into the survey design, and the various means of sample collection, processing, and analysis available within the emerging field, have come to light. Through trial and error, the surveys designs have evolved, and multiple pieces of equipment have been tested, resulting in varying degrees of detection and confidence. Our case study results stress the importance of tailoring and optimizing the equipment, methods, and survey design to the objective of the survey, thereby maximizing confidence in the results. This is of particular importance when results pose an implication on the protection or recovery of the species.

175 Archived Environmental DNA (eDNA) Samples: An Evaluation of Sample Performance Over Time

D.A. Bright, AECOM / Environment; A. Weir, Bureau Veritas Laboratories / Forensic & DNA Services; C.C. Helbing, University of Victoria / Biochemistry & Microbiology; J. Hobbs, J. Hobbs Ecological Consulting, Ltd.; D. Bright, Hemmera; W. Murray, Bureau Veritas Laboratories / Forensic & DNA Services; M.J. Allison, J.M. Round, University of Victoria / Biochemistry and Microbiology; A. Mirzabadeh, H. Allen, Bureau Veritas Laboratories / Forensic & DNA Services; L.C. Bergman, University of Victoria; E. McCormick, Bureau Veritas Laboratories / Forensic & DNA Services; K. Ovaska, L. Sopuck, Biolinx Environmental Research

Reliable detection of target species using environmental DNA (eDNA) is a significant and valuable scientific tool. Based on the premise that animals shed their DNA into their environment, key advantages of using eDNA compared with conventional detection methods include: enhanced sensitivity and accuracy; lower sampling effort and cost; an expanded time-frame for sample collection; and reduced invasiveness to the habitat and organism. eDNA samples may also be archived for future testing for additional species of interest without the need to return to the field site to collect additional samples, provided that samples are properly preserved and stored. Confidence in eDNA results can be achieved by following best eDNA practices in the field and laboratory. It is important that the quality of eDNA samples be assessed prior to analysis to control for false negatives (type II errors). eDNA samples that are too degraded or that contain assay inhibitors, found naturally occurring in the environment, may not generate a positive signal during analysis and could be falsely interpreted as a “non-detect” for the target species, when in fact the sample quality is unsuitable for analysis. This applies both to newly-collected samples and historical samples that are retrieved from archive for testing. Little is known about the performance of archived eDNA samples over time and the ability to generate meaningful data on species presence when stored samples are analyzed at a future date. Providing metrics to this question will enable users to appropriately incorporate eDNA sample archiving into their eDNA programs with the intent that samples can be interrogated in the future with confidence. Two filter preservation methods are commonly used: ethanol immersion and silica preservation. We will provide perspectives on the utility of each of these preservation methods. Of the two, silica preservation has many advantages over ethanol while
not compromising on effectiveness. We also will discuss the results of a performance experiment of archived eDNA filter samples preserved with silica over time under different storage conditions.

**Soil Contaminants: Fate, Bioavailability, Environmental Toxicology in Ecological and Human Health Risk Assessment**

**176 Environmental Fate of Saflufenacil, a New Fluorinated Herbicide**

*J. Gauthier, University of Toronto / Environmental Chemistry; S. Mabury, University of Toronto / Chemistry*

Saflufenacil is a protoporphyrinogen IX oxidease (PPO) inhibitor herbicide used for the treatment and control of dicot weed species in crops such as corn, wheat, and soybean. Recently, PPO inhibitor herbicides have seen significant increase in use, particularly for the treatment of a growing number of glyphosate-resistant species. While previous saflufenacil research has focused on metabolic profiling and mode of action in target species, there remains limited knowledge surrounding the environmental fate and distribution of saflufenacil. In this research we apply saflufenacil on an agricultural field to directly monitor its potential to undergo photolysis, biological degradation, and environmental transport. Soil samples taken over the course of the growing season were analyzed using a modified high-throughput dispersive liquid-liquid extraction technique. This was combined with LC-MS/MS resulting in method detection limits (MDLs) for saflufenacil and its metabolites of 0.034 ng/g in soil with recoveries of 87% +/- 10%, sufficient for analysis below the application rate of 63 g a.i./ha. Additional partitioning experiments were conducted to examine transport through soil, water, and non-targeted crop species; while high-resolution mass spectrometry and fluorine NMR were employed to probe potential degradation pathways. The predominant metabolic breakdown pathway in soil yielded three key metabolites which were detectable above the MDL in all field samples as long as 7 months following initial exposure. Notably, saflufenacil was also found at high levels in non-targeted species, suggesting the potential for environmental persistence and unintentional distribution. Through this research we have gained a more thorough understanding of the environmental fate of saflufenacil, and techniques developed for monitoring its fate and distribution are readily applied to other novel fluorinated agrochemicals, providing a more comprehensive overview of environmental contamination in soils.

**177 Reducing mobility/bioavailability of metals, metalloids and PFAS contaminants simultaneously using mixed mode remediation materials**

*M. McLaughlin, University of Adelaide / Soil Science*

Contaminated soils are rarely contaminated by just one chemical; sites are often contaminated by a cocktail of metals, metalloids and organic compounds which often makes remediation of the contamination problematic. For example, removal of hydrophobic metals and metalloids requires polar solvents (acids/chelates) which will not displace hydrophobic organic contaminants. Furthermore, in situ remediation of one contaminant may exacerbate the mobility and/or bioavailability of another e.g. remediation of lead-contaminated soils by addition of phosphate to precipitate lead phosphates may mobilise arsenate. We have developed mixed-mode remediation agents using a variety of materials which have the ability to bind metals, metalloids and hydrophobic contaminants simultaneously. Some of these remediation agents are developed from relatively low cost materials and have now found commercial use, but development continues using new materials such as metal-graphene composites which offer similar or enhanced properties. Data for remediation of a metalloid anion (arsenic), a metallic metal cation (cadmium) and hydrophobic/hydrophilic contaminants (PFAS chemicals) indicate that mixed-mode remediation agents have significant potential for use in remediating soils contaminated by a variety of chemicals. Graphene-based products have significant potential but costs of graphene production need to drop for these materials to have wide application.

**178 The Role of Naturally Occurring Colloids in the Transport and Fate of Antibiotic Resistant Genetic Debris**

*N. Chowdhury, Duke University / Civil and Environmental Engineering*

The association of extracellular DNA (eDNA) and naturally occurring colloids is evaluated to elucidate the role of particles in the transport and fate of antibiotic resistant genetic debris in natural soil and aquatic environments. DNA fragments are isolated from common antibiotic resistance genes. The impact of DNA fragment length, DNA GC (guanine-cytosine) percent, particle association with organic components and water hardness are evaluated. Adsorption isotherms are developed for fragments of eDNA to model colloids - kaolinite and silica nanoparticles. Adsorption isotherms of DNA to kaolinite fit to the Langmuir model indicate that shorter DNA fragment length is favorable for adsorption and DNA guanine-cytosine content within the range tested (34%-54%) does not significantly impact equilibrium adsorption. The fit to the Langmuir model also suggests that adsorption abides by Langmuirian assumptions - mono-layer coverage of the particle and an equal energy of binding sites. Equilibrium adsorption is established within an hour, fits pseudo-second order kinetics and is size dependent. DNA fragments adsorb to silica nanoparticles when humic acid or high (but not environmentally relevant) concentrations of divalent ions (10 mM CaCl₂) are present in solution. Adsorption isotherms of DNA to humic acid functionalized silica nanoparticles fit the Freundlich model - an empirical model that doesn’t assume mono-layer coverage or equal energy of binding sites. Smaller DNA fragments preferentially adsorb to humic acid-silica and GC content has no significant effect on adsorption. The addition of CaCl₂ at environmentally relevant concentrations (2 mM) does not allow DNA to adsorb to silica nanoparticles, but does enhance adsorption to humic acid-silica. The addition of CaCl₂ and humic acid have an interactive effect in promoting adsorption of DNA to the surface of the nanoparticles. This suggests that water hardness, presence of organic material and eDNA fragment size are important predictors for adsorption of antibiotic resistance genes to naturally occurring colloids. Future aims will investigate the role of particle association in regulating the persistence of genetic materials and the bio-availability of particle associated genetic material in uptake by bacteria.

**179 Incorporating community data into risk assessment schemes using community similarity dose-responses**

*M. Renaud, CFE - Centre for Functional Ecology / Department of Life Sciences, University of Coimbra; P. Martins, CFE - Centre for Functional Ecology; T. Natal da Luz, CFE - Centre for Functional Ecology / Department of Life Sciences, University of Coimbra; S. Siciliano, University of Saskatchewan / Department of Soil Science; J.F. Sousa, CFE - Centre for Functional Ecology / Department of Life Sciences University of Coimbra*

Current Ecological Risk Assessment schemes use mostly single species test data at lower tiers to extrapolate/predict effects in the field (higher tier). Inter-species sensitivity can be incorporated by using data on multiple species combined in models such as species sensitivity distributions. However, this approach does not take into account important ecological interactions between species. Microcosm experiments using natural soil communities can be used to include species interactions and are specially suited for site-specific approaches using a relevant community and soil from a site of interest. Some species disappear in contaminated environments while others may thrive from reduction in competition/predation. This increased complexity in the response of communities to environmental stressors poses issues in the interpretation of results, especially to define environmental thresholds. In this study we propose a novel statistical approach, using community similarity, to interpret community responses to stressors in a microcosm community experiment. Laboratory community experiments were performed using a natural community.
and increasing doses of metal mixtures of lead, copper, nickel, zinc and cobalt in three fixed ratios. Two ratios based on regulatory guidelines (CSQG and ARL) and a third ratio based on average metal concentrations in a metal contaminated site (SUD). Each ratio was tested using a control and ten mixture doses in toxic units. Metal mixture effects on the soil community were analysed using the proposed community similarity dose response curves. The community similarity between test and control treatments decreases as contamination increases, producing a dose response curve that allowed the calculation of community effect concentrations (ECx). Under this concept, a community ECx provides the percentage of change x caused by a contaminant in a community. These community ECx values could potentially be used directly to establish environmental protection thresholds, in a transparent manner, which does not require expert judgement, and is supported by data.

180 Introducing adverse ecosystem service pathways (AESP) as a tool in predictive soil ecological risk assessment

K. Awuah, K. Jegede, University of Saskatchewan / Toxicology Centre; B.A. Hale, University of Guelph / SES; S. Siciliano, University of Saskatchewan / Department of Soil Science

The soil ecosystem is complex and is responsible for providing several benefits to humans, benefits known as ecosystem services (ES). These benefits result from the interactive processes and activities of soil organisms with support from the physicochemical properties of the soil. Risk assessment of multiple stressors on complex systems requires understanding of the relationships between components of the system, both in the presence and absence of stressors. We developed adverse ecosystem service pathway (AESP) models to study the soil ecosystem and its response to a metal mixture containing Cu, Pb, Zn, Co, and Ni. We sampled 47 soils and measured 15 soil processes that represents five ES including food production and water purification. Using a Pearson bivariate correlation matrix, we confirmed that ES were interrelated and linked to soil properties. Results from t-tests showed that the processes underlying ES were significantly reduced in metal impacted soils except for the soil enzyme activities measured ($p < 0.05$). We built two AESP models using soil properties as the main predictors of ES and predicted the regional impacts of metal mixtures in the Prairie Provinces of Canada. The predictions showed areas sensitive to metal contamination in the Prairies and estimated the depreciation of benefits we derive from the Prairies. The results confirm that AESP models could be a useful tool in understanding complex ecosystems and in predictive risk assessment, management of natural resources and climate change.

181 Evidence of anthropogenic pollution in playground soil throughout Oklahoma City, Oklahoma

S. Hileman, J.B. Belden, Oklahoma State University / Integrative Biology

Polycyclic aromatic hydrocarbons (PAHs) and metals are generally ubiquitous in the environment and have been found to be of concern with regards to human health. PAH and metal contamination may correspond with atmospheric deposition, and in urban environments soils may contain elevated levels of both categories due to proximity to sources like vehicular traffic. Sampling in the Oklahoma City Metropolitan Area has indicated that PAH accumulation (and especially carcinogenic PAHs or cpAH concentration) has been significant, and in many cases cpAH load has been measured above the USEPA’s residential soil screening level of 1100ppb. The Oklahoma City Metropolitan Area varies in urban landscape causing school proximity to major areas of traffic to differ. Included in this initial sampling were soils from public elementary school playground areas. Because schools in this metropolitan range tend to have a high degree of concern, there is the potential for oral exposure to these contaminants in sensitive age groups by way of hand-to-mouth actions involving soil. Recent data from playground soil at elementary schools throughout the Oklahoma City Area have shown elevated but varied cpAH levels. This preliminary investigation has also shown metals to be present, but in lower levels. These sites should be further investigated to determine potential sources of contamination.

182 Gastrointestinal Mobilisation and Oral Bioaccessibility of Polycyclic Aromatic Hydrocarbon Nonextractable Residues from Soils and Related Cancer Risks

A.C. Umeh, Global Centre for Environmental Remediation (GCER); L. Duan, R. Naidu, M. Esposito, University of Newcastle / GCER and CRC CARE; K.T. Semple, Lancaster University / Lancaster Environment Centre

Highly sequestered polycyclic aromatic hydrocarbons (PAHs) residues in soils are difficult to extract by exhaustive solvents, particularly in long-term aged soils. As a result, it has been speculated that these PAH residues do not pose risks to human health following incidental ingestion of PAH-contaminated soils. Whether PAH nonextractable residues (NERs) in soils will be mobilised in the human gut fluid and in sufficient concentrations that may pose unacceptable levels of cancer risks remain largely uncertain. In this study, we first subjected soils collected from historically contaminated manufactured gas plant (MGP) site soils to exhaustive solvent extractions to remove total-extractable fractions and to produce soils containing only PAH NERs. Another aliquot of the unextracted soils was subjected to gastrointestinal digestion using a physiologically based gastrointestinal model that incorporates a silicon rod (Si-Org-PBET) as an intestinal sink for PAHs. In addition, gastrointestinal mobilisation of PAH NERs from the solvent-extracted soils using Si-Org-PBET was assessed. The incremental levels of cancer risks following incidental ingestion of PAH-contaminated soils was then determined, following a widely used deterministic cancer risk assessment approach. The oral bioaccessibility of 6 carcinogenic PAHs that were monitored ranged from 24 - 36%, indicating that only a small fraction of total PAHs in soils were bioaccessible in the gastrointestinal solution. Hence, total-extractable PAH concentrations overestimated risks from exposure to PAHs in the long-term contaminated soils. In addition, the in vitro gastrointestinal fluid mobilised small amounts of PAH NERs from the soils and associated cancer risks were within acceptable target levels (> 10E-6). Overall, gastrointestinal mobilisation of long-term contaminated soils containing highly sequestered PAH nonextractable residues is unlikely to exert unacceptable levels of cancer risks and therefore do not need to be considered in human health risk assessments. These observations may be useful for risk-based approaches for contaminated land management and decision-making, particularly where incremental levels of cancer risks following exposure to PAH residues in long-term contaminated soils are of interest.

183 Bioavailability of Organic Chemicals from Soil for HHRA: Study Design Considerations

Y. Lowney, Alloy, LLC / Health Sciences

Incorporating bioavailability adjustments into human health risk assessment (HHRA) for chemicals in soil is gaining regulatory acceptance. Continuing development of guidance from USEPA and state health/environment agencies facilitates greater acceptance of bioavailability adjustments in the risk assessment process. This is enhanced by efforts such as the documentation and training efforts by the Interstate Technology and Regulatory Council (ITRC). To date the guidance on bioavailability of chemicals from soil has largely focused on inorganic chemicals in soil, particularly lead and arsenic. Site-specific evaluations have addressed bioavailability adjustments for organic chemicals from soil, such as dioxins and polycyclic aromatic hydrocarbons. However no broad guidance for incorporating adjustments, or even appropriate research methods have been endorsed by regulatory agencies in the U.S. This presentation will outline some of the study design challenges that are different between inorganic and organic chemicals, and discuss the potential implications, in terms of quality and potential biases in final results.
**Life Cycle Assessment - Advancements and Applications**

184 Life cycle impact of titanium dioxide nanoparticle synthesis through physical, chemical, and biological routes

*F. Wu, Jinan University / School of Environment; Z. Zhou, Brigham Young University / CBEE; A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering*

The sustainable manufacturing of nanoparticles (NPs) has become critical to reduce life cycle energy use and the associated environmental impact. With the ever-growing production volume, titanium dioxide (TiO2) NPs have been produced through various synthesis routes with differing input materials and reactions, which result in differential reactivity, crystallinity, surface areas, and size distributions. In this study, life cycle assessment is used to analyze and compare the environmental impact of TiO2 NPs produced via seven routes covering physical, chemical, and biological syntheses. The synthesis routes are chosen to represent mainstream NP manufacturing and future trends. Mass-, surface area-, and photocatalytic reactivity-based functional units are selected to evaluate the environmental impact and reflect the corresponding changes. The results show that impact associated with the upstream production of different precursors is dominant for the chemical route. Compared to the chemical route, the physical route requires substantial quantities of supporting gas and high-energy inputs to maintain high temperature; therefore, a higher environmental burden is generated. A high environmental burden is also modeled for the biological route due to the required bacterial culture media. This present study aims to identify the most efficient synthesis route for TiO2 NP production, lower the potential environmental impact, and improve green synthesis and sustainability.

185 Global Environmental Impacts of Single-Walled and Multi-Walled Carbon Nanotube Synthesis Methods and Implications of Scaling Up

*S. Temizel Sekeryan, University of Wisconsin / Civil and Environmental Engineering; F. Wu, Jinan University / School of Environment; A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering*

Carbon nanotubes (CNTs) are well known for their mechanical resistance, durability, and flexibility, which make them preferable for a wide variety of industries including electronics, optics, composites, energy and environment, automotive, aerospace, coatings, paints and pigments. The average production volume of CNTs was approximately 4000 tons/year in 2018, and this is expected to reach about 5 times more by 2024, globally. CNTs are categorized by their wall numbers as single-walled (SCWNTs) and multi-walled (MWCNTs). Although there is not a clear distinction between the volume of SWCNTs and MWCNTs produced, it is in consensus that MWCNTs are the dominant form in the market. CNTs may be synthesized by several chemical and physical methods and their synthesis have greater impacts on the products they are embedded in. This research performs a cradle-to-gate life cycle impact assessments (LCIAs) on 7 different SWCNTs and 5 different MWCNTs synthesis methods in order to evaluate global environmental footprints associated with manufacturing. A mass-based functional unit is selected as 1 kilogram of CNTs produced, and LCIA are conducted using SimaPro 8.5.2 Software with Cumulative Energy Demand (CED) and TRACI 2.1 Impact Assessment Methodology. Inventories are compiled both from CNTs synthesis papers and previously applied LCIA. The results showed that manufacturing SWCNTs with high-pressure carbon monoxide method is the most environmentally conscious method, whereas chemical vapor deposition (CVD) is the most impactful method. Furthermore, manufacturing MWCNTs with arc discharge method is found to be the most environmentally friendly, while CVD is the most impactful one among different methods considered. Switching methods would save up to 0.4 billion tons of CO2-eq. per year, which corresponds to 8% of the total greenhouse gases emitted in the United States in 2016. Given that the production is anticipated to peak in the next years, scaled up processes may offer lower environmental impacts. However, the literature on industrial scale production is currently limited. In order to address the significance of large-scale production, scaling up factor is developed in the current study by using LCIA for both laboratory and large-scale inventories. It is found that scaling up would save releasing 65% of emissions annually. This study aims to show that it is worthwhile to shift methods to have more environmentally friendly products.

186 Evaluation of new solar cells technologies for transparent photovoltaics in the United States

*S. Shakla, E. Lee, Michigan State University / Civil and Environmental Engineering; R. Lunt, Michigan State University / Chemical Engineering and Materials Science; A. Anctil, Michigan State University / Civil and Environmental Engineering*

Transparent organic photovoltaics (TPV) can harvest energy from the near-infrared and ultraviolet region of the solar spectrum and used in new applications such as windows. In addition to producing electricity, TPV absorption can change the energy demand of the building. There is a need to design materials that maximize both the energy efficiency and solar energy production. This study quantifies the annual net energy benefit of three new classes of organic materials by simulating electricity and heating demand from different types of buildings in various locations. Experimental work included material synthesis, device fabrication, solar power efficiency measurement, degradation measurement and spectral properties which was used to calculate the embodied energy of TPV manufacturing using life cycle assessment. The overall net energy benefit was calculated by combining the change in energy consumption, the photovoltaics electricity production and the manufacturing energy for each type of solar cells. The energy payback time (EPBT) and energy return on investment (EROI) were calculated and for C3AIPc based TPV the EPBT ranged from 51 days to 1.1 year depending on the location and type of module. Additional results for other types of solar modules will be presented.

187 Effect of Sediment Chemistry on Life Cycle Impact Assessment for Metals in Freshwaters

*K.J. Farley, Manhattan College / Civil and Environmental Engineering; K.J. Rader, Mutch Associates, LLC; R.F. Carbonaro, Mutch Associates, LLC / Chemical Engineering; L. Assem, International Copper Association; E. Nordheim, Aluminium REACH Consortium; C. Albersam, International Council on Mining and Metals; C.E. Schlekat, NiPERA; C. Cooper, International Zinc Association / Department of Marine Sciences; E.J. Van Genderen, International Zinc Association*

The USEtox Life Cycle Impact Assessment (LCIA) modeling approach for freshwater compartments was originally developed to describe the fate and transport of non-polar organic chemicals. For metals, water chemistry (e.g., pH, DOC, competing cations) plays a significant role in determining metal partitioning. Recent research addressed this issue using the Windermere Humic Aqueous Model (WHAM) to compute water column KD values based on defined input parameters for freshwater and marine archetypes for use in USEtox LCIA model simulations. However, the effects of sediment chemistry on LCIA has not been considered. The purpose of this study is to evaluate the effects of sediment chemistry on LCIA for metals using the risk assessment screening-level model, TICKET-UWM, to calculate LCIA Comparative Toxicity Potentials (CTPs) directly for freshwater environmental compartments. TICKET-UWM includes simultaneous consideration of dissolved and particulate phase transport between a well-mixed water column and an (oxic or anoxic) sediment layer, along with detailed chemical speciation calculations for metal binding to inorganic ligands, dissolved (DOC) and particulate organic carbon (POC), and Fe/Mn oxide surfaces; precipitation of metal hydroxides, carbonates, and sulfides; and dissolution kinetics for metal concentrates/massives and metal sulfide precipitates. The model also provides a direct evaluation of toxicity using either Free I on Activity Model (FIAM) or Biotic Ligand Model (BLM) calculations.
The modeling approach presented above provides a simple method for linking risk assessment models such as TICKET-UWM to LCIA model calculations. The approach allows non-linear responses associated with metal partitioning (in the water column and sediment) to be considered in developing LCIA CTPs for freshwaters. TICKET-UWM simulations will be presented for aluminum (Al), copper (Cu), nickel (Ni) and zinc (Zn) to highlight the effects of sediment chemistry (pH, sediment POC, redox conditions), sediment-water transfer processes and metal-sulfide oxidation rates on computed LCIA CTPs for freshwaters.

188 An exposome-based approach using Big Data to compare the health impacts of multi-stressor exposures
O. Jolliet, University of Michigan; K. Stylianou, University of Michigan / Environmental Health Sciences

High-throughput exposure strategies comparing exposure to various nutritional, chemical and physical stressors are needed for exposome wide associations. This presentation shows how recent Big Data and models enable us to predict exposure and impacts for multiple stressors. Occupational exposures were assessed across the entire US industry, based on a) measured noise levels, and noise-induced hearing loss burden rates for 287 sectors and sector-specific job occupation distributions, as well as b) observed organic chemical concentrations at work place for 49,000 measured sector-based concentration values for 235 organic chemicals. c) Dietary exposures and nutritional impacts were assessed using NHANES survey and the decomposition of individual diet into 16 dietary risk factors, accounting for 400 risk-outcomes, stratified by 15 age groups and gender, coupled with food composition and consumption data for 20,000 individuals. d) Physical activity is charaterized using MET and outcome-specific relative risks, and e) Consumer exposures to chemicals in multiple products are assessed using stochastic usage and chemical contents databases for more than 9,000 product-chemical combinations. f) PM2.5 environmental exposures are assessed based on residence location and a multiscale model predicting local concentrations. All exposures are then coupled with corresponding dose-responses to obtain individual burden in uDALY/pers-day. Potential impacts are highly variables depending on individual behavior and can typically range a) from 0 to 14 uDALY/pers-day depending on job occupation for hearing impairments due to noise; b) from 0 to 1600 uDALY/pers-day depending on industry sector for impacts of organic pollutants on workers; c) from a typical impact of 250 uDALY/pers-day lost from detrimental food, up to a benefit of 300 avoided uDALY/pers-day depending on selected diet, with main impacts associated with cardiovascular disease, diabetes and cancers; d) from a benefit of 0 to 400 avoided uDALY/pers-day as a function of physical activity; e) from 0 to 300 uDALY/pers-day for exposure to chemicals in consumer products and f) from an impact of 0 to 40 uDALY/pers-day lost associated with fine particulate 2.5um, depending on residence location. We enter an exciting era in which you can “Tell me when and where you lived and worked, what you consumed, exercised and ate... and I will tell you who you are (your exposome!).

189 Circular Economy: Life Cycle Assessment perspectives
W.H. Motta, Latec/UFF / Sustainable Managing System

Since the industrial revolution, natural resource use and waste had constantly grown. This is due a “take-make-consume and dispose” pattern of growth - a linear model which assumes that resources are abundant, available and cheap to dispose of. This study addresses the circular economy, this means an environmental performance from: product design through eco-design, productive and operational eco-efficiency, the use of renewable sources of energy, and also re-using, repairing, refurbishing and recycling existing materials and products. One of the proposals of the circular economy states that the raw material used in the product has other “lives” in other new products. The aim is that all resources need to be managed more efficiently throughout their life cycle to confront the ecological crisis. To support and direct the necessary efforts for this transition to a more circular economy a life cycle approach is needed, in this case specifically the use of LCA, that is a methodology that has been increasingly accepted as a way to assess the environmental impacts associated with all stages of a product’s life cycle. By providing detailed information of all the impacts throughout the product life cycle. LCA has a crucial role in the transition to a circular economy, as this methodology is able to validate, for example, the option to reuse a residue or change a production process, demonstrating the reduction of environmental impacts resulting from these decisions. The discussions underline the need of understanding and integrating these axes of knowledge, considering the huge potential to provide new means to overcome the ecological crisis. This bibliographical study, seeks to present the importance of LCA as supporter to the path for a circular economy.

190 Lowering the actor’s footprints and increasing their handprints: a win-win methodological approach to achieve the net positive development
J. Burek, Massachusetts Institute of Technology / Materials Systems Laboratory; G. Norris, Harvard School of Public Health / Sustainability and Health Initiative for NetPositive Enterprise SHINE; J. Gregory, Massachusetts Institute of Technology / Materials Systems Laboratory/ MIT Concrete Sustainability Hub; R. Kirchain, Massachusetts Institute of Technology / Materials Systems Laboratory

Footprints are the negative environmental, economic, and social impacts of production and consumption activities. Their scope spans the upstream supply chains and for many products it includes the downstream customer chain as well. Life cycle assessment (LCA) method has been the most prominent methods for calculating footprints. The main goal of the footprint paradigm is to reduce the negative impacts. However, the scale and rates of footprint reductions are falling short of reaching the set climate change goals. The limitations of the footprint assessment include inability for actors to achieve a zero footprint, reducing the actors’ own footprint will not make more than a minor reduction compared to the scope of the total problem being addressed, and the actor’s positive or negative change(s) outside their footprint is invisible in the footprint-only frameworks. Thus, researchers have introduced the handprints. This research focuses on developing a robust, comprehensive, and standardized method for handprint assessment in addition to footprint assessment. The paradigm shift consists in expanding the scope and moving towards net positive development in which footprints (negative impacts) become less than or equal to handprints (positive impacts). The expansion in the scope, in which there are no boundaries to the zone of impacts, stimulates actions and enables ripple effects. The overall positive impact then becomes a measurable contribution to solving regional and global environmental problems. Also, actors are held accountable for change(s) they create and incentivized to bring about positive change anywhere in the world. The method for measuring footprints and handprints is based on the LCA method. We will work closely with US-based and international industry stakeholders and the MIT Sloan School of Management sustainability program and assess their handprints. The study will examine how corporate stakeholders and sustainability programs might affect changes and increase their positive impacts. This will help achieve a widespread implementation and use of handprints. Broader goal of the study is to promote innovation in reducing their negative impacts and creating positive solutions to societal challenges.

191 Environmental Payback and Life Cycle Impact of Carbon Nanotube Supported CO2 Capture Technologies
F. Wu, Jinan University / School of Environment; Z. Zhou, Brigham Young University / Department of Chemistry and Biochemistry; S. Temizel Sekeryan, University of Wisconsin / Civil and Environmental Engineering; R. Ghakhrar, A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering

The current global climate change caused by excessive carbon dioxide (CO2) emissions has attracted widespread public concern in recent years. Current industrial methods generally utilize monoethanolamine (MEA) for CO2 capture; however, the CO2 regeneration requires a high temperature and energy demand during every adsorption/desorption (A/D)
process, along with nearly 0.5% of MEA loss. Carbon nanotubes (CNT) have high durability, stability, large surface areas and relatively low cost, making them preferable supportive materials for amines as adsorbents for post-combustion CO2 capture. Thus, CNT supported polyethyleneimine (CNT-PEI) was developed in previous studies to overcome these limitations. To identify the most impactful processes during the manufacture and improve synthesis efficiency, the environmental impacts of two CNT-PEI, physically adsorbed (Phy-CNT-PEI) and covalently bonded (Cov-CNT-PEI), were assessed through life cycle assessment (LCA). Meanwhile, the environmental payback periods were analyzed to recognize the sustainability of the newly developed systems. Results suggest CNT and PEI syntheses contributed greatly to the overall environmental impacts for both types of CNT-PEI. The environmental payback periods were compared between the MEA and Phy-CNT-PEI, with the break even point at 23 and 912 A/D cycles, respectively. However, Phy-CNT-PEI saves up to 60% energy demand compared to the MEA method for every A/D cycle due to its lower heat capacity. With the relatively high and stable CO2 capacity, additional 38 A/D cycles (954 in total) for Phy-CNT-PEI could reach equivalent lifetime CO2 remission with 1 kg MEA (11.76 kg CO2 remission/kg MEA). Moreover, the rate of cumulative CO2 remission for Phy-CNT-PEI is much higher than MEA, indicating the potential of being adapted for future industrial CO2 capture. Future development of CNT-PEI for CO2 capture should focus on lowering the impact caused by CNT and PEI syntheses in particular.

**40 Years of SETAC Science: Past, Present and Future - Part 2**

**192 A spotlight on environmental modeling**

D. Mackay, Trent University / Chemistry; J.A. Arnot, ARC Arnot Research & Consulting; D.M. Di Toro, University of Delaware / Civil and Environmental Engineering

In its broadest sense environmental modeling encompasses a wide range of efforts to understand and quantify the behavior, fate, exposures and effects of chemicals in ecosystems. It includes disparate activities including prediction of key chemical properties from molecular structure, estimation of partitioning properties between abiotic media and to biotic phases, especially lipids, inter-media transport processes, assessments of toxicity and assembly of multi-compartment mass balance models at scales ranging from planktonic biota to whales and humans and over a range of scales from indoors to urban, local contaminated sites to regions and to continental and global. A brief and incomplete historical and personal selection of major modeling milestones is presented, showing that SETAC has played a key role in these advances by bringing together players from governments, business and universities to share perceived needs and advancements for both scientific and chemical management purposes. Turning to the future, problematic and potentially fruitful future topics for modeling are outlined recognizing changing needs and capabilities in this information age. These include the perplexing issue of model validation to achieve greater regulatory acceptance (or reduce regulatory reluctance), treatment of mixtures and bioavailability, the advent of high throughput testing for toxicity and biotransformation, and especially the need to promote and support complementary and mutually supportive monitoring and modeling thus demonstrating the strengths and weaknesses of both. Finally, SETAC can play a critical role by promoting greater cooperation between modeling groups across sectors and internationally.

**193 Environmental measurements and modelling: Fruitful interactions over 40 years**

D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Environmental measurements are a key part of the conceptualization and validation of models for bioaccumulation and chemical fate. Usually the measurements have come first and models have followed to try to explain observations. The interaction between the two areas, often at SETAC conferences, has led to many advances in knowledge. An example is the debate that occurred in the 1980s over whether bioconcentration factor (BCF) estimated using log Kow, or in lab studies, was sufficient to predict concentrations of PCBs and other halogenated organic compounds (HOCs) in fish. Measurements showed elevated concentrations top predators like lake trout were under-predicted by BCF models using simple partitioning from water. However models that included predator-prey relationships, dietary uptake, and bioenergetic information, successfully explained the observed concentrations. Subsequently an explanation for biomagnification based on fundamental physical chemistry principles of diffusion from compartments of high fugacity (GI tract) to lipid pools of lower fugacity was advanced which supported the empirical based modelling. Trophic magnification factors (TMFs), in which food web biomagnification is estimated across trophic levels defined using stable nitrogen isotope ratios of individual organisms, represent the ultimate in field-based measurements. Here again TMF results often conflict with lab based BCFs due to biotransformation, omnivorous feeding, or non-steady state conditions due to local emissions. Measurement and modelling have also had a fruitful relationship in studies of global distribution and fate of HOCs. The discovery in the 1970s and -80s of HOCs in air and biota in the Arctic, an area viewed as being too remote to be subject to chemical contamination from human activities, led to concepts such as “global fractionation” and “cold condensation” which explained the presence of more volatile substances, e.g. less chlorinated PCBs relative to mid latitudes. Measurements of PFOS in arctic animals, and later in seawater, came as a surprise initially because PFOS was water soluble and non-volatile. But modelling were eventually able to explain the observations based on ocean transport, volatile precursors and biomagnification via protein binding. SETAC has an important role to play in bringing together environmental analytical chemists and modelers to broaden the range of chemicals for which there are measurements as well as environmental fate data.

**194 What’s Past is Prologue: Identifying Priority Research Questions for Aquatic Toxicology**

B.W. Brooks, Baylor University / Department of Environmental Science

Identifying strategic research needs represents important exercises for individual researchers and organizations in the academic, government, business and nongovernmental organization sectors. Pursuit of sustainable environmental quality by the “SETAC sciences” represents a noble goal, yet over the past 40 years research in aquatic toxicology has often been reactionary, necessarily and pragmatically responding to the next challenging class of contaminants or uncertainties associated with risk assessment and management. We partnered with SETAC World Council (and the American Chemical Society’s Environmental Chemistry and Agrochemicals Divisions in North America) to launch the Global Horizon Scanning Project, which aimed to identify geographically specific research needs to address stressor impacts on environmental quality. Priority research questions were solicited from SETAC members and other environmental professionals within the five SETAC geographical units (GU), then synthesized by expert teams of academic, industry and government representatives to form lists of the top research questions that, if answered, would substantially advance our understanding of how a range of environmental stressors (chemical, physical, biogeochemical) impact environmental quality in different geographic regions. We then held workshops for SETAC Africa (in Langebaan, South Africa), SETAC Europe (in Barcelona, Spain), SETAC Latin America (in Buenos Aires, Argentina), SETAC North America (in Salt Lake City, USA), and SETAC Asia-Pacific (one workshop focused on Oceania (in Nelson, New Zealand); another workshop in Singapore focused on other parts of Asia-Pacific). Each workshop was chaired by SETAC members representing academic, business and government sectors. Questions received were scientific in orientation, and covered diverse aspects of fields related to SETAC’s mission to advance sustainable environmental quality. This presentation provides synthesis of major research themes within and across SETAC GUs related to priority research questions in aquatic toxicology, with a particular focus on biologically active substances. Addressing
these questions will not be easy, but doing so promises to fuel innovation, support the workforce and decrease uncertainty when assessing and managing threats to water quality.

195 Aquatic Toxicology Has Evolved Via Environmental Toxicology & Chemistry; But Where Is It Going?
G.A. Burton, University of Michigan / School for Environment and Sustainability; H. Callow, Univ of Michigan / School for Environment and Sustainability; E. Nelson, University of Michigan / School of Natural Resources & the Environment; J. Lynch, SETAC

A few of us have been around since ET&C began, so have benefited from reading high quality science through our long careers. It has been interesting to follow the rise of different focus areas within SETAC and ET&C and how the science quickly improved as scientists benefited from other publications. Typically, the initial publications simply identify a possible concern, such as presence, persistence or bioaccumulation, focusing on the exposure side of risk assessments. As the science improves, the effects side of risk is determined, but initially at elevated concentrations to identify risk. The science matures when exposure and effects in the environment are linked accurately. Several examples will be provided of these trends over the past 40 years. Our science is now Excelling in the genomic area, just as in human toxicology and these tools will provide for more complete ecosystem impairment surveys, better assessments of biodiversity impairments and decrease the costs of assessments. Nevertheless, the lack of many reliable Adverse Outcome Pathways and the unknown linkages between biomarkers and population/community impairments will limit the use of genomic tools by regulatory agencies in the foreseeable future. SETAC and ET&C must seize the opportunity to better achieve our motto’s goal of “Environmental Quality Through Science” by providing environmental managers with useful tools that produce realistic assessments of which stressors matter most, even if they are not chemicals.

196 Evolution of Wildlife Toxicology Through SETAC
B.A. Rattner, US Geological Survey / Patuxent Wildlife Research Center

Wildlife toxicology is a component of ecotoxicology, and from a phylogenetic perspective it includes amphibians, reptiles, birds and mammals. Its focus is principally on assessing toxic chemical exposure and effects on reproduction, health and well-being of wildlife. This field encompasses a range of integrated activities (e.g., monitoring, hypothesis-driven research, forensics, assessment of exposure, effects and risk), biological scales (molecular through ecosystem), research venues (e.g., vivarium, mesocosm, field), and is multidisciplinary in nature. It has been shaped by chemical use and misuse, ecological mishaps, catastrophic poisoning, and research in the allied field of human toxicology. Initially wildlife toxicology had a strong emphasis on laboratory tests (LD50, LC50) in bobwhite (Colinus virginianus) and mallards (Anas platyrhynchos), and then evolved to include large-scale field studies as part of re-registration requirements of many pesticides. Between 1980 and 2000, the focus was on hazard and risk to wildlife of halogenated and organophosphorus pesticides, industrial contaminants, petroleum hydrocarbons and various metals, biomarker development and application, exposure routes, bioaccumulation and biomagnification, interspecific toxicity extrapolation, and food web studies. Prior to the establishment of SETAC, discussions of hypotheses and presentation of data were thinly spread among scientific societies (e.g., North American Wildlife Conference, Wildlife Disease Association, and various biomedical, ecological, ornithological, and zoological societies) and meetings of conservation groups and regulatory bodies. SETAC provided a recognized forum for discussion, presentation and publication of wildlife toxicology data, and fostered academic training programs in this area. Recently, a global SETAC Wildlife Toxicology Interest Group has been established to enhance communication of research findings and promote the use of non-destructive, sublethal, and scientifically sound methods, and when possible animal alternative models, in support of risk assessment, environmental management and policy processes.

197 Interacting Environmental Stressors Impact Wildlife-Human-Ecosystem Health: Considering One Health as a Conceptual Framework
M. Ottinger, University of Houston / Department of Biology and Biochemistry

Emerging contaminants, including those that are endocrine disrupting chemicals (EDCs) as well as legacy chemicals combine to expose wildlife and human populations to complex mixtures with the potential for short-term toxicity and long-term impaired physiological function. Chemical mixture exposure may also coincide with exposure to metals, thereby potentially exacerbating deleterious effects of chemicals, even those present as body burdens. Vulnerability to chemical exposure varies with species and life stage. Moreover, effects of EDCs may not correspond to risk as assessed by toxic equivalents. One Health provides a platform to conceptualize the close interactions and interdependence of human and ecosystem health. Stressors, both environmental and disease are critical factors in maintaining optimal One Health of both. Birds provide unique clades of organisms that reflect both regional and global health, particularly the migratory populations. The focus of this presentation will be considering response of birds, at individual and population levels to anthropogenic stressors, particularly exposure complex mixtures associated with industry and urbanization pressures as well as in the context of impacts of habitat loss and climate. Metrics of health will be considered as key indices for ascertaining the health of avian populations; these metrics will also be considered in the context of the contributions of SETAC members to policy/regulatory development. The availability of retrospective data from long-term datasets in avian populations will be discussed as an approach to ascertain changes over long time periods. These retrospective and ongoing data collection are critical for the development of predictive tools that provide reliable guidance for managers. The availability of other long-term datasets for avian populations from a global view will also be considered as a key component of global One Health.

198 Panel Discussion on Past Successes and Future Needs in Aquatic and Wildlife Toxicology
R.J. Kendall, Texas Tech University / Environmental Toxicology; E.J. Dorward-King, Newmont Mining Corporation / Sustainability and External Relations

A spotlight session at the 40th Annual Meeting of the Society of Environmental Toxicology and Chemistry (SETAC) represents an opportunity to reflect on our progress, consider the current state of the science, and look to the future in environmental toxicology and chemistry in the day-long session “40 Years of SETAC Science: Past, Present, and Future.” There will be two panel discussions during this session: one from the morning session and this one from the afternoon session reflecting speeches in environmental fate and modeling, aquatic toxicology, and terrestrial and wildlife toxicology. The six representative speakers and several invited guests will participate in the panel discussion to allow questions and interaction with the SETAC audience. The speakers will address development of the science of environmental fate and modeling, aquatic toxicology, and terrestrial and wildlife toxicology, particularly through SETAC over the past four decades, will evaluate and address the current state of the science and will give perspectives on future scientific needs that could be encouraged through SETAC. This is an excellent opportunity for coordinated discussions from the audience with key leaders in the field that represent long-standing contributions to the science of environmental toxicology and chemistry. We appreciate the opportunity to contribute to this spotlight session as SETAC’s 40th Annual Meeting in Toronto, Canada. We believe this session will be of historical significance since some of the participants in this panel will represent expertise in environmental toxicology and chemistry and in SETAC since its founding. We welcome SETAC members and guests to join us for this anticipated and very interesting panel discussion where they will have the opportunity to ask questions and interact with significant leaders in our field of science.
Aquatic Toxicity Testing of ‘Difficult-to-Test’ Substances - Meeting the Multi-Faceted Challenge

199 Design and Conduct of Aquatic Toxicity Tests with Difficult Test Mate
A. Samel, FMC Corporation / Environmental Sciences; A.J. Jones, FMC Agricultural Solutions / Environmental Sciences; T. Scown, FMC / Environmental Sciences; H.O. Krueger, Eurofins Agroscience / Science and Reg Affairs

Test material with certain physicochemical characteristics can affect exposure concentrations in aquatic systems and make it especially challenging to design and conduct regulatory aquatic toxicity tests. For core regulatory aquatic toxicity tests, exposure concentrations not maintained within a certain range or with precipitate present are often rejected by regulatory reviewers. Test material properties that can impact the maintenance of test concentration levels throughout the test include volatility, sorption potential, hydrolytic or photolytic instability, and very low solubility in dilution test media. Because of the requirement to maintain constant exposure levels to the test organisms, study design is critical from preparation of test solutions, to test solution delivery to test chambers, to analytical confirmation of test solutions. The stability of the test material will determine if the test design will be a static, static-renewal, or flow through test system and test material solubility will determine the highest test concentration for the test. If a solvent is needed, the solubility and stability data for the test material in the organic solvent is necessary. If the test material sorbs to surfaces, the test system will need to reach equilibrium before the test can be begin. Water samples for analytical confirmation may need to include organic solvent to mitigate any potential for the test material to adsorb to the sides of the analytical sample vials. Volatile test material will require specially designed test chambers to minimize head space where test material could partition. The purpose of the presentation is to discuss measures to consider when designing tests for difficult to test compounds.

200 Interpretation of algal growth rate data for aquatic classification and hazard assessment of rapidly degrading substances; ZPT as a case study
S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; K. Clark, Lonza AG / Product Safety and Toxicology

Algal growth rate inhibition at 72 hours, expressed as 72h ErC50s and ErC10s, is the preferred algal endpoint for aquatic classification according to the European CLP Regulation. OECD 201 Test Guideline is preferred to meet objectives of classification, labelling and hazard assessment. Neither the CLP regulation nor OECD 201 are well adapted to address rapidly degrading substances and taxonomic diversity in assessments. The use of 72h ErCx values based on mean measured concentrations of rapidly degrading substances can significantly overestimate toxicity. Characterizing acute toxicity of rapidly degrading substances with a 72h ErC50 can also be inconsistent with the definition and concept of acute toxicity in the CLP regulation, which is an effect during a short term exposure relative to lifecycle. The use of shorter study durations could be a solution for rapidly degrading substances, but the first validity criterion in OECD 201 relates to biomass increase and may not be fulfilled in less than 72h, particularly for slower growing taxa than those described in OECD 201. These points are illustrated by recent studies conducted with zinc pyrithione (ZPT) with the marine diatom, Skeletonema costatum. ZPT is photolytically unstable and rapidly degraded in algal toxicity studies due to required lighting conditions. Concentrations drop rapidly to < 50% of initial concentrations by 24h and continue declining to ~ 10% of initial by 72h. The 72h ErC50 based on mean measured concentrations is less than an initial concentration that caused no discernible growth rate inhibition at any time point. S. costatum growth in the controls was constant, consistent and exponential but did not reach 16x increase before 72h. According to the guideline, shorter study durations were not considered valid.

Similarly, OECD 201 does not allow for use of nominal concentrations in this case. The conclusion that the 72h ErC50 is the most relevant for classification in this situation, despite being lower than an initial concentration showing no effects, is neither reasonable nor consistent with the principle of acute aquatic toxicity. For rapidly degrading substances, a better approach to assessing acute and chronic algal inhibition (toxicity) is needed. Options could include use of nominal concentrations for toxicity estimates, use of recovery tests to assess algalicidal concentrations, shorter test durations and specific considerations of the taxa under evaluation.

201 Challenges with use of Water Accommodated Fractions and Alternative Methods for Ecotoxicity Testing of Difficult Substances
L. Sweet, Lubrizol; Z. Rong, Lubrizol Corporation; J. Liu, Nanjing Institute of Environmental Sciences, MEP; D. Jie, Yaxintechn

Ecotoxicity testing with algae, invertebrates, and/or fish on registered substances is required by many global chemical regulations. Although aquatic toxicity testing is relatively straightforward for mono-constituents, testing on multicomponent, poorly soluble, and UVCBs (Unknown, Variable composition, Complex reaction products or Biological material) substances can be very challenging from study performance and regulatory acceptance standpoints. The number of UVCBs requiring ecotoxicity testing is significant, with thousands of substances registered under EU REACH identified as UVCBs. The multi-dimensional complexity of UVCBs requires that aquatic toxicity tests be reliably designed to address their unique properties. Unlike the mono-constituent substance in which a clear dose-response relationship can be demonstrated, complex substances like UVCBs do not exhibit clear properties (e.g. toxicity, water solubility). For mono-constituents, the measured concentration is distinct and aquatic toxicity can be reliably identified based on the measured concentrations in exposure solutions. However, it is difficult to validate toxicity results with measured concentrations for UVCBs because the relative solubility in exposure solutions is impacted by the loading rate of each individual component, which may or may not be able to be measured. Moreover, the interaction of components in the UVCB can cause complex changes in their relative solubility. Water accommodated fraction (WAF) method is a technique developed for ecotoxicity testing of difficult substances like UVCBs and is recommended by OECD. The mass fraction in a series of WAF solutions is not in a linear relationship with the nominal loading rate. Hence, toxicity cannot reliably be attributed to a single measured component or a mixture of components but rather to the loaded UVCB as a whole. Here, we present an overview of challenges with WAFs from ecotoxicity testing on over 100 UVCBs. It was shown that regulators have different views about how much to load WAFs past the UVCB’s water solubility limit, e.g., 10 to 100 fold. We also show that use of filters to remove undissolved material can lead to studies being deemed unreliable. Further, studies can be deemed unreliable if nominal loading rates vs measured components are used to report study endpoints. We also provide an overview of the pros and cons of alternative methods to WAFs like passive dosing. Side by side comparisons of measured UVCB components in water are shown to differ depending on WAF, passive dosing, or saturated column study designs. The importance of understanding the technical and regulatory challenges of WAFs and alternative designs for testing UVCBs is highlighted.

202 Deriving bioconcentration factors of complex mixtures using in vivo benchmarked dietary exposure studies
R. Samson, Stockholm University, ACES; K. Knudmark Sjøholm, Technical University of Denmark (DTU) / DTU Environment; P. Mayer, Technical University of Denmark / Department of Environmental Engineering; C.L. Chen, South China Normal University / Environmental Research Institute; M. MacLeod, Stockholm University / Department of Environmental Science and Analytical Chemistry, ACES

The bioconcentration factor (BCF) is an established criterion for the (regulatory) assessment of chemicals. While BCF testing is standardised for single component chemicals, there is a lack of standard methods for
the assessment of complex mixtures. The main challenges for the BCF measurement of complex mixtures is the lack of available analytical standard as well as ensuring the reproducibility and general quality of the individual measurements. In previous work, we developed a robust method for the measurement of key components of two complex mixtures, cedarwood and pine oil, using a single dietary exposure experiment on rainbow trout with internal benchmarking. The use of dietary exposure with internal benchmarking allowed for measurements of hydrophobic substances in a mixture with correction for growth-dilution and differences in uptake. However, the challenge regarding the availability of standards to assess all relevant constituents of complex mixtures still needed to be addressed. In this study, we combined the internal benchmarking approach with a suspect screening method using SPME-headspace sampling and gas-chromatography (GC) coupled with high-resolution (Orbitrap) mass-spectrometry (MS): Following a single dietary exposure, the SPME-headspace method allowed for the analysis of samples without the need for extraction or clean-up. Using the high resolution and sensitivity of the Orbitrap-MS we were able to analyse the chemical activity and depuration rate constant of a variety of substances as a mixture. The method was validated using aliquots of fish exposed to cedarwood oil, which had previously been analysed for the BCF of the main constituents using conventional analysis with standards. The methods showed good agreement for the analysed main constituents. In addition to the cedarwood oil, we analysed the chemical activity and depuration rate constants of a certified reference diesel oil. Our novel method for the determination of depuration rate constants and estimation of BCFs of many chemical components of complex mixtures in a single test provides new information for assessing the bioaccumulation potential of complex mixtures, as well as an opportunity to reduce the need for test animals in regular BCF tests.

203 Passive dosing and aquatic toxicity testing of complex organic mixtures - Linking toxicity to concentrations in the silicone and lipid donors

L.N. Trac, Technical University of Denmark / Environmental Engineering; K. Knudsmark Sjøholm, Technical University of Denmark (DTU) / DTU Environment; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

Environmental hazard and risk assessment of complex organic mixtures can be complicated, because the individual constituents in the mixture have various physicochemical properties and toxicity. One important experimental challenge is to establish and maintain well-defined exposure concentrations to such mixtures in an aquatic toxicity test. The present study aims to (1) enable aquatic toxicity testing of complex mixtures at defined and controlled exposure and (2) provide approaches to assess whether the test mixtures exhibit baseline or excess toxicity based on their concentrations in the silicone or lipid donor. Two passive dosing (PD) methods were applied to dose-response testing of complex mixtures with the fresh water crustacean Daphnia magna. The first method used a polydimethylsiloxane (PDMS) silicone rod as donor (i.e. silicone PD), which was placed in the aqueous solution and headspace, whereas the second method used a lipid donor (Miglyol oil) for the passive dosing only via the headspace (i.e., headspace PD, HS-PD). The test mixtures were several petroleum products and essential oils. These mixtures were loaded to PDMS rods and Miglyol oil by weighing to desired mass concentrations (% in these donors. The exposures to test mixture at the saturation level in the two PD systems were analytically confirmed against the pure test mixtures using headspace GC-MS and it was also shown that these two PD methods cross validated each other. The EC50 values for the petroleum mixtures and essential oils in the D. magna acute immobilization tests ranged between 5-6 % and 0.6-3.2 % mass concentration, respectively, on the silicone base. The EC50 values for all tested mixtures on the lipid base ranged between 85-390 g mixture per kg lipid, which corresponds to 425-1590 mmol kg⁻¹ lipid when assuming an average molecular mass of 200 g mol⁻¹ for the tested mixtures. These lipid based EC50 values were well above the reported concentration range of 40-160 mmol kg⁻¹ lipid, which thus indicates baseline rather than excess toxicity. The present study provided an improved experimental basis for aquatic toxicity testing and assessment of complex organic mixtures.

204 UVCB risk assessment framework: Substance identity and characterization considerations

S.E. Deglin, ILSI Health and Environmental Sciences Institute (HESI); M.R. Embry, Health and Environmental Sciences Institute (HESI); J. Arey, ExxonMobil Biomedical Sciences, Inc; M. Fernandez, Environment and Climate Change Canada / Ecological Assessment Division; R. Hoke, DuPont / Electronics & Imaging; J. de Knecht, RIVM / Environment Health and Safety Division; D. Lyon, Shell Oil Company / Shell Health Risk Science Team; K. Jenner, Givaudan / Global Regulatory Affairs & Product Safety; M. Lampi, ExxonMobil Biomedical Sciences, Inc. / Toxicology & Environmental Sciences; E. Leinala, OECD; M. MacLeod, Stockholm University / Department of Environmental Science and Analytical Chemistry; P. Mayer, Technical University of Denmark / Department of Environmental Engineering; D. Salvito, Research Institute for Fragrance Materials RIFM

Assessing the risks associated with substances of Unknown or Variable Composition, Complex Reaction Products, and Biological Materials (UVCBs) presents numerous challenges. International regulatory programs have highlighted the complexities of UVCB fate and exposure characterization, risk assessment, and registration. As such, this work aimed to develop approaches for assessing the ecological risks of UVCBs to meet regulatory needs. As an initial step, a framework was developed for grouping UVCB substances according to chemical and/or functional classes, exposure and use patterns, production volume, potential toxicity and other criteria. This ongoing effort will provide a better understanding of the nature of these substances and their sector of use, as well as insight into which UVCB classes may present the most significant challenges for testing and assessment. Additionally, a tiered approach to substance identification and characterization was developed to provide guidance on the minimum amount of information needed for a confident, risk-based assessment. The first step of this approach (Tier 0) relies on basic and readily available information. For example, Tier 0 substance identity and characterization information includes substance specifications, QA data, and basic chromatographic and/or elemental analyses. Tier 0 exposure and hazard information were also considered in the development of the Tier 0 substance identification and characterization information to ensure it would work towards an overall risk assessment framework. This work presents an initial effort to determine the minimum level of substance identity information required to perform a robust and fit-for-purpose ecological risk assessment for UVCB substances, along with criteria that could be used in a weight of evidence approach for substance identification and characterization, and exposure assessment. Examples are presented of UVCB mapping and classification as well as application of the tiered approach for substance characterization for risk assessment purposes. The results are anticipated to help streamline the data gathering and testing requirements for the risk assessment. [The views of the authors of this presentation are those of the authors and do not represent the views of their respective organizations]
Epigenetics and Environmental Exposures: Mechanisms and Effects from Invertebrates to Fishes

207 Pharmaceutical and climate change stressors alter microRNA and protein abundance in zebrafish (Danio rerio)
H. Ikert, B.A. Katzenback, P.M. Craig, University of Waterloo / Department of Biology

As the human population continues to grow, increased anthropogenic stress is placed on the aquatic environment. A greater understanding of the possible effects that this increase in anthropogenic stressors is having on aquatic organisms is needed. Pharmaceuticals such as venlafaxine (VFX), a heavily prescribed and readily detectable antidepressant, are found downstream of wastewater treatment plants. As a result of climate change, increased surface water temperatures and decreased dissolved oxygen levels have been observed. The result of combining these stressors is unknown. In this study, a multi-stressor approach was used to determine the cumulative, sublethal effects of VFX, temperature and oxygen levels on microRNA (miRNA) and proteins in adult zebrafish (Danio rerio). miRNA are small, conserved, non-coding RNA which act by decreasing mRNA translation, effectively decreasing protein abundance. Therefore, these miRNA changes impact the functional responses of downstream targets and are a method of environmental and epigenetic regulation of phenotypic responses. We can predict which miRNA will change, use these as biomarkers, and validate functional changes by quantifying protein abundances. Adult zebrafish were exposed to control (27°C, 100% O2, 0 μg/L VFX) or stressed (32°C, 50% O2, 1.0 μg/L VFX) conditions for 24 hours (acute) or 21 days (chronic). RNA was extracted from liver, gonad, and muscle tissue and RT-qPCR (reverse transcription - quantitative polymerase chain reaction) was performed on specific miRNA predicted in silico to respond to the exposure. The livers were also used for protein quantification using iTRAQ (isobaric tags for relative and absolute quantification). This allows for identification and differential abundance analysis of all protein levels in the liver. Comparison between stressed and non-stressed fish demonstrated altered miRNA abundance. Interestingly, miRNA changes were different between sex, tissue, and length of exposure. The changes in miRNA will be compared to changes in protein abundance in order understand the functional impacts of altered miRNA. This functional linkage of miRNA response to target protein abundance is crucial in understanding how epigenetic responses to environmental disruption affect fish health and fitness, and will allow us to use miRNA as biomarkers of stress exposure.

208 Individual variation in sensitivity to AHR ligands in birds; does epigenetics play a role?
J. Head, McGill University / Natural Resource Sciences; C. Goncalves Athanasio, Ontario Tech University / Biosciences; K. Mittal, E. Boulanger, McGill University / Natural Resource Sciences

Lipophilic environmental contaminants such as dioxin-like compounds (DLCs) and polycyclic aromatic hydrocarbons (PAHs) can be found in high concentrations in the eggs of wild birds. We are interested in how this early-life exposure to contaminants relates to individual differences in sensitivity to re-exposure later in life, and whether epigenetic mechanisms are involved. In the current study, the DLC, tetrachlorodibenzo-p-dioxin (TCDD), or the PAH, benzo[k]fluoranthene (BkF) was injected into fertilized chicken eggs prior to incubation. At embryonic day 19, livers were harvested and slices of the tissue were grown in culture. Liver slices were then re-exposed to graded concentrations of each of the test chemicals. Both BkF and TCDD were associated with dose-dependent induction of several genes associated with the aryl hydrocarbon receptor (AHR) response pathway including cyp1a4, cyp1a5, and ahr (but not ahr or ahrn). A large degree of variability was observed in the responsiveness of liver slices cultured from different individuals, with a larger proportion of highly responsive individuals present in the BkF pre-treated group. This sensitivity to induction was associated with small but significant...
increases in methylation of the cypla4/5 shared promoter. Ongoing work is examining the role of histone acetylation in the response to re-exposure to AHR ligands at this locus. We are also investigating whether embryo mortality associated with a low degree of cypla inducibility, is responsible for the effects we have observed. Understanding the molecular basis for individual variability in sensitivity to DLCs is important for improving risk assessment for these ubiquitous environmental chemicals.

209 Dynamics of environmentally induced DNA methylation signatures in germ cells

X. Wang, R. Bhandari, University of North Carolina, Greensboro / Biology

Exposure to environmental chemicals can have far reaching health effects especially when it occurs during the sensitive windows of embryonic development. In our previous study, A 7-day embryonic BPA exposure resulted in transgenerational male sub-fertility in medaka. To further understand the mechanisms associated with transgenerational inheritance of impaired male fertility, we surveyed bisphenol A-induced epimutations in PGCs, soma, and sperm at crucial time points of life history stages across three generations. Here, we show that medaka PGC reprogramming undergoes a global erasure of methylation marks from the 8 day post-fertilization (dpf) stage until 15 dpf stage, and de novo methylation starts at 25 dpf stage and ends at the time of gametogenesis (50 dpf), during which several additional new methylation marks are also established. Low concentration BPA caused hypomethylation of germ cell genome globally. BPA-specific epimutations escaped epigenetic reprogramming in PGCs and that additional epimutations were specifically established in PGCs de novo in response to embryonic BPA exposure. Only a fraction of the BPA-specific epimutations that escaped reprogramming or that were established during gametogenesis were subsequently inherited by sperm. A subset of BPA exposure-specific epimutations were transmitted to somatic cells during blastula stages in subsequent generations. In summary, we found that the BPA-induced epimutations can survive reprogramming; germ cells establish unique BPA-specific epimutations during gametogenesis and sperm formation de novo; and a germline-to-soma transfer of epimutations occurs during early embryogenesis of subsequent generation causing alterations in expression pattern of the target genes in somatic tissues.

210 Early life exposure to endocrine disruptors causes multigenerational and transgenerational epigenetic changes in a fish model

K. Major, B. DeCourtney, Y. Rericha, Oregon State University / Environmental and Molecular Toxicology; J.P. Forbes, University of North Carolina Wilmington / Department of Biology and Marine Biology; A.C. Mehinto, Southern California Coastal Water Research Project / Toxicology; W. White, Oregon State University / Fisheries and Wildlife; M. Britton, J. Li, University of California Davis; M. Settles, University of California Davis / Genome Center; R.E. Connan, University of California, Davis / Anatomy, Physiology & Cell Biology, School of Veterinary Medicine; S.M. Brander, Oregon State University / Environmental and Molecular Toxicology

The inland silverside, Menidia beryllina, is a euryhaline fish native to the Eastern United States and a model organism in ecotoxicology. We previously showed that low-level exposure to endocrine disrupting chemicals (EDCs) can cause a variety of effects in M. beryllina, from changes in gene expression to phenotypic deformities. In the present study, we explore the potential for early life exposure to EDCs to cause epigenetic changes in inland silversides, with a particular focus on transgenerational effects. EDCs included contaminants of emerging concern (the pyrethroid insecticide bifenthrin and the synthetic progestin levonorgestrel), as well as an estrogen (ethinylestradiol), and an androgen (trenbolone) at exposure levels between 3 and 9 ng/L. In a multigenerational experiment, we exposed parental silversides to EDCs from fertilization until 21 days post hatch (dpf). We assessed DNA methylation patterns for three generations (P0, F1, and F2) in whole body larval fish using reduced representation bisulfite sequencing (RRBS). We found significant (p < 0.05) differences in promoter and/or gene body methylation in treatment fish relative to controls for all EDCs. Using gene ontology enrichment and pathway analyses, we found that differentially methylated genes in EDC treatments included hormone receptors, genes involved in steroidogenesis, prostaglandin synthesis, sexual development, DNA methylation, protein metabolism and synthesis, cell signaling, and neurodevelopment. Differential gene methylation relative to control was often present in the F1 generation, exposed as primordial germ cells within larval parents, and sometimes noted into the F2 generation, which was unexposed to EDCs. These findings show that EDCs can cause altered methylation in genes that are functionally relevant to impaired phenotypes documented in EDC-exposed animals, and that EDC exposure has the potential to have effects on subsequent generations of unexposed fish.

211 Reprogrammed: Venlafaxine disrupts early neural development and behaviour in larval zebrafish across multiple generations

W.A. Thompson, University of Calgary / Biology; M.M. Vijayan, University of Calgary / Biological Sciences

The antidepressant venlafaxine is a serotonin and norepinephrine reuptake inhibitor (SNRI) commonly prescribed to treat depression. As a result, this drug is routinely detected in the municipal wastewater effluent outfalls in our waterways in parts per billion concentrations. Recently we showed that venlafaxine deposition in the embryos alters neurogenesis and early life stage behaviour in zebrafish (Danio rerio) larvae. However, it is not known whether venlafaxine impact is associated with changes in developmental programming events. In this study, we tested the hypothesis that venlafaxine deposition in embryos affects developmental programming, leading to impacts on brain development and behaviour in zebrafish that are evident in multiple generations. Zebrafish embryos were microinjected with either vehicle, 1, or 10 ng venlafaxine immediately after fertilization. Zebrafish larval behaviour, neurogenesis, and serotonin distribution was assessed in the F0 (exposure), F1, and F2 generations. In the F0 generation, venlafaxine treatment led to a dose-dependent reduction in larval activity, which was also evident in the F2, but not the F1 generation. Both venlafaxine doses disrupted neurogenesis at 24 hours post-fertilization (HPF) in the diencephalon of treated fish (F0 generation). This effect on neurogenesis was also evident in the F2 progeny but only in the 10ng venlafaxine treated fish. Venlafaxine exposure reduced serotonin in specific brain regions at 48 and 120 HPF in the F0 generation, and a similar decrease was also seen in the F1 and F2 generation at 48 HPF. We also assessed the methylome of exposed adult gonads in the F0 generation, to determine potential epigenetic markers in response to venlafaxine exposure. Venlafaxine appears to alter the methylson of genes associated with cell proliferation, vesicular transport, and cell adhesion. Taken together, these results suggest that venlafaxine exposure at early critical life stages can shift developmental programming, leading to changes in brain development and behaviour that persists across multiple generations of zebrafish.

212 Changes in Transgenerational Plasticity in Daphnia magna Under Thermal Stress Across Ten Generations

H. IM, J. Jung, Korea University / Environmental Science and Ecological Engineering

Effect of temperature on zooplanktons such as Daphnia magna is concerned due to thermal effluents and global warming. The purpose of this study was to evaluate the effect of elevated temperature (25°C) on oxidative stress responses, growth, reproduction and cellular energy allocation of D. magna across ten generations compared to optimum temperature (20°C). We found that F3 generation acts as a turning point with the lowest number of offspring, the highest adult somatic growth rate and the highest oxidative stress responses at elevated temperature. D. magna responded with rapidly changing phenotypic plasticity from F0 to F3 generation, but showed no more phenotypic change between F6 and F9 generation. This result suggests that D. magna has entered a new phase of equilibrium state where no more plasticity occurs after an acclimation phase for prolonged high temperature exposure.
Long-term exposure to environmental contaminants can cause genetic adaptations in populations of aquatic organisms. Evolutionary toxicology and resurrection ecology offer powerful tools for the investigation of changes in sensitivities and adaptive trajectories of populations exposed to contaminants and environmental stressors over decades to centuries. Dormant resting eggs produced by Daphnia species as a result of unfavourable environmental conditions are archived in sediments and can be dated and hatched to produce clonal lineages (i.e., same genotypes) of historical populations. However, these tools have not previously been used to examine impacts from environmental contaminants, particularly in combination with the changes in temperature that are expected to occur with future climate change scenarios. Our research examines how genotypes of clonal lineages of Daphnia species from single populations, separated through generations of evolution, differ in their response to exposure of environmental stressors. Specifically, 20 resurrected D. magna lineages collected from the field (Lake Ring, Denmark), spanning approx. 100 years and previously sequenced, were exposed in 48-h immobilization tests (OECD 202) to phenanthrene (Phe), a common polycyclic aromatic hydrocarbon (PAH) ubiquitous in aquatic environments. The EC50s observed among the clonal lineages ranged from 6 to >30 μM, indicating a wide response in sensitivity of the daphnia. Follow-up studies with 21-d daphnia tests (OECD 211) will further investigate the effects of aqueous Phe exposure in combination with changes in temperature on the sensitivity and fitness, as well as genomic analysis of the clonal lineages of D. magna. The genomic analysis, including metabolomic profiling and transcriptomics, of tolerant and non-tolerant daphnia populations will aid in elucidating the micro-evolutionary adaptations of genes in response to changing environments, providing further insight into the mechanisms of stress tolerance and adaptation. Overall, the toxicological and genomic data obtained from exposure of daphnia populations to environmental stressors will provide unprecedented opportunities to gain insight into long-term and potentially future evolutionary responses of a keystone sp., providing feedback for risk assessment and future management of lake systems (e.g., collapse of grazers/impacts on upper trophic levels).

214 Transgenerational fitness of ocean acidification in marine rotifer: Genetic toxicology and epigenetic approach
Y. Lee, H. Kang, C. Jeong, J. Lee, Sungkyunkwan University

Ocean acidification (OA) is caused by alteration of global ocean chemistry due to increased pCO2 in the atmosphere and is predicted to cause deleterious impacts on the marine ecosystem. While the potential impact of OA for most of marine species are known to be sensitive, its transgenerational effects remained largely unknown. In this study, we show the capability of the marine rotifer Brachionus koreanus to adapt to low pH conditions (pH 7.7 and 7.3). In B. koreanus, growth rate, fecundity, and life span were retarded with induction of DNA damages in response to low pH seawater, whereas their offspring had exhibited the alleviating effects along with the increased parental exposure period, showing positive carryover effects to cope with low pH stresses. In consistent, DNA damage was fully repaired in the offspring from 7 days of OA-experienced adults, indicating that DNA repair system would be a possible adaptive mechanism. To gain a better understanding on DNA repair system in B. koreanus, we measured DNA repair activity at the transcriptional level and found significantly increased level of genes related to DNA repair in offspring. This transcriptional modulation was regulated by histone modification, as the enhanced histone acetylation was observed by ChIP-qPCR that is targeting for those of DNA repair genes. Here we show positive carryover effects of OA on DNA repair system in B. koreanus that were enhanced by histone acetylation. This study provides valuable insights into the potential impact of ocean acidification and survival strategy of aquatic invertebrates as shown in rotifer.

Unraveling Complexity: Characterizing the Toxicity and Risk of Chemical Mixtures in the Environment

215 Combining chemical and ecotoxicological monitoring of emerging polar micropollutants: Towards an integrated environmental risk assessment approach
S. Meers, Ghent University / Laboratory for Environmental Toxicology and Aquatic Ecology; F. Vanryckegehm, Ghent University / Department of Green Chemistry and Technology - Research Group Environmental Organic Chemistry and Technology; S. Huysman, L. Vanhaecke, Ghent University / Department of Veterinary Public Health and Food Safety - Laboratory of Chemical Analysis; K. Demeestere, Ghent University / Department of Green Chemistry and Technology - Research Group Environmental Organic Chemistry and Technology; C.R. Janssen, Ghent University / Department of Animal Sciences and Aquatic Ecology - Laboratory of Environmental Toxicology and Aquatic Ecology; K. De Schamphelaere, Ghent University (UGent) / Environmental Toxicology

The ever-increasing production and consumption of chemicals worldwide is associated with their increasing release into the aquatic environment and ultimately into marine waters. The need for characterizing the real impact of complex mixtures to aquatic organisms is recently receiving increased attention. This requires the development of alternative methods for the assessment of the toxicity of environmentally realistic contaminant mixtures (ERCMs). The generally low contaminant concentrations in marine waters are not only a challenge for analytical methods but also require adaptations for the effect assessments. In this research, we combined chemical and ecotoxicological monitoring of the Belgian part of the North Sea (BPNS) by using passive sampler extracts. We developed and applied a novel margin of safety (MoS) approach for marine waters combining passive sampling, high-resolution mass spectrometric analyzes of a broad range of emerging micropolllutants and ecotoxicity testing with the marine micro-algae Phaeodactylum tricornutum. This MoS approach is based on testing of concentration series of up-concentrated passive sampler extracts. MoS are ultimately defined as the factor of concentration increase of ERCMs resulting in no-observed effects (the highest test concentration with no statistically significant effects). Chemical analyses of a total of 179 substances revealed the presence of a variety of personal care products (highest measured concentration of 13 ng/L for piperonyl-butoxide), pesticides (65 ng/L for thiacloprid), pharmaceuticals (156 ng/L for sotalol), steroids (39 ng/L for prednisone) and phthalates (2,500 ng/L for monomethyl phthalate) in Belgian marine waters. The use of passive samplers allowed us to combine chemical analysis and ecotoxicity testing of contaminant mixtures at realistic concentration levels but also in up-concentrated samples. This further enabled the determination of MoS for ERCMs of approximately 6 - 10 times the current seawater levels for the representative marine diatom P. tricornutum in the BPNS. Overall, our research provides a novel approach for a combined chemical-analytical and ecotoxicological based MoS approach as tool for (predictive) risk assessment and management in marine waters. This presentation will summarize the final results of the NewSTHEPS project (for further information, see www.newstheps.be).

216 Risk assessment for pesticide mixtures on aquatic ecosystems in China: a proposed framework
S. Li, Syngenta / Crop Protection; L. Chen, State Key Laboratory for Biology of Plant Disease and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences; Y. Zhou, X. Zhou, H. Jiang, Institute for the Control of Agrochemicals, Ministry of Agriculture and Rural Affairs; X. Liu, State Key Laboratory for Biology of Plant Disease and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences; S. Yuan, Institute for the Control of Agrochemicals, Ministry of Agriculture and Rural Affairs

With an increasing number of registered mixture formulations in China, environmental risk assessment of pesticide mixtures to aquatic ecosystems is of increasing interest to local scientists, risk assessors, and risk
A pragmatic approach has been proposed based on widely accepted scientific concepts and strategies. The proposed approach has three tiers, tier 0 (preliminary stage), tier 1, and tier 2 (refinement stage). Because of the large number of pesticide mixtures available in China, a unique tier 0 stage is proposed with practical criteria to identify mixtures requiring further evaluation. For Tier 1 assessment, exposure is assessed based on specific application schemes and local scenarios in China; hazard is evaluated using the concentration addition model as the default approach. Given the unique characteristics of environmental mixtures, data variability and ratio changes of active ingredients are also evaluated for hazard assessment. More accurate assessments with decreased uncertainties can be achieved by refinements in Tier 2, such as alternative models, consideration of co-formulants, and higher-tier effect and exposure analyses. The proposed risk assessment approach will be demonstrated using a case study.

217 Interactive effects of cadmium and benzo[a]pyrene in zebrafish (Danio rerio) during acute aqueous exposure

V. Kodzhabakhchev, S. Niyogi, University of Saskatchewan / Biology; L.P. Weber, University of Saskatchewan / Veterinary Biomedical Sciences

Anthropogenic activities have resulted in the contamination of cadmium (Cd), a highly toxic trace metal, in many aquatic ecosystems around the world. Similarly, anthropogenic activities have also led to the release of a multitude of organic pollutants including polyaromatic hydrocarbons (PAHs) into the aquatic ecosystems. Benzo[a]pyrene (BaP) is of particular concern among PAHs because of its ubiquitous nature. While guidelines have been established to regulate these pollutants in the environment (e.g., Canadian water quality guidelines restrict concentrations to 1 µg/L and 0.015 µg/L for Cd and BaP, respectively), such guidelines have primarily been established using single-toxicant exposure data. Thus, there is a crucial gap in our knowledge regarding how these toxicants interact and alter the toxicological effects in aquatic organisms. The present study examined the effects of acute (72-hr) aqueous exposures of Cd (5.8 and 22 µg/L) and BaP (0.45 and 1 µg/L), both individually and in binary mixtures, in adult zebrafish. Our results demonstrated that tissue accumulation of Cd increased significantly in the presence of BaP relative to Cd-only exposures. Cd tissue burden was found to be 18.5 ng/g tissue in fish exposed to only 5.8 µg/L, whereas Cd tissue burden was recorded to be 104.5 ng/g and 46.9 ng/g in fish exposed to 0.45 or 1 µg/L of BaP in combination with 5.8 µg/L Cd, respectively. Additionally, while single-toxicant exposures caused a strong induction of metallothionein-2 (MT) and cytochrome p450Ia (CYP1a) mRNA in the gills, co-exposures generally resulted in the downregulation of these genes. For example, 0.45 µg/L BaP caused an approximately 10-fold increase in CYP1a transcript levels relative to the control; however co-exposure to 5.8 or 22 µg/L Cd and 0.45 µg/L of BaP caused a 2- and 0.5-fold decrease in CYP1a gene expression, respectively, relative to the control. Moreover, lipid peroxidation (LPO) was measured in the gill and liver as a marker of oxidative damage induced by Cd and/or BaP. While individual exposures to both toxicants increased LPO relative to the control, no significant increase in the LPO level was observed in any of the Cd and BaP co-exposures. Overall, our findings indicated that although the interaction of Cd and BaP resulted in increased Cd body burden and downregulation of detoxifying genes (MT and CYP 1a), it did not translate into additive or more-than-additive toxic effects (oxidative damage) in zebrafish.

218 Tackling The Toxicity Of Metal Mixtures To Daphnia Magna: A Biotic Ligand Model Approach

T. Boloori, Huntsman Marine Science Centre / Aquatic Toxicology; Y. Iwasaki, National Institute of Advanced Industrial Science and Technology AIST Japan / Research Institute of Science for Safety and Sustainability; D. Evans, Trent University / Trent School of the Environment

Metal mixture toxicity has drawn world-wide attention by both scientists and policy makers due to an increasing recognition of the occurrence of mixtures of metals in surface waters. The present study was undertaken to determine the acute toxicity of binary mixtures of nickel, copper, zinc, and cadmium to the freshwater invertebrate, *Daphnia magna*, to increase understanding of the impacts of metal mixtures. The experimental approach included single and binary metal toxicity tests based on the 48h acute toxicity bioassay protocol of Environment Canada. The acute toxicity of single metals followed the order of Cd > Cu > Zn > Ni. Based on the calculated 48h EC50 value of single metals, a toxic unit (TU) approach was used to combine two metals in a binary mixture, in which ITU was equal to the 48h EC50 value of a metal in single exposure. The toxicity of binary metal mixtures to *D. magna* followed the order of Cu-Cd > Cu-Zn > Zn-Cd > Cu-Ni > Zn-Ni > Cd-Ni, which demonstrated three types of interactions (i.e., less than additive, additive, and greater than additive). For comparison, the toxicity of binary metal mixtures was predicted using a biotic ligand model (BLM) based on the free ion concentrations of metals, the affinity constant of metals, and the toxic potency of each metal. In this model, it was hypothesized that the toxicity of metal mixtures is the result of competition of metals with Ca2+ at the biotic ligands, which can lead to whole-body deficiency of Ca2+ in *D. magna*. The BLM model calculated the toxic potency of single metals with the following order of Cu > Cd > Zn > Ni. Although the mortality in binary metal mixtures tests was often overestimated using the BLM model in this study, the BLM or a revised version could be promising in conservative environmental risk assessment.

219 Alterations to Juvenile Mahi mahi Swimming Performance and Respirometry Following Acute Exposures to Flowback and Produced Water

E. Folkerts, University of Alberta / Biological Sciences; R.M. Heuer, M. Grosell, University of Miami / Marine Biology and Ecology; G. Goss, University of Alberta / Biological Sciences

Worldwide, horizontal hydraulic fracturing is an emerging industrial practice used to extract oil and natural gas reserves from nominally permeable geological formations. Despite its increasingly prevalent use, toxicological investigation on the wastewater by-product of these processes, flowback and produced water (FPW), is relatively understudied. Recent chemical characterization of this heterogeneous mixture has revealed the existence of numerous potential cardio-respiratory toxicants. The aim of this study was to determine if acute FPW exposures alter swimming performance and respirometry in juvenile Mahi mahi (*Coryphaena hippurus*); an aerobic fish with an extreme pelagic lifestyle. Previous work on isolated Mahi cardiomyocytes identified certain contractile properties to be affected following exposure to low concentrations of FPW. We theorize that these FPW induced deleterious cardiac effects observed at the cellular level may contribute to changes at the whole organism level, i.e. fish swimming performance and respirometry. After acute 24 hr exposures to sub-lethal concentrations of FPW, significant impacts to juvenile Mahi critical swim speed (*Ucrit*) were observed. These findings were accompanied by significant reductions in aerobic scope. To eliminate salinity as a contributing factor, a saline control exposure was employed. No changes to swimming performance and respirometry were observed in saline matched controls. We conclude that contaminant stressors besides major salt ions (such as organics and/or metals) are responsible for the observed effects. Mahi tissue analyses corroborate these whole organism findings and support the notion that acute FPW exposures negatively impact cardio-respiratory systems of Mahi. This is one of the first studies associating deleterious effects at the cellular level with changes to whole organism physiology and performance following FPW exposure. Our results validate the cardio-respiratory system as an important endpoint to consider for FPW risk assessment and adverse outcome pathway analysis.
220 Determination of Mixture Neurotoxicity Using the Hyper- and Hypoactivity Behavior of Zebrafish Embryo in the Spontaneous Tail Coiling Test

A.O. Ogungbemi, Helmholtz Centre for Environmental Research - UFZ / Bioanalytical Ecotoxicology; R. Massei, Helmholtz Centre for Environmental Research UFZ / Dept. of Effect-Directed Analysis; R. Allenburger, UCF Centre for Environmental Research / Bioanalytical Ecotoxicology; S. Scholz, E. Kuster, Helmholtz Centre for Environmental Research (UFZ) / Department of Bioanalytical Ecotoxicology

Recently, there has been an increase in the number of people suffering from neurological diseases and incidents of nervous system-related diseases are increasingly associated with exposure to pesticides and pharmaceuticals. These chemicals interfere with the functioning of the nervous system and very little disruptions can lead to long term neurological diseases such as Parkinson and autism. Generally, chemicals occur in the environment as mixtures and it is therefore more realistic to assess the toxicity of chemical mixtures rather than single chemicals. To detect mixture neurotoxicity, it is important to be able to differentiate neuroactive mode of action for single chemicals within a mixture of other chemicals. Even more important is to investigate the additive, synergistic and antagonistic effects of neuroactive chemical mixtures within a pool of other substances. Zebrafish embryo is a suitable tool to test mixture effects. While only few studies have studied behavioral effects of mixtures, most studies on zebrafish embryo were based on lethal and sublethal endpoints. Since behavioral endpoints might be more sensitive to detect neuroactive substances and also more relevant for ecological effects, then it is probably more reasonable to encourage the use of behavioral tests for screening neuroactive chemical mixtures. In this study, we employed the use of the spontaneous tail coiling (STC) of the zebrafish embryo to detect the effect of both single and mixed neuroactive substances. We addressed the questions: 1) Can the STC test predict the mode of action of neuroactive substances i.e. acetylcholinesterase inhibition by chlorpyrifos or activation of Gamma aminobutyric acid receptor by abamectin. 2) What is the resulting effect of a mixture of neuroactive substances with similar and dissimilar mode of action? First results showed that chlorpyrifos and abamectin caused hyperactivity (EC50 = 2.57μM) and hypoactivity (EC50 = 0.54μM) of the STC respectively and this was assumed to be indicative of their mode of action in zebrafish embryo. The results for similar and dissimilar mixtures with varying mixture approaches predicted by concentration addition and independent action models will be discussed.

221 Comparison of Fine Particulate Matter from Biomass and Non-biomass Burning Households

C. Roper, Oregon State University / Department of Environmental and Molecular Toxicology; L.S. Frine, Oregon State University / Chemistry / Environmental and Molecular Toxicology; D. Barrett, Oregon State University / Department of Environmental and Molecular Toxicology; P. Hystad, Oregon State University; S. Simonich, Oregon State University / Depts of Chemistry and Environmental Molecular Toxicology; R.L. Tanguay, Oregon State University / Sinnhuber Aquatic Research Laboratory and the Environmental Molecular Toxicology

Household air pollution is a global public health disparity issue with nearly 3 billion people using highly polluting fuels in their homes for cooking and heating. A disproportionate amount of those exposed are women and children of low socioeconomic status. Fine particulate matter (PM2.5) is a component of household air pollution with well-established health effects and is significantly elevated in households burning biomass fuel compared to non-biomass burning households. There is a lack of exposure-response data to determine the health impacts of different fuel sources and outside of concentration, little is understood about these complex exposures. We performed a robust characterization of PM2.5 from biomass and non-biomass burning households through concentration, composition, oxidative potential, and bioactivity assessments. As part of the Prospective Urban and Rural Epidemiological (PURE-Air) study, PM2.5 was collected with a stationary monitor in the kitchen and personal monitors on female and male participants in 24 households. Filters were stratified into groups based on fuel source, monitor type, and participant sex. Chemical analysis via quantification of polycyclic aromatic hydrocarbons (n=115) and elements (n=75) was conducted. Assessment of oxidative potential was performed for the stratified groups as well as for individual filters. Bioactivity was determined using a range of concentrations in the developmental zebrafish assay (n=32/treatment) with mortality and morphological/behavioral changes being assessed at 24 and 120 hours post fertilization. Significant differences in chemical concentrations were observed between PM2.5 from kitchen monitors in biomass and non-biomass burning households. Bioactivity was observed in zebrafish with an earlier incidence of significant mortality and morphological effects following exposure to PM2.5 from biomass burning compared to the non-biomass households. Data analysis is underway for zebrafish behavior, oxidative potential, and personal monitors worn by male and female participants in the households. Associations between concentration, composition, oxidative potential, and bioactivity will be made and we hypothesize to find suites of constituents associated with multiple endpoints. This research provides robust characterization of that will be applicable to epidemiology studies to identify additional characteristics of for health effects associations.

222 Combing chemical analysis and quantitative toxicogenomics approach to assess the impact of Hurricane Maria on drinking water quality in Puerto Rico

Y. Lin, Cornell University / Civil and Environmental Engineering; T. Jiang, Northeastern University / Department of Civil and Environmental Engineering; M.S. Rivera, I. Cotto, Northeastern University; C. Carpenter, Cornell University; P. Larese-Casanova, Northeastern University / Department of Civil and Environmental Engineering; R.W. Giese, Northeastern University / Department of Pharmaceutical Sciences; D.E. Helbling, Cornell University; A. Pinto, Northeastern University / Department of Civil and Environmental Engineering; R. Massei, Helmholtz Centre for Environmental Research; I.Y. Padilla, University of Puerto Rico at Mayaguez / Civil Engineering and Surveying; Z.Y. Rosario-Pabón, University of Puerto Rico Medical Sciences Campus; A.N. Alshawabkeh, Northeastern University / Department of Civil and Environmental Engineering; A. Gu, Northeastern University / Department of Civil and Env Engineering

Hurricane Maria (HM) devastated Puerto Rico (PR) on September 20th, 2017, and one majorly overlooked problem is the water quality degradation for municipal and private well water systems due to the releases of various mixture of chemicals via flooding. This project aims to evaluate the impact of HM on drinking water quality across PR from both temporal and spatial scales, by focusing on chemical contaminants and water toxicity. Tap water samples were collected from participants’ households across PR from December 2017 to February 2018 and compared with samples prior to the hurricane. A high-throughput quantitative toxicogenomics assay with yeast cells targeting genotoxicity, oxidative stress, and other cellular toxicity, and a RT-qPCR assay with human A549 cells targeting inflammation, genotoxicity, oxidative stress, EDC, AHR and apoptosis effects, were employed for toxicity assessment. In parallel, water samples were analyzed for 18 metals on ICP-MS, and organic extracts were subjected to targeted and suspect screening for 234 organic micropollutants including PR human exposure-relevant chemicals on high-resolution LC-MS. Drinking water in PR showed higher average contamination levels after Hurricane Maria. The average concentrations of 14 out of 18 metals detected and 20 out of 27 organic micropollutants increased after the HM with the concentrations of As, benzophenone, perfluorooctanoic acid and sucralose being significantly higher (p<0.05) in the 20 samples after the HM. Higher contamination levels for both metals and organics, as well as higher molecular toxicity levels were observed in the 28 samples collected at northern PR where 7 active superfund sites were located. Compared to pre-hurricane samples, biomarkers involved in genotoxicity and general stress (osmotic stress, trehalose synthesis, signal transduction, apoptosis, etc.) showed higher up-regulation levels in yeast cells upon exposure to post-hurricane tap water extracts. Correlation analysis indicated that the occurrence of benzophenone, PFOA, and certain...
pesticides such as 2,4-D, MCPA and mecoprop was significantly correlated with genotoxicity, oxidative stress and AHR pathway (p < 0.05). Our combined approach of targeted chemical analysis and a HTS quantitative toxicogenomics assay provides a feasible and efficient alternative for time-sensitive research such as post-disaster toxicity responses, providing bases for further assessment of potential risk and health outcomes.

Emerging Landscape for Toxicity Testing: WET Method Challenges and Refinements to Applied In Vitro Assays for Effluents

223 National Pollutant Discharge Elimination System (NPDES) Permitting Whole Effluent Toxicity (WET) - An Implementation Perspective from Permit Writers

V.A. Lozano, US Environmental Protection Agency / NPDES Wastewater Section; S. Zavala Bogdan, US Environmental Protection Agency / NPDES Permits and TMDL Branch; A. Tien, US Environmental Protection Agency / NPDES Wastewater Section

The USEPA WET methods have been questioned, litigated, validated, updated, and reaffirmed by the EPA; however, concerns still exist regarding their efficacy. As new chemical compounds are manufactured, approved and utilized; the use of these WET methods to detect the additive and synergistic effects from dischargers on receiving streams is still the only approved test method available to NPDES permit writers. Yet questions regarding; the efficacy of these methods, the need for improved methods, and the overall value of these methods are ever present. This session will provide an NPDES permitting perspective on the current implementation practices, proposed methods development concerns, and research needs for treatment options to assist in supporting the currently effective and approved WET test methods. It will also explore the perspective that many of the problems associated with the WET test are implementation problems due to NPDES permit requirements lacking specificity to control variability amongst WET laboratories, not necessarily issues with the methods themselves. These issues, coupled with excessive focus on statistical endpoints, replicates, data variability, and lack of effective training, may be causing confusion and lead to NPDES permit writers being reluctant to incorporate WET concepts into effective permit writing and WET laboratory data analysis.

224 Recommendations for practical considerations in reviewing WET testing results and laboratory operations

W.L. Goodfellow, Exponent / Ecological and Biological Services Practice

Whole Effluent Toxicity (WET) testing methods and procedures have been refined over several decades; however, there are often minimal to no barriers to entry for laboratories without credentials for or experience performing WET testing methods unless the testing is being performed in a state with a certification program or under the National Environmental Laboratory Accreditation Program (NELAP). Even when testing is performed by laboratories that are state or nationally accredited, it does not guarantee that the results are of high quality, only that they met a minimum level of acceptable quality. WET results are used for important activities such as determining regulatory compliance (NPDES) that have real cost implications if not performed adequately and could impact organizational reputation. Furthermore, additional tests used in toxicity reduction evaluation (TRE) and toxicity identification evaluation (TIE) may not be subject to state or national accreditation; however, the need for high quality data still exists. This presentation will explore practical considerations for evaluating WET testing results and assessing laboratory operations, such as reviewing laboratory reports, result outputs, and raw bench sheets, and provide recommendations about what to look for in laboratory operations outside of reviewing test protocols and other laboratory quality assurance documentation.

225 What’s the buzz: EPA-ORD is developing method guidance for more species for effluent and ambient toxicity testing methods

T.J. Norberg-King, US Environmental Protection Agency / ORD/ NHEERL/Mid-Continent Ecology Division; J.M. Lazorchak, US Environmental Protection Agency / ORD/NERL/Systems Exposure Division

EPA currently has toxicity testing methods for effluent and ambient testing that were promulgated under the Clean Water Act Part 136. The promulgated freshwater methods for acute lethality include cladocerans (Daphnia magna, D. pulex, Ceriodaphnia dubia) and three fish species (fathead minnow (Pimephales promelas), rainbow trout (Oncorhynchus mykiss), and brown trout (Salvelinus fontinalis)). The short-term chronic freshwater methods that are promulgated include three species, a cladoceran (C. dubia), the fathead minnow (P. promelas), and a green alga (Raphidocelis subcapitata). Beginning in 2019, EPA’s Office of Research and Development (ORD) has begun to focus on additional species or test methods to add to the suite of freshwater test species to provide additional options for species sensitivity. In the first stage, EPA will be developing protocols for the short-term chronic test with the cladoceran, D. magna, and acute and short-term chronic test protocols for the freshwater mussel (fatmucket, Lampsisilis siliquoides). Both the Duluth and Cincinnati laboratories within the Office of Research and Development will be developing these test protocols and refining the various test conditions for each species within the EPA laboratories. These standardized procedures will aid in the detection of both known and unknown chemical and biological contaminants in wastewater and ambient water in support of EPA’s Office of Water, EPA regions, State and others. The second phase includes plans to develop effluent and ambient water protocols for additional species, such as acute and short-term methods for the mayflies, amphipods, midges, a short-term procedure using trout, and possibly another plant species. In this presentation, we will outline the general study plans for the daphnids and the mussels. We will discuss options for joining a listserv (or a similar system) to communicate the methods and to incorporate the public review of the methods during this development stage. Disclaimer: This presentation does not necessarily reflect the views or the policies of the USEPA.

226 Evaluation of In Vitro Fish Alternatives in Ecotoxicology and Their Role in WET Testing: A Review of the Development of Currently Available Models

J. Scott, SLR Consulting / Integrative Biology; M. Minghetti, Oklahoma State University / Integrative Biology

Whole effluent toxicity (WET) testing has been vital to ensure wastewater discharges are properly monitored and assessed to reduce harmful environmental impacts. While the current scope of WET testing methods has maintained integrity through a set of standardized aquatic toxicity testing, advancements in ecotoxicological techniques has been gaining momentum. Moreover, moving away from live vertebrate testing and enhancing toxicological measurement capabilities are major ethical and practical drivers in both the research and private sectors. Recently, the Organisation for Economic Co-operation and Development (OECD) and the International Organization for Standardization (ISO) have accepted methods for the use of in vitro alternative (i.e. zebrafish embryo test: OECD 236:2013, ISO 15088:2007; and fish gill cell line, RTgill-W1: ISO 21115:2019 ) for acute toxicity testing of chemicals and effluents. Successful approval is based on previous studies showing significant correlations between in vitro and in vivo acute toxicity tests. Moreover, these methods have shown high repeatability (low intra-laboratory variability) and reproducibility (low inter-laboratory variability) in predicting the toxicity of a broad range of chemicals. The use of the RTgill-W1 cell line have shown potential as a replacement of fish in WET testing, as well as a complementary tool to current toxicity identification and reduction evaluation strategies in wastewater treatment facility operations. The use of this in vitro assay for WET testing offers a high throughput approach which allows simultaneous measurement of multiple toxicological endpoints, cost efficiency and expedited results. However, considerations of in vitro limitations must also be made to better understand their role
towards advancing WET testing methods. The compliance of in vitro technologies with the 3Rs (replacement, refinement, and reduction) is certainly a strength which emphasizes their ethical value. However, their utilization as an alternative to fish may be best driven by economics rather than ethics. Thus, a close comparison of the cost of in vivo and in vitro test should be evaluated. This review aims to inform on the applicability and reliability of these technologies and discuss whether they should be accepted as either an all-encompassing alternative to live animals in WET testing, a complimentary screening process, or a more relevant toxicity forensic tool.

227 Refining culturing and effluent testing methods for the mayfly, Neocloeon triangulifer

Fordecades, toxicity tests with aquatic invertebrates have been conducted and yet a small number of model organisms are routinely used. Test organisms are usually easily cultured in the laboratory, have rapid life-cycles, exhibit sensitivity to a variety of pollutants with reproducible results, and are generally available year-round. The USEPA effluent testing program uses short-term chronic freshwater tests (4d to 8d) with cladocerans (Cladocera, Ceriodaphnia dubia), green algae (Sphaeroptela, Raphidocelis subcapitata) and fish (Cypriniformes, Pimephales promelas). EPA also has standardized Hyalella azteca (Amphipoda) and Chironomus dilutus (Diptera) test methods for sediments; yet EPA's effluent and ambient testing manuals do not provide acute or short-term test methods for H. azteca, C. dilutus or mayflies (Ephemeroptera). Because mayflies have been shown to be among the most sensitive species to major ions, metals, and pesticides, we have focused on effluent method development for the mayfly, Neocloeon triangulifer, a parthenogenetic species with a short life cycle (~30d at 25C). While methods for conducting acute 4d and chronic (~25-30d) toxicity tests with this mayfly have been published, a need exists to extend and standardize the methodology for applicable methods for testing in short-term exposures (e.g., 7d or 10d). Studies began with identifying an optimal starting age, test duration, and optimal sub-lethal endpoint for whole effluent toxicity testing. We found that chronic values from tests using < 24-h-old organisms were ~4-fold more sensitive than those using 7-d-old organisms. Survival was never a more sensitive endpoint than either calculated weight or biomass. Efforts to refine the various aspects of diatom culture technique on food quality and therefore mayfly growth are underway and optimizing the diet for these organisms may be critical for achieving consistently high growth rates with low intra-treatment variability. We also determined the influence of amendments to culture water and food, and temperature on sensitivity to reference contaminants and effluents. Results of the study should provide data needed to guide the development of a toxicity test method to support NPDES permit decision-making. Abstract does not necessarily represent the position or policy of the USEPA.

228 Key factors affecting laboratory variability in the chronic Ceriodaphnia dubia test

K.N. Prosser, Pacific EcoRisk / Quality Assurance; S.L. Clark, B.C. Jorgenson, Pacific EcoRisk

The US Environmental Protection Agency (USEPA) freshwater chronic toxicity manual (EPA-821-R-02-013) provides guidance for performing the chronic Ceriodaphnia dubia test with effluents and receiving waters. The method was specifically designed to provide flexibility for laboratories to perform testing under various test conditions, including recommendations for control/dilution waters, food type and preparation, and test chamber material, whereas other factors such as organism age are tightly controlled. However, such flexibility in how the method is performed, in addition to other factors (e.g., personnel experience, laboratory experience, etc.), can influence intra- and inter-laboratory variability.

Such variability has resulted in increased attention by regulated parties and some regulatory agencies as to what can be done to improve the performance of testing with this species. With a consistent training program for >15 years, we believe that we have minimized personnel and laboratory experience as significant drivers for test variability, and transitioned to evaluations of different foods and waters. Through those efforts, we identified food source and type as key factors that influenced both culture and test variability. In this presentation, we evaluated a historical record of nearly 4,000 chronic C. dubia tests performed in our laboratory from 2008-2019 for patterns of test variability. Over the temporal period of this testing, we observed a considerable decrease in intra-laboratory variability once we began to prepare our own Pseudokirchnerella subcapitata (previously Selenastrum capricornutum) and Yeast-Cerophyll-Trout Chow foods. Following that adjustment, we observed remarkably consistent test performance and reduced variability over an extended period of time. To investigate other factors that influence intra-laboratory test variability, we evaluated organism age (e.g., 0-8, 9-16, and 17-24 hrs) and individual organism performance (e.g., mortalities, fewer than three broods. With this study, we hope to highlight factors influencing test variability to aid groups discussing method variability and approaches to harmonize method performance across laboratories.

229 Comparison of three LED light correlated color temperatures on Ceridaphnia dubia survival, fecundity, and neonate reference toxicity test performance

R. Cooper, Arkansas State University; J.L. Bouldin, Arkansas State University / Biological Sciences

LED lights come in a variety of correlated color temperatures (e.g. soft warm white, cool white, daylight) and their ability to maintain stable culture and test conditions for laboratory organisms is unknown. Therefore, over a three-month period we tested for a difference in Ceridaphnia dubia survival and fecundity, as well as neonate performance in reference toxicity tests (NaCl) from culture boards maintained with LED lights at three correlated color temperatures (3000K, 4000K, and 5000K) with comparable light intensity. We compared survival, 14-d average total neonates, number of broods and days to third brood of 8 or more neonates, and number of days to first brood for culture boards. Endpoints for reference toxicity tests included NOEC, LOEC, and control group percent variation. We found no significant differences between any parameters tested, and conclude that there is no difference between LED lights at comparable light intensity over the three evaluated correlated color temperatures for C. dubia cultures.

230 Characterization of effluent discharges from a mobile offshore drilling unit - learnings from a remote arctic whole effluent toxicity testing study

A study was performed to evaluate the potential biological impacts from 6 types of miscellaneous discharges from a remote arctic oil and gas mobile offshore drilling unit (MODU) including: deck drainage, desalination unit waste, boiler blowdown, fire control system test water, non-contact cooling water, and bilge water. Samples were evaluated for toxicity using a rapid (< 1 h) initial screening test (echinoderms [Dendraster excentricus] fertilization test), and if toxicity was found, further testing was conducted using 3 chronic whole effluent toxicity (WET) tests. This additional testing included the embryo larval development (72-h echinoderm [D. excentricus]; 7-d mysid [Americamysis bahia] survival, growth, and fecundity invertebrate test; and 7-d topsmelt [Atherinops affinis] survival and growth fish test). Toxicity identification evaluations were performed on effluents that consistently elicited a toxic response during WET testing. To place the results of the toxicity testing into the
context of environmental risk, the spatial extent of potential biological effects was investigated using the CORMIX mixing zone model. The output of the modeling indicated that discharge of selected effluents did not result in concentrations or duration of exposure that would elicit toxic effects to organisms living in the surrounding environment. This study provides a comprehensive data set that was used to characterize potential toxicity and environmental risk of MODU “miscellaneous discharges” which could help inform future risk assessments of these discharges. Furthermore, this study overcame significant logistical constraints related to performing routine effluent testing in offshore arctic environment. Aspects related to optimization for future WET testing programs and considerations for alternatives assessment methods based on the data collected will be discussed presented.

Canadian Oil Sands Part 1: Advances in Chemical Characterization, Reclamation and Monitoring Research

231 Polycyclic Aromatic Compound (PAC) Source Characterization within In Situ Oil Sands Operations, Cold Lake, Alberta

K. Smythe, University of Ottawa / Earth and Environmental Sciences; C. Cooke, P. Drewnick, Alberta Environment and Parks / Environmental Monitoring and Science Division; J.R. Thiendon, University of Ottawa / Department of Biology; J. Korosi, University of Ottawa / Biology; J. Cornett, University of Ottawa / Department of Earth Sciences; J.M. Blais, University of Ottawa / Biology

Most of the published environmental research on Canada's oil sands concentrates on open-pit mines and bitumen processing operations. Less is known about the environmental impacts attributed to in situ operations; which in 2012 surpassed open-pit mining as the dominant method of oil sands extraction in Canada. The Cold Lake oil sands deposit in Central-Eastern Alberta is unique as it is isolated by approximately 150km from open pit mines, upgraders, refineries, tailings ponds and other bitumen processing operations. The Cold Lake oil field requires the use of in situ steam injection to extract bitumen as its reserves are situated deep below the surface, making them inaccessible through open-pit mines. Here we examine polycyclic aromatic compound (PAC) profiles in Pb-210 dated sediment cores from 11 lakes throughout the Cold Lake area to track temporal changes in PAC deposition between pre-industrial and present levels. We use alkylated PACs, predominantly petrogenic contaminants, to evaluate in situ operations as potential contamination sources to surrounding lakes. We predict that similarly to open-pit operations, concentrations of alkylated PACs in lakes sediments will increase with industrial activity and will correspond to proximity from in situ operations. Preliminary trends demonstrate increasing concentrations of alkylated PACs at the onset of industrial activity in lakes heavily surrounded by in situ operations, however those less heavily surrounded by in situ activity do not show a consistent increase in the total concentration of alkylated PACs. These results suggest that in situ operations are a potential source of contamination to the surrounding areas however may not be a dominant source of PAC enrichment to lakes situated farther away. With >80% of Canadian bitumen reserves requiring in situ techniques for extraction, there is still limited research on the contamination attributed to this method. We address this shortcoming by providing a spatial and temporal analysis of the contamination attributed to in situ techniques to highlight the importance of ongoing monitoring surrounding these operations. Additionally, this study allows for the environmental implications of open pit mining operations to now be compared to that of in situ techniques.

232 5 Years of Monitoring Polycyclic Aromatic Compounds in Air in the Athabasca Oil Sands Region: Temporal Trends and Source Attribution

J. Schuster, Environment and Climate Change Canada / Air Quality Research Department; T. Harner, Environment and Climate Change Canada / Air Quality Research Division; K. Su, A. Wnorowski, J. Charland, Environment and Climate Change Canada

The Athabasca Oil Sands Region in Northern Alberta is the largest deposit of bitumen in the world. The activity of the petroleum industry in the area encompasses surface mining, in situ mining and upgrader facilities as well waste tailing ponds. Polycyclic aromatic compounds (PACs) are chemicals of concern released from the oil sand industrial activity. They are detrimental to human and ecological health and as semi-volatile pollutants can undergo long-range atmospheric transport. PACs such as polycyclic aromatic hydrocarbons (PAHs) have a wide range of sources in addition to the petroleum industry. Other PACs such as halogenated PACs (alkPAHs) and dibenzo-3,4-thiophenes (DBTs) are predominantly present in bitumen but were also observed as products of forest fires. PAC levels in air in the Athabasca Oil Sands Region were monitored continuously from 2011-2015 with both passive and active air samplers. The data from samples collected with high volume air samplers at three sampling sites gives a 6-day temporal resolution of PAC concentrations in air over 5 years. The data from the passive air samplers (PAS) represents 2 months integrated air concentrations from 15 sampling stations close to industry, in local communities and at background sites. Levels of PACs in air over the 5-year period did not vary substantially temporally and were dominated by alkPAHs. Concentrations in air were in the ranges of 0.3-43, 0.15-460, and 0.04-130 ng/m3 for ∑PAHs, ∑alkPAHs, and ∑DBTs, respectively. Elevated concentrations were observed in vicinity of mining areas and during seasonal forest fire events. The impact of different sources is expressed in different PAC fingerprints at the individual PAS sampling sites. The combined PAC data over 5 years delivers a comprehensive picture of temporal and spatial trends of PACs in the Athabasca Oil Sands Region.

233 Identification of Halogenated Polycyclic Aromatic Hydrocarbons in Biological Samples from the Alberta Oil Sands Region

Z. Xia, J.G. Idowu, University of Manitoba / Chemistry; C.H. Marvin, Environment Canada / National Water Research Institute; P. Thomas, Environment and Climate Change Canada / National Water Research Institute Research Centre; B. Crimmins, Clarkson University / Civil and Environmental Engineering; M. Fry, University of Manitoba / Biological Sciences; J. Stetefeld, University of Manitoba / Chemistry; G.T. Tomy, The University of Manitoba / Department of Chemistry

Polycyclic aromatic compounds (PACs), a complex class of compounds, can be formed from incomplete combustion or diagenesis of plant matter forming petroleum oils. A preliminary study in our group has shown that halogenated polycyclic aromatic hydrocarbons (HPAHs) can also be detected in environmental samples from the Alberta Oil Sands Region (AOSR). Here we extend our earlier work and present information on the detection of HPAHs in the region using comprehensive two-dimensional gas chromatography coupled with high-resolution time-of-flight mass spectrometry (GCxGC-HRTOF-MS) at a resolving power of 25,000. Knowledge of the electron ionization (EI) fragmentation behavior of individual HPAH isomers, achieved by injecting authentic standards in full-scan MS mode, was paramount in identifying the suite of HPAHs in samples from the AOSR. Confirmation of compounds in biological samples was based on the measured mass accuracy of 2 characteristic ions prominent in the EI mass spectra of each compound.
234 Remediation of Organic and Inorganic Constituent of Oil Sands Process Water by Boron-doped Diamond (BDD) Electrolysis Treatment

S. Ganiyu, University of Alberta / Department of Civil and Environmental Engineering; M. Gamal El-Din, University of Alberta / Civil and Environmental Engineering

The current bitumen extraction processes in Alberta, Canada from oil sands produce large volumes of process water termed oil sands process water (OSPW), which contains various compounds such as petroleum related hydrocarbons - naphthenic acids (NAs), polycyclic aromatic hydrocarbons (PAHs), surfactants, trace elements, anions, and other treatment chemicals, which do not pose a problem while the OSPW is being recycled. Most of these compounds are below the toxicity threshold for aquatic life untreated and undiluted but a few, particularly the dissolved organics, must be treated if this water is to be returned to the Athabasca watershed. There have been records of toxicological effects of OSPW on several aquatic organisms and plants, and it is highly recalcitrant to many water treatment technologies. In this study, the fate of organic and inorganic constituents of OSPW during electrooxidation treatment with highly potent boron-doped diamond (BDD) electrode was investigated. The efficiency of the process was followed by monitoring the decay of dissolved organic carbon (DOC), classical and oxidized naphthenic acids, aromatic hydrocarbons, acute toxicity as well as reduction/transformation of the inorganic ions. Complete degradation of classical and oxidized NAs and PAHs can be achieved within 2 h of electrolysis at current density above 2.5 mA cm⁻². The DOC removal efficiency of 14%, 25%, 50%, 67% and 85% was obtained at current densities of 1.25, 2.5, 5, 10 and 20 mA cm⁻², respectively, after 2 h. Interestingly, the energy consumption per volume of OSPW and DOC removal were minimum, in the range of 0.9 - 17.4 kWh m⁻³ and 0.08 - 0.6 kWh g DOC⁻¹, respectively. The inorganic ions such as C₁⁻, SO₄²⁻ and CO₃²⁻ were transformed mostly into reactive species that participated in the oxidation of the organic pollutants. Finally, the electrolysis treatment with BDD electrode is a very exciting and efficient technology for the reclamation of OSPW.

235 Comparison of the effects of extraction techniques on mass spectrometry profiles of dissolved organic compounds in oil sand process-affected water

H. Alharbi, King Saud University / College of Food and Agricultural Science; G. Morandi, University of Saskatchewan; P.D. James, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; S. Wiseman, University of Lethbridge / Biology; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences

Recent advances in mass spectrometry have facilitated chemical characterization and profiling of complex environmental mixtures such as oil sands process-affected water (OSPW) and identification of previously unresolved chemicals. However, because OSPW is a complex mixture of salts, metals, suspended particulate matter and dissolved organics, extraction techniques are required to reduce effects of signal suppression/enhancement. In this work, Orbitrap, ultrahigh resolution mass spectrometry was used to perform a comprehensive comparison of solid phase extraction (SPE), and liquid-liquid extraction (LLE) techniques on profiling of dissolved organic chemicals in OSPW. When operated in negative ion mode, extraction of naphthenic acid (NAs-O₂⁻) was observed on acidicification of OSPW samples for C18 and LLE techniques. However, when applying a hydrophilic lipophilic balance sorbent (ABN) SPE technique, the extractability of NAs was independent of pH. When operated in positive ion mode, for all extraction methods, nitrogen- and sulfur-containing species were more abundant and diverse in basic extracts than in acidic extracts and ABN extracted the greatest number of chemical species including nitrogen, sulfur and oxygen containing species. Overall, this study supports the utility of hydrophilic lipophilic balance SPE techniques for the profiling of species of dissolved organic chemical in OSPW at environmentally relevant pHs.

236 Biodegradation of dissolved organics in Base Mine Lake: Is it happening and how long does it take?

E.K. Asiedu, University of Alberta / AET Division; A. Ulrich, University of Alberta / Civil and Environmental Engineering; J.W. Martin, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES and Science for Life Laboratory

Introduction: The current strategy for the remediation of over 1 billion cubic metres of oil sands process-affected water (OSPW) employs the use of end pit lakes (EPLs). In this method, OSPW will be stored in evacuated mines until overall toxicity is reduced through natural or managed processes. Base Mine Lake (BML) is the only existing oil sands EPL. Using BML OSPW, the in situ biotransformation of thousands of dissolved organic species was monitored here for the first time. Laboratory microcosms containing BML OSPW (n=3, T=21°C) were monitored alongside positive (Merichem added) and negative (autoclaved) controls for over one year and aliquots analyzed using high pressure liquid chromatography-Orbitrap mass spectrometry in positive and negative mode. Additionally, BML OSPW samples taken every August from 2013 to 2017 were analyzed to review the changes which have occurred in the last 5 years. Objective: To evaluate the in situ microbial biotransformation of the dissolved organics in BML and identify persistent classes of compounds which may remain in the future. Results: The profile of organics in BML OSPW showed no difference compared with negative controls after 272 days. A closed bottle experiment containing BML OSPW showed intervention could stimulate biotransformation and as such, nutrients were added to the experimental incubations on day 379. A decrease in the concentrations of naphthenic acids (NAs, O₂⁻) was observed in BML microcosms after the addition of acetate (day 409) but NA concentrations decreased by only 7% by the last day of the experiment (day 424). Some heteroatomic groups (O₃⁻, O₂S⁻) also decreased following intervention while others increased (O S⁻, O₅⁻). All other groups (O⁻, O₄⁻, O₅⁻, O₄S⁻, O₄S⁰) did not change during the experiment. In the field-based project, relative distributions of organics in BML from 2013 to 2017 demonstrated no change. However BML 2017 displayed the lowest concentrations of all BML samples studied. Conclusions: Results confirm NAs in OSPW are recalcitrant and that microbial biotransformation in BML may be suppressed due to low nutrient availability. Furthermore the majority of heteroatomic groups appear to be at least as persistent as NAs. Changes in the chemical profile following intervention show that the microbial community in BML OSPW is able to change its chemical environment and that biostimulation may be necessary to decrease concentrations of toxic organics in future EPLs. Implications: Additional management strategies may be required to increase the efficiency of oil sands EPLs and promote biodegradation of toxic dissolved organics found therein.

237 Non-Target Profiling of Bitumen Influenced Waters to Identify Tracers Unique to Oil Sands Process-Affected Water in the Athabasca Watershed

C. Milestone, Sheridan College / School of Chemical and Environmental Sciences; C. Sun, University of Alberta / Laboratory Medicine & Pathology; J.W. Martin, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES and Science for Life Laboratory; G. Bickerton, J.W. Roy, Environment and Climate Change Canada; R. Frank, M. Hewitt, Environment and Climate Change Canada / Water Science and Technology Directorate

The objective of this study was to identify unique chemical tracers of oil sands process-affected water (OSPW) to enable future discrimination tailings pond seepage from natural bitumen influenced waters from the Alberta McMurray formation. The approach involved comparing a unique sample set of OSPW (n=4) and OSPW-affected groundwater (n=15) to natural bitumen influenced groundwater (n=20), using high resolution mass spectrometry (HRMS). This identified four potential tracers of OSPW seepage that were then subjected to structural elucidation. One potential tracer, tentatively identified as a thiophene-containing carboxylic acid (C₁₀H₁₂O₂S) was only detected in OSPW and OSPW-affected samples, thereby showing great diagnostic potential. The remaining three
unknowns, postulated to be two thiochroman isomers with a ketone functional group on the S-containing cyclic moiety and two hydroxyl groups likely located on an alkyl side-chain (C<sub>12</sub>H<sub>21</sub>O<sub>3</sub>S<sup>-</sup>), and an ethyl-naphthalene (C<sub>9</sub>H<sub>11</sub>), were found in either one or two background groundwaters, respectively. Additional unknown ions with diagnostic potential were also detected at lower concentrations, or evident as co-eluting isomer mixtures, and with improved sample preparation and/or separation could further augment differentiation of industrial and natural sources of bitumen influenced waters.

238 Quantifying the relative contributions of mining-related and naturally occurring naphthenic acids in groundwater near oil sands tailings ponds

A relatively straightforward method to differentiate naphthenic acids (NAs) associated with oil sands process-affected water (OSPW) from those found naturally in groundwaters in contact with the bituminous McMurray Formation remains the Holy Grail for environmental scientists working in Canada’s oil sands region. Despite recent advances in high- and ultrahigh resolution mass spectrometry, the data generated by these analyses do not lend themselves to an easily interpretable format suitable for quantification and apportionment of anthropogenic and natural sources of NAs. A previous novel approach to this challenge utilized intramolecular carbon isotope values generated by online pyrolysis (δ13C-pyr) to characterize and quantify the acid extractable organics (AEOs) fraction containing NAs (Ahad et al., 2013). This method was able to distinguish bitumen- from non-bitumen-derived AEOs but could not discriminate between mining-related and natural sources of bitumen-derived AEOs. This study builds upon those results using data analysed from samples collected across two different study sites and four field campaigns (2014-2017). In conjunction with δ13C-pyr and high-resolution Orbitrap mass spectrometry analysis, we employed an additional isotopic tool — sulphur isotope analysis (δ34S) of AEOs. As observed previously, OSPW was characterized by elevated δ13C-pyr values and high proportions of O2 and O25 species classes, and δ13C-pyr values in groundwater reflected mixing between various sources. The combined use of both δ13C-pyr and δ34S allowed for discrimination of AEOs into three relevant groups: 1) OSPW-derived; 2) naturally occurring bitumen-derived (i.e., McMurray Formation), and; 3) naturally occurring non-bitumen-derived. The relative proportions of these three sources determined in groundwater samples utilizing an isotopic mixing model revealed seepage of low levels of OSPW-derived AEOs at both study sites. Relatively higher proportions of OSPW at one of the sites highlighted the potential for this technique to verify preferential flow-paths of tailings pond seepage. (Reference: Ahad, J.M., Pakdel, H., Savard, M.M., Calderhead, A.I., Gammon, P.R., Rivera, A., Peru, K.M. and Headley, J.V., 2013. Characterization and quantification of mining-related “naphthenic acids” in groundwater near a major oil sands tailings pond.

New and Existing Chemical Contaminants in Changing Arctic and Antarctic Environments - Part 1

239 Organochlorine pesticide and industrial compound fluxes to surface snow from four glacial sites on Svalbard, winter 2013-1014

M.H. Hermansson, Hermanson & Associates, LLC / Environmental Chemistry; E. Isaksson, Norwegian Polar Institute; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

During spring 2014, seasonal surface snow was collected from 4 glacial sites on Svalbard and analyzed for 35 organochlorine pesticides and 8 industrial compounds (mostly chlorobenzenes) using high-resolution GC-MS. The sites were Holtsedalffonna, Kongsvegen, Lomonosovfonna and Austfonna, roughly trending from west to east, a maximum distance of 220 km. Lomonosovfonna and Holtsedalffonna are high-elevation sites (> 1000 m.a.s.l.), and are above the tropospheric boundary layer (TBL) all year and receive inputs only from long-range atmospheric transport. Kongsvegen and Austfonna are both at about 700 m.a.s.l. and above the TBL during summer and may receive local inputs during winter, although that is unlikely because all land-based surface sources would be frozen. The most concentrated of all 43 substances was current-use pesticide chlorpyrifos, and was highest at Lomonosovfonna where it was 5 times greater than Holtsedalffonna and Austfonna. The most concentrated of the industrial compounds was pentachloroanisole (PCA) which again was highest at Lomonosovfonna, and was 67% greater than the second-most abundant site, Kongsvegen. Most compounds varied by less than a factor of 2 among sites, and include pentachlorobenzene, hexachlorobenzene, 3,4,5,6 tetrachloromethoxybenzene, heptachlor epoxide B, heptachlor, delta-HCH, dactal, cis-chlordane, dieldrin, and 4, 4'-DDE. This suggests a common source or a common process involving transport to each site. All other pesticides were below detection, including all other compounds in the DDT group, toxaphene paralrs 26, 50, 62, endosulfan II and endosulfan sulfate, endrin aldehyde and endrin ketone, methoxychlor, dicofol, and mirex. Air mass back trajectories, showing the frequency of flow from likely contaminant source regions to each of the sites, are similar, suggesting that differences in contaminant amounts are not a result of different flows from likely long-distance source regions. Fourteen of 35 pesticides were below detection, all of them legacy compounds, suggesting that limitations on use have been effective at lowering long-range atmospheric transport of these substances. On the other hand, the high amounts of PCA, which is on the Stockholm Convention Annex A (elimination) in association with pentachlorophenol, indicates that some substances remain in the environment and are moving in comparatively large amounts.

240 Partitioning of emerging contaminants to Arctic dissolved organic matter

L. O’Connor, J. Kerrigan, Y. Chin, University of Delaware / Civil and Environmental Engineering

Anthropogenic organic pollutants have been commonly detected in the Arctic, and include new classes of brominated flame retardants (BFRs) and current use pesticides (CUPs). In this study, we focus on the environmental fate of chlorpyrifos (CUP) and tetrabromobisphenol A (TBBPA, which is a flame retardant). These chemicals are produced and used at lower latitudes and transported to higher latitudes through global distillation processes. These two chemicals have been detected in various environmental compartments in the Arctic where they are both used or manufactured. These chemicals have been found in the indigenous Alaskan Yupik communities at relatively high concentrations, and we believe that the exposure pathway is through bioaccumulation up the food chain. One process that can limit exposure and bioaccumulation of these compounds is through their interactions with Arctic dissolved organic matter (DOM). We hypothesize that the presence of DOM in Arctic surface waters at sufficiently high enough concentrations (> 10 mg/L) will bind these chemicals making them less bioavailable. Solubility
Tuesday Platform Abstracts

enhancement studies for chlorpyrifos and TBBPA) were conducted with various types of Arctic DOM (Innavait Creek and a tundra seep adjacent the Sagavanirktok River). The DOM concentrations ranged from 5 mg/L to 90 mg/L with two controls at 0 mg/L and the compounds were analyzed by liquid chromatography. Our measured solubility values for TBBPA and chlorpyrifos were in excellent agreement with reported those reported in the literature (0.3 and 9 μM respectively). Surprisingly, we observed loss of TBBPA in the presence of DOM, which was unexpected. Solubility enhancement experiments of chlorpyrifos are ongoing.

241 Photochemical Degradation of Polycyclic Aromatic Hydrocarbons and BTEX in Snow and Ice

T. Kahan, University of Saskatchewan / Chemistry; P. Malley, A. Stathis, Syracuse University / Department of Chemistry; S. Chakraborthy, A. Stubbs, University of Saskatchewan / Department of Chemistry; A. Hendrickson-Stives, Pennsylvania State University / Department of Chemistry

As the Arctic warms and new shipping routes become available, human activity in the Arctic will increase, causing perturbations to biogeochemical cycles. In the Arctic, these cycles are heavily influenced by chemical processes in snow and ice. Therefore, in order to quantify and predict the effects of human activities on these cycles - and to mitigate harmful effects - we need to understand ice's role as a chemical reactor. We do not yet have this understanding. Many environmentally-relevant reactions proceed via different mechanisms and rates in snow and ice compared to in liquid water, but the reasons for these differences remain largely unknown, and we lack predictive capabilities for pollutant fate in snow-covered regions. We have measured photolysis rates for several pollutants associated with fossil fuel usage, including PAHs (polycyclic aromatic hydrocarbons) and BTEX (benzene, toluene, ethylbenzene, and xylenes) in artificial snow and ice. We show that photolysis is accelerated in frozen aqueous solution compared to in the liquid phase, and that it occurs via different mechanisms. Photolysis rates are greatly affected by the presence of common environmental co-solutes such as dissolved organic matter (DOM) and sodium chloride (NaCl). We have used Raman microscopy to investigate the surface properties of solute-containing ice and to help relate sample composition to reactivity. Our results indicate that pollutant fate in polar regions will depend strongly on the composition of the ice; for example, photolysis rates for a given pollutant can be very different in relatively pristine ice compared to in sea ice. Our results will improve our ability to predict pollutant fate in polar regions, and may inform evidence-based emission regulations.

242 Strong signals of remobilized margin PAHs to the basin in a warming Arctic

Y. Lin, Xiamen University / Collage f the Environment & Ecology; M. Cai, M. Chen, Xiamen University; P. Huang, College of Ocean and Meteorology; R. Lei, Polar Research Institute of China; M. Chen, Xiamen University; D. Gui, Polar Research Institute of China; H. Ke, Xiamen University

Arctic warming will amplify the margin inputs coming from the continent and shelf, yet their effects remain poorly understood for persistent organic pollutants (POPs), such as polycyclic aromatic hydrocarbons (PAHs), which gain concern due to their high carcinogenicity and burden on the ecosystem. Here we present how distribution and transportation (PAHs), which gain concern due to their high carcinogenicity and burden on the ecosystem. Here we present how distribution and transportation of dissolved PAHs in the Arctic Basin can be explained by a new insight into the Arctic Oscillation. This hypothesis was further visualized by ice-back trajectories and the different relationships of PAHs with the fraction of river and ice melting water. The mass balance model of PAHs revealed a new scenario with overwhelming input by margin sources (68%) and output by volatilization (84%). Our study highlights the strong signals of remobilized margin POPs (especially from Eurasia) in the Canadian Basin, suggesting significant changes in their pathways, balances and ecological consequences are underway with climate change.

243 Organophosphate Esters in Water of the Largest High Arctic Lake and its Tributaries

Y. Sun, South China Sea Institute of Oceanology, Chinese Academy of Sciences / Aquatic Contaminants Research Division; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; D.C. Muir, C. Spencer, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Machnis, Memorial University / Department of Chemistry; I. Lehnherr, University of Toronto Mississauga / Department of Geography; Y. St. Louis, University of Alberta / Biological Sciences; K. St. Pierre, University of British Columbia / Institute for the Oceans and Fisheries

Organophosphate esters (OPEs) have been detected in Arctic aquatic ecosystems, but the influence of glacial melt on the environmental behavior of OPEs in the recipient aquatic ecosystems is still unknown. In this study, water samples were collected from Lake Hazen (the world’s largest High Arctic Lake by volume) and its tributaries to investigate the distribution and depth profiles of 14 OPEs in Lake Hazen and to explore the input of OPEs to Lake Hazen and the output of OPEs from Lake Hazen by glacial rivers in 2015 and 2018. The concentrations of Σ14OPEs in water of Lake Hazen and its tributaries in 2015 ranged from 6.81 to 19.3 ng/L and from 4.51 to 31.6 ng/L, respectively. Tris(2-butoxyethyl) phosphate and three chlorinated-OPEs (tris(2-chloroethyl)phosphate, tris(2-chloroisopropyl) phosphate, tris(1,3-dichloro-2-propyl)phosphate) were the dominant OPEs in Lake Hazen watershed. Levels of Σ14OPEs in Lake Hazen water column showed a decreasing trend from 0 to 225 m, began to increase below 225 m and peaked at 250 m. Concentration of Σ14OPEs in water of Lake Hazen (mean ± SE, 12.3 ± 0.77 ng/L) were lower those in inputs to Lake Hazen from glacial rivers (15.8 ± 4.04 ng/L) and output from Lake Hazen (Ruggles River, 15.1 ng/L). The concentration of Σ14OPEs in Skeleton Creek (20.9 ± 5.05 ng/L) was higher than those in glacial rivers, indicating that small stream may be a more important input source of OPEs into Lake Hazen. A mass balance was estimated for OPEs in the Lake Hazen watershed. Glacial river inputs to Lake Hazen and the output from the Ruggles River in 2015 were 15.5 and 16.5 kg, respectively, suggesting glacial inputs of OPEs can be completely discharged by the Ruggles River. The concentrations of Σ14OPEs in glacial rivers in 2018 (4.48 ± 0.52 ng/L) were significantly lower than those in 2015 (15.8 ± 4.04 ng/L), indicating that the melting of glaciers may play an important role in determining the concentrations of OPEs in the tributaries of Lake Hazen. This study highlights that OPEs can be subject to long-range transport to the Arctic and the melting of glaciers can release OPEs into aquatic ecosystems in the High Arctic of Canada.

244 Wastewater sources of per- and polyfluorinated alkyl substances (PFAS) and pharmaceuticals in Canadian Arctic Communities

K. Stroski, Baylor University / Environmental Science; K. Luong, The University of Winnipeg / Richardson College for the Environment; J.K. Challis, University of Saskatchewan / Toxicology Centre; L.G. Chaves-Barquero, University of Manitoba / Department of Chemistry; M.L. Hanson, University of Manitoba / Department of Environment and Geography; C.S. Wong, Southern California Coastal Water Research Project Authority / Chemistry

Effective removal of organic contaminants in wastewater effluent pose a challenge to small communities worldwide. Treatment in the Canadian Arctic is exceptionally challenging due to infrastructure demands and harsh climates. To better understand the efficacy of current treatment options and risks posed by pharmaceuticals on receiving waters in the Arctic, four representative communities within the Canadian territory of Nunavut were evaluated: Iqaluit, Baker Lake, Cambridge Bay, and Kugluktuk. Per- and polyfluorinated alkyl substances (PFASs) were also investigated in Cambridge Bay. These communities have treatment
ranging from primary lagoons, engineered wetlands, and natural lakes. Pharmaceuticals were measured using the organic diffusive gradients in thin film (o-DGT) passive sampler in summer 2018. Of the 34 compounds studied, seven were found at least once: atenolol, carbamazepine, metoprolol, naproxen, sulphapyridine, sulfamethoxazole, and trimethoprim. Concentrations varied (10 - 5000 ng/L) between communities and treatment method showed no distinction in removal performance towards specific compounds. Iqaluit had the poorest overall performance while Baker Lake had the best. Measured pharmaceutical concentrations do not appear to pose a significant hazard to receiving waters at this time, based on known toxicological endpoints. PFAS concentrations were found to be over 100-fold greater in Cambridge Bay wastewater than previously reported Arctic seawater. Results suggest that wastewater may be an important point source of PFASs in Arctic communities. The o-DGT passive samplers performed well in marine Arctic settings. We recommend further testing of wastewater efficiencies in Arctic communities along with evaluations of seasonal variations.

245 Intensive fishing as a method to reduce mercury concentrations in a Northern Pike population in a small subarctic lake

H. Dixon, Wilfrid Laurier University / Biology; J.B. Whitehouse, University of Waterloo / Biology; M. Low, G. Low, Dehcho Aboriginal Aquatic Resource and Oceans Management Program; H.K. Swanson, University of Waterloo / Biology

Sanguez Lake is a small (1.8 km²) Subarctic lake in the Dehcho region of the Northwest Territories, which has traditionally been fished by Jean Marie River First Nation. However, high levels of mercury (Hg) in the Northern Pike (Esox lucius) population from this lake have led to concerns regarding the use of this species as a subsistence food source. In an effort to mitigate the level of Hg in Northern Pike, an intensive fish-down was implemented, where large (>500 mm) Northern Pike were removed from the lake to reduce competition and promote faster growth, which should result in lower Hg levels. Sanguez Lake was originally sampled in Fall 2013, and the fish-down began in 2016, with fishing occurring in Fall of 2016, 2017 and 2019, as well as in Spring of 2018 and 2019. To determine the effectiveness and extent of stimulating growth-dilution in this species, Hg concentrations in Northern Pike tissue were compared between years and seasons. Significantly higher Hg concentrations were measured in 2013 compared with later years during the fish-down. The slope of the relationship between mercury and fork length decreased in this species, suggesting their long-range transport and the transfer of multiple contamination to the Euro-Arctic marine trophic webs.

246 Multiple exposure of the Boreogadus saida populations to legacy and emerging pollutants from inner and outer Bessel fjord (NE Greenland)

F. Spataro, IRSA-CNR Water Research Institute / Italian National Research Council; L. Patroccoli, Water Research Institute Italian National Research Council; S. Corsolini, University of Siena / Dept Environmental Science; K. Prabel, UiT The Arctic University of Norway; J. Rauseo, T. Pescatore, N. Ademollo, IRSA-CNR Water Research Institute / Italian National Research Council CNR

NE Greenland, the remote region of the Northern hemisphere, has attracted considerable scientific interest due to the peculiar characteristics and the biological, ecological, and eco-toxicological adaptations of the organisms living in this area, which is still few investigated. Reports by Arctic Monitoring and Assessment Program (AMAP) highlight that the list of chemicals found in Arctic ecosystems are continuously growing and show increasing temporal trends for some current-use chemicals. Specimens of the marine gadoid Boreogadus saida were caught from RV Helmer Hanssen in Bessel Fjord (BF), NE Greenland (76°N), in September 2017, during the scientific expedition TUNU-VII (UiT The Arctic University of Norway). The general aims were to evaluate the bioaccumulation of legacy end emerging contaminants in populations of B. saida from mid and outer Bessel Fjord (BF) waters, and from the continental shelf. Liver and muscle samples were analysed to determine the concentration of Polyaromatic Hydrocarbons (PAHs), Bisphenol A (BPA), Nonylphenols (NPs) and Organochlorine Pesticides (HCHs, Endosulfan, DDE, DDT) including some Current Use Pesticides (e.g. Chlorpyrifos, Dacthal). PLE extraction and analytical determination using LC-MS and GC-MS showed the occurrence of these contaminants in the majority of samples. The contaminant longitudinal pattern was outer BF ≥ mid BF > shelf. Only for NP1-2EO, BPA and 4-NP we found the muscle more contaminated than the liver; a possible reason is that the detoxification/removal of these compounds from the liver occurs more rapidly respect to other POPs resulting in a continuous and chronic exposure. The pesticides concentration pattern was the same between the different areas. The ΣDDT residue was due to the metabolite p,p'-DDE (>80%). The Endosulfan technical formulations is dominated by the α-isomer; the increase in β-Endosulfan is consistent with increasing distance to possible application sites, the α- and β-isomers degrade at different rates in temperate aquatic systems and there is some evidence suggesting that the β-isomer can be converted to the α-isomer in the environment. Results confirm the presence of selected legacy and emerging contaminants in this species, suggesting their long-range transport and the transfer of multiple contamination to the Euro-Arctic marine trophic webs.

Sequencing the Exposome Using Nontarget Mass Spectrometry: Aims, Perspectives and Challenges - Part 1

247 A Novel High-Resolution Mass Spectrometry Toolbox for Unravelling the Chemical Exposome

S. Samanipour, M. Reid, NIVA Norwegian Institute for Water Research / Environmental Chemistry; K.V. Thomas, QAEHS The University of Queensland

Non-target analysis (NTA) combined with high resolution mass spectrometry (HRMS) is considered the most comprehensive monitoring approach for characterization of the chemical exposome. NTA has thus far not fulfilled its promise of comprehensive analysis and been adopted as a routine approach due to the richness of HRMS data, sample complexity, and the challenges faced by the analysts to perform NTA. NTA data are typically very large (3-4 GB per sample), noisy, and complex so analysts must perform multiple data pre-processing steps to be able to identify features in a sample. These steps may include feature detection, feature prioritization, and database matching. Due to the complexity of these datasets, each step taken in an NTA workflow is prone to error and thus false detection. Here we present a collection of open source tools that we have developed to specifically improve and simplify the NTA workflow from feature detection to identification, while maintaining maximum transparency. These tools have been tested on complex environmental samples such as wastewater influent and wastewater sludge and have outperformed commonly used methodologies. Additionally, we present the implementation of these tools within the framework of an open access web platform. This cloud-based web platform will provide both a hub for data processing and a repository for data. The repository facilitates future analysis (i.e. retrospective NTA and/or suspect screening). We envisage that the platform will be a focal point for future developments in NTA.
248 Non-targeted analysis supported by data and cheminformatics delivered via the USEPA CompTox Chemicals Dashboard

A.J. Williams, US Environmental Protection Agency / National Center for Computational Toxicology; A. Chao, US Environmental Protection Agency / Office of Research and Development National Exposure Research Laboratory; T. Transue, T. Cathey, General Dynamics Information Technology; E.M. Ulrich, J.R. Sobus, US Environmental Protection Agency / Office of Research and Development National Exposure Research Laboratory

Non-targeted analysis (NTA) uses high-resolution mass spectrometry to better understand the identity of a wide variety of chemicals present in environmental samples (and other matrices). However, data processing remains challenging due to the vast number of chemicals detected in samples, software and computational requirements of data processing, and inherent uncertainty in confidently identifying chemicals from candidate lists. Analysis of the resultant mass spectrometry information relies on cheminformatics to identify and rank chemicals and the USEPA has developed functionality within the CompTox Chemicals Dashboard (https://comptox.epa.gov/dashboard) to address challenges related to this analysis. These tools include the generation of “MS-Ready” structures to optimize database searching, retention time prediction for candidate reduction, consensus ranking using chemical metadata, and in silico MS/MS fragmentation prediction for spectral matching. Combining these tools into a comprehensive workflow improves certainty in candidate identification. This presentation will review how the CompTox Chemicals Dashboard via its flexible search capabilities, rich data for ~875,000 chemical substances, and visualization approaches within this open chemistry resource provides a freely available software tool to support structure identification and NTA. This abstract does not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

249 Use of LC-HRMS to assess transformations of anthropogenic chemicals during anaerobic digestion

S.L. Nasan, Connecticut Agricultural Experiment Station / Environmental Science; C. Brueck, C. Prasse, Johns Hopkins University / Environmental Health and Engineering

Anaerobic digestion is an increasingly used technology to produce energy and recover resources from materials such as animal manure, food waste and sewage sludge. In the case of manure, the digested material is often applied on agricultural land as a fertilizer. Manure contains a variety of anthropogenic chemicals including antibiotics, antifungals, and insect repellents used to treat animals, as well as pesticides used on feed crops. Little is known about how these contaminants transform during anaerobic digestion, and whether they still have biological activity when they are land applied. This project focused on the application of liquid chromatography coupled with high resolution mass spectrometry (LC-HRMS) for the elucidation of contaminant degradation kinetics for several anthropogenic compounds and the identification of transformation products that are formed during anaerobic digestion of dairy manure. Digestion media samples were extracted using a modified QuEChERS method and analyzed using LC-HRMS in full MS mode with data dependent MS2 acquisition. We used a combination of literature review and pathway prediction software tools to compile a list of potential transformation products which were used for suspect screening analysis. We also used statistical methods including principle component analysis and volcano plots to visualize changes in the overall composition of the digestion media over time. In our initial experiments, we observed degradation of three out of eight tested compounds which were investigated further to identify potential transformation products. We were also able to demonstrate significant differences in the chemical composition of digested material between samples with and without contaminants added.

250 Mapping the chemical contaminant burden in lake trouts using a combination of targeted and non-targeted approaches

C. Simonnet-Laprade, INRA-LABERCA; S. Bayen, McGill University / Food Science and Agricultural Chemistry; D. McGoldrick, Environment and Climate Change Canada; T. McDaniel, Environment and Climate Change Canada / Water Quality Monitoring and Surveillance; P. Marchand, R. Cariou, B. Le Bizec, G. Dervilly-Pinel, LABERCA UMR1329 INRA / Oniris Laboratoire d’Études des Résidus et Contaminants dans les Aliments

Humans are exposed to a larger number of chemicals, notably through food consumption. In particular, fish is known to be a major route of exposure for a range of well-known toxic contaminants. To date, many efficient targeted analytical strategies allow for the determination of their concentrations in biological tissues. Such approach is however limited to known, regulated and/or suspected substances. This study proposes to establish a comprehensive strategy for characterizing the chemical contamination of fish samples using a combination of targeted and innovative untargeted mass spectrometry-based analytical procedures. Fish homogenates (n = 37, Lake trout Salevelinus namycush) were collected from Lake Ontario and Lake Superior (Canada) in August 2018. Several classes of organic contaminants of emerging concern (new brominated flame retardants, phthalates, bisphenols, chlorinated alkanes, organophosphate esters flame retardants) were analyzed using sensitive targeted analytical strategies. These methods rely on conventional extraction and purification steps, followed by analysis combining liquid or gas chromatography (LC/GC) systems coupled to conventional or high-resolution mass spectrometers (MS/MS or HRMS). In addition, an innovative untargeted global profiling was implemented to highlight emerging organo-halogen compounds. This strategy was applied to purified solvent extracts characterized with LC-HRMS (Q-Orbitrap spectrometer, scan mode analysis). The new ergonomic interface HaloSeeker v1.0 was used to automatically screen halogenated (Cl, Br) compounds on the basis of two properties: the discriminating mass defect engendered by heteroatoms and the highly specific isotopic patterns. Initial results from targeted methods show the presence of several halogenated compounds, including hexabromocyclododecane (HBCD, 9.2-26.6 ng g^-1) and lipids for the sum of α, β, and γ congeners). The compilation of data, via chenomometric methods, will be presented in the context of the exposure.

251 Identifying Toxicologically Significant Compounds in Urban Wildfire Ash using in Vitro Bioassays and High Resolution Mass Spectrometry

T.M. Young, University of California, Davis / Civil and Environmental Engineering; G. Black, University of California, Davis / Agricultural & Environmental Chemistry; M.S. Denison, University of California / Environmental Toxicology; G. He, University of California, Davis / Environmental Toxicology; C.F. Vogel, University of California, Davis / Center for Health and the Environment

As the risk for urban wildfires increases, a greater understanding of the potential chemical exposures associated with these fires is needed. The urban landscape includes not only trees and brush, but also building materials, including paints and other coatings, furniture and other durable goods, solvents, pesticides, plus all the other consumer products found in a typical home. A wide range of yet-to-be identified chemicals is likely to form when the broader mix of chemicals in homes are burned at high temperatures, with particular concern for combustion products resulting from burning chlorinated, brominated, or other halogenated compounds. Household-level composite ash samples were collected in Sonoma County, California, USA, soon after the Tubbs fire on November 1, 2017 (3 destroyed homes in each of 4 neighborhoods) along with 3 samples from an undeveloped site upwind of the burned residential areas. Samples were solvent extracted and the extracts were analyzed using high resolution mass spectrometry (gas and liquid chromatography with quadrupole time-of-flight mass spectrometers; GC-Q/TOF-MS and LC-Q/TOF-MS). Separate extracts were analyzed using a suite of in vitro bioassays for their bioactivity toward nuclear receptors (aryl hydrocarbon
receptor (AhR), estrogen receptor (ER), androgen receptor (AR)) and their influence on the expression of genetic markers of stress and inflammation (interleukin-8b (IL-8b), cyclooxygenase-2 (COX-2), and cytochrome P450 (Cyp1A1)). All genetic markers (Cyp1A1, IL-8b, COX-2) as well as the AhR activity were significantly higher in wildfire samples than in controls, while AR and ER activity were not. Samples from residential areas were not significantly different from ash samples from the reference site but substantial variability in bioactivity was observed across samples. Results of extensive suspect and nontarget screening to identify the chemicals responsible for elevated bioactivity using the multiple streams of HRMS data acquired and open source data analysis workflows based on the programs MS-DIAL and MS-FINDER are reported.

252 Suspect Screening of Indoor Pollutants with Reduced and Statistically Controlled False Discovery Rate
S. Kutarna, University of Toronto; H. Peng, University of Toronto / Department of Chemistry

Non-targeted analysis (NTA) with high-resolution mass spectrometry (HRMS) is a promising strategy to identify unknown pollutants in the environment. However one of the primary issues in NTA is a high false discovery rate (FDR). In addition, manual interpretation of mass spectrometry results leads to limited reproducibility. In this study, we developed a one-step automatic platform (R package) for suspect screening of pollutants in indoor dust, with reduced and statistically-controlled FDR. A post-acquisition mass calibration algorithm was also developed to improve the mass accuracy of Orbitrap mass spectrometers to sub-ppm. This reduced the searching space of indoor pollutants from the USEPA Toxic Substances Control Act (TSCA) chemical database by 4.3-fold. A robust scoring algorithm was established by incorporating isotopic peak distribution, mass tolerance, neutral loss, retention time prediction and in silico MS2 fragmentation patterns to rank the detected pollutants. A target-decoy database searching strategy was also proposed to statistically control FDR and determine the cutoff score. The in silico target-decoy based FDR matched well to the experimental FDR determined by authentic standards, indicating the good performance of the proposed strategy. With this platform, 596 pollutants were detected in 24 house dust samples in under 2 days, at 5% FDR. Many well-studied pollutants such as fatty acids, bisphenol A, phthalates, and flame retardants were detected as the most abundant chemicals. 46 chlorinated compounds were also detected including well-known triclosan and chlorine-containing organophosphate flame retardants. But the majority of detected chlorinated compounds have never been reported before in indoor environments and several of them were validated by commercially available standards. The automatic data analysis platform developed in this study will provide an important basis for future reproducible and FDR-controlled suspect screening studies.

253 Top-down exposomics of persistent and bioaccumulative organics
K. Pollitt, Yale University / Environmental Health Sciences; K.J. Jobst, McMaster University / Department of Chemistry and Chemical Biology; E.Z. Lin, Yale University / Environmental Health Sciences; J. Koelmel, Yale University / School of Public Health Environmental Health Sciences YSPH Global Health Concentration; L.S. Cahill, J.G. Sled, Hospital for Sick Children

The exposome represents all environmental exposures during the course of a lifetime. Persistent organic pollutants (POPs) are an important subset of environmental toxicants that exhibit common characteristics, such as persistence, toxicity and a tendency to bioaccumulate in wildlife and humans. The identity of most environmental toxicants and their impact on the environment and human health are unknown. This contribution reports on a sensitive, quantitative and high-throughput approach to identify new exposures, viz. Top-down analysis of 200 μL of serum using polydimethylsiloxane sorptive extraction. A set of legacy and emerging halogenated POPs were targeted by gas chromatography-high resolution mass spectrometry (GC-HRMS). Unknown and suspected POPs were screened from the complex HRMS data sets based on accurate mass and isotope ratio measurements using a script tool (R code). Experiments performed with standard reference materials (SRM 1957/1958, (non)fortified serum; and SRM 2585, household dust) showed good agreement with certified values. Method detection limits were constrained by background levels, in line with traditional methods. However, for polychlorinated biphenyls (PCBs) and selected organochlorine pesticides (OCPs), the detection limits are comparable to those reported by the National Health and Nutrition Examination Survey (NHANES). These methods were applied to a cohort (n=125) of pregnant mothers at low (n=57) and high (n=68) risk of placental insufficiency. Previous studies have established that exposure to PCBs can impact the vascular structure of the placenta, resulting in limited oxygen and nutrient transport with concomitant fetal growth restriction. Correlation analysis was performed to identify potential associations between unknown POPs and birth weight. Preliminary results indicate the presence of multiple classes of POPs, including number of unrecognized halogenated chemicals whose identities have not yet been reported.

254 Quantitative and Qualitative Assessment of Silicone Wristbands to Characterize the Personal Exposome using QC-HRAM MS
N.J. Herkert, Duke University / Civil and Environmental Engineering; E. Cooper, Duke University / Nicholas School of the Environment; G.J. Getzinger, Duke University / Civil and Environmental Engineering; K. Hoffman, Duke University / Nicholas School of the Environment; L. Trasande, New York University School of Medicine; L. Ferguson, Duke University / Civil and Environmental Engineering; H.M. Stapleton, Duke University / Nicholas School of the Environment

Silicone wristbands are becoming an increasingly important tool for characterizing personal exposures to organic contaminants. They have been used in a variety of applications to measure a wide range of chemicals including organophosphate flame retardants (OPFRs), brominated flame retardants, pesticides, polycyclic aromatic hydrocarbon, nicotine and others. Levels of SVOCs found on wristbands have been shown to correlate with levels in both serum and urine, suggesting they are capturing representative exposure data. In this study, wristband samples (n=110) from a pregnancy cohort in New York were analyzed with targeted methods for OPFRs, phthalates, PCBs, and pesticides, and a suspect screening approach was employed to characterize additional exposures in the wristbands using a Q-Exactive GC/IT and Orbitrap GC/MS- MS system (Thermo Scientific(TM)). In addition, all samples were analyzed for brominated flame retardants using a single quadrupole GC-MS (Agilent 6890N and 5975, respectively) operated in negative chemical ionization (ECNI) mode. Average percent recovery across all 21 isotopically labelled internal standards was 94%. Of the 85 target compounds 43 were detected above the MDL in more than 50% of the samples. Phthalates were the most prevalent chemical class, with Bis(2-ethylhexyl) terephthalate (DEHT) having the highest median concentration. Organophosphate flame retardants were the second most prevalent chemical class, triphenyl phosphate (TPHP) having the highest median concentration. More than ~8500 features were identified after deconvolution of the mass spectra when performing suspect screening. Approximately 350 of these features matched one or more of the three spectral libraries used and were detected in more than 50% of the samples. Unsurprisingly, many of these high confidence compounds were plasticizers and personal care product additives. Many of the compounds detected on the wristbands were significantly and positively correlated, and, based on responses, are likely present at levels similar to that of targeted plasticizers and personal care product additives, such as DEHT. These results suggest that pregnant women are exposed to hundreds of different chemicals in the ambient environment daily, and emphasize a need to further characterize these mixtures and their potential health impacts.
Microplastics in the Environment: Transport, Fate and Ecological Effects - Part 1

255 Microplastics in a global, multimedia context

R.C. Hale, College of William & Mary / Aquatic Health Sciences; M. Seeley, M.J. LaGuardia, Virginia Institute of Marine Science / Aquatic Health Sciences

Microplastics in the marine environment have garnered considerable attention recently. Some have suggested that they present dire consequences. Others have dismissed the issue as inconsequential. However, it is clear that plastic production and debris generation, the precursors to microplastics, are increasing globally at an alarming rate. Early research on microplastics has largely been descriptive. Published samplings vary widely in regards to what they collect. Analytical techniques are improving, but are still limiting (particularly for microplastics < 20 um). Thus, most studies underreport actual amounts in samples. Much research on environmental behavior, even in the lab, overlooks the reality that the plastic products in use are compositionally complex in terms of polymer type and additive content (on average 7% by weight). Add to that size, shape, form and texture elements. Understanding and solving issues related to the microplastics problem must consider their transient physical nature, i.e., as an intermediary class between macro- and nanoplastics. Also, most plastics are manufactured, used, and eventually discarded in the terrestrial environment. Thus, trying to solve the ocean microplastics issue by solely focusing on the oceans is destined to disappointment. Data on microplastic levels in vast expanses of the globe are still lacking. The African and Asian Pacific regions are expected to drive the increase in plastic demand in coming decades, but lack the infrastructure to manage resulting wastes. The effectiveness of wastewater treatment is over-estimated, as in many regions treatment is non-existent or primitive. Interestingly, waivers still exist for “primary-only” treatment for several large US and Canadian plants that discharge to the ocean based on a dilution of degradable contaminants argument. Even advanced treatment systems falter during severe storm events. Wastewater sludges, the repository for many of the microplastics removed, are often “recycled” into soils. This restarts their journey to the oceans via circuitous routes. We spend >90% of our lives in increasingly airtight enclosures (homes, workplaces, vehicles). Therein we are in close proximity to a vast array of plastics. Such plastics also have the greatest loads of toxic additives. Thus, consumption of microplastic-contaminated seafood is likely far less of a risk than indoor exposure.

256 A comprehensive model of macro-, micro- and nano-plastic fate and transport in catchment soils and surface waters

L. Nizzetto, M. Norling, R. Hurley, Norwegian Institute for Water Research; J. Crossman, University of Windsor; A. Rico, IMDEA Water Institute; J. Ledesma, Blanes Center for Advanced Studies / Integrative Freshwater Ecology; T.C. Schell, IMDEA Water Institute / Ecotoxicology; M. Futter, Swedish University of Agricultural Science / Aquatic Sciences and Assessment

Here, we present a new, catchment-scale model of plastic fate and transport built upon the existing INCA-Microplastics modelling tool. The new model operates at a daily time step and is forced by readily available climate and land use data. When available, observations of plastic stores and fluxes can be used to aid model calibration. The new model supports an arbitrary number of plastic types and size classes, facilitating simulation of the behavior in aquatic and terrestrial environments of macro-, micro- and nano-plastics. The model includes all key processes needed for credible simulation of plastic fate and transport in the terrestrial environment, including etheroaggregation. Time-varying plastic inputs associated with atmospheric deposition, biosolid application or unintentional release can be represented. The model simulates vertical movement of plastic particles in soil and lateral fluxes to surface waters. Physically based hydrologic and sediment mobilization routines allow for realistic simulation of plastic mobilization from and deposition to the streamed. Effects of weathering on plastic physical properties (e.g., density, mean particle size, surface charge, etc.) can be simulated. Importantly, this allows the model to capture the behavior of both virgin and aged plastic particles in soils and freshwaters. The model is implemented in the MOBIUS framework, a generic, open access model building platform which facilitates rapid prototyping of new model structures. We demonstrate the capabilities of the new model using data collected from urban and agricultural catchments in the UK, Canada and Spain. Our results highlight both the need for a comprehensive model of plastic fate and transport as well as unanswered research gaps needing further empirical study.

257 Primary and secondary nanoplastics have limited acute toxicity but chronic effects on Daphnia magna

G. Xu, McGill University / Department of Chemical Engineering; R. Cheong, McGill University; L. Liu, McGill University / Food Science and Agricultural Chemistry; L. Hernandez, McGill University / Chemical Engineering; A. Azimzada, McGill University; S. Bayen, McGill University / Food Science and Agricultural Chemistry; N. Tufenkji, McGill University / Department of Chemical Engineering

Microplastics (MPs) are ubiquitous in aquatic environments and their potential environmental impacts are of increasing global concern. Moreover, weathering of a single MP particle can yield billions of nano-plastics (NPs < 0.1 um), and the NPs are speculated to be a bigger threat due to higher environmental concentration and bioavailability. Primary NPs are originally manufactured to be that size, while secondary NPs originate from fragmentation. To date, little is known about the long-term impact of NPs in freshwater systems, particularly secondary NPs. Thus, we employed a freshwater model invertebrate, Daphnia magna, to investigate the chronic impacts of model primary NPs, fluorescence-labeled polystyrene NPs (PS-NPs), as well as plastic leachate that contained secondary NPs and plastic-associated chemicals. In the first experiment, parent Daphnia (F0) was exposed to 20 nm PS-NPs until the production of the first neonates (F1) followed by a two-generation recovery period. The PS-NP fluorescence was mainly detected in the gastrointestinal tract and brood chamber in F0 and transferred to the next two generations. Exposure to PS-NPs caused a concentration-dependent decrease in appendage curling rate but increased reproduction in F2. In the second chronic experiment, Daphnia exposed to plastic leachate showed reduced appendage curling rate but increased growth and reproduction, which could be due to the release of endocrine disrupting compounds. These results provide evidence that the acute toxicity of primary and secondary NPs was low even at high concentrations but their sublethal effects over long-term exposure should not be overlooked.

258 Microplastic co-occurrence with chemical contaminants in invasive mussels (Dreissena sp.) in the Milwaukee river watershed, Lake Michigan, USA

T. Hoellein, C. Rovegno, Loyola University Chicago / Biology; A. Uhrin, NOAA / Marine Debris Division; E. Johnson, NOAA/National Centers for Coastal Ocean Science / NCCOS Mussel Watch Program; C. Herring, IMSG/NOAA Marine Debris Program / Institute of Environmental Toxicology

Invasive zebra and quagga mussels (Dreissena sp.) in the Laurentian Great Lakes of North America serve as biomarkers for common legacy contaminants, but are also exposed to microplastic particles (<5nm in size), a contaminant of emerging concern. Little research has examined microplastic ingestion by dreissenid mussels, or the relationship between microplastic and common mussel contaminants. We measured microplastic abundance in mussels within the Milwaukee River and harbor of Lake Michigan, USA. Reference mussels were collected from open water in Lake Michigan and deployed in cages at 4 locations in the river and harbor in June 2018, representing a gradient of influence from wastewater effluent and river discharge. Mussels were collected after approximately 30 and 60 days in situ, sorted according to size class, and analyzed for microplastic and legacy contaminants in the soft tissue.
Surface water samples were collected simultaneously with caged-mussel recovery and analyzed for microplastic and legacy contaminants. We expect the largest mussels from sites adjacent to wastewater outfalls to have the greatest abundance of microplastic and legacy contaminants. These data will also be combined with concurrent research on microplastic in surface water, sediment, and fish in the Milwaukee River watershed. Overall, results will reveal the potential utility of dreissenid mussels as biomonitor of microplastic pollution, the impact of microplastic on mussels, the relationship between emerging and legacy chemical pollutants, and inform models of chemical contaminants in the Great Lakes and other freshwater ecosystems.

259 Microplastics in municipal mixed-waste organic outputs induce minimal short to long-term toxicity in key terrestrial biota

J. Judy, University of Florida / Soil and Water Science; M. Williams, A. Gregg, CSIRO Land and Water; D. Oliver, CSIRO; A. Kumar, CSIRO / Land and Water; Program- Environmental Contaminant Mitigation and Biotechnology; R.S. Kookana, CSIRO / Land and Water; J. Kirby, CSIRO / Advanced Materials Transformational Capability Platform Land and Water

Sustainable alternatives to landfill disposal for municipal mixed wastes represents a major challenge to governments and waste management industries. In the state of New South Wales (NSW) Australia, mechanical biological treatment (MBT) is being used to reduce the volume and pathogen content of organic matter isolated from municipal waste. The product of this treatment, a compost-like output (CLO) referred to as mixed waste organic output (MWOO), is being recycled and applied as a soil amendment. However, the presence of contaminants in MWOO including trace organics, trace metals and physical contaminants such as microplastic fragments has raised concerns about potential negative effects on soil health and agriculture following land application. Here, we used multiple lines of evidence to examine the effects of land application of MWOO containing microplastics in three soils to a variety of terrestrial biota. Treatments included unamended soil, MWOO-amended soil and MWOO-amended soil into which additional high-density polyethylene (HDPE), polyethylene terephthalate (PET), or polyvinyl chloride (PVC) microplastics were added. Tests were conducted in soil media that had been incubated for 0, 3 or 9 months. Addition of microplastics had no significant negative effect on wheat seedling emergence, wheat biomass production, earthworm growth, mortality or avoidance behaviour and nematode mortality or reproduction compared to controls. There was also little evidence the microplastics affected microbial community diversity, although measurements of microbial community structure were highly variable with no clear trends.

260 Fragmentation rate of micro and nano-particles from expanded polystyrene by sunlight exposure

Y. Song, S. Eo, Korea Institute of Ocean Science and Technology (KIOST); S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs Research Group; W. Shim, Korea Institute of Ocean Science and Technology

The expanded polystyrene (EPS) is one of common plastic debris items in both freshwater and marine environments worldwide. In addition, its gas-blown foamed structure can be susceptible to physical and chemical weathering. However, fragmentation process of EPS, making a micro- and nanoplastics, by sunlight exposure remains largely unknown. We aimed to quantitatively determine micro- (0.8-500 µm) and nanoparticles (2-800 nm) of EPS produced by sunlight exposure including size distribution. The unique ‘foamed’ structure which has many pores inside produced micro- and nano-sized particles in flat, laminar and irregular shape by sunlight exposure. The abundance of produced particles increased by increasing sunlight exposure duration (micro particles: 3.4 x 106 ± 1.7 x 105 – 6.7 x 107 ± 1.1 x 107 particles/cm2 exposed EPS surface area and nanoparticles: 4.0 x 107 ± 1.2 x 107 – 5.7 x 108 ± 2.9 x 108 particles/cm2), and the average size of fragmented EPS particles were in the range of 2.03-2.88 µm for microparticles and 138-189 nm for nanoparticles, respectively. The abundance of microparticles increased by decreasing size, but nanoparticles showed bimodal size distribution based on 100 or 80 nm. The 50% weight loss of EPS cube by sunlight weathering is estimated to be in 3.49 years, and approximately 2.6 x 108 particles/cm2 fragmented particles could be produced in one year by sunlight exposure according to linear regression equation ($y=99.3-0.00283x$, $r^2=0.98$, $p<0.01$ for weight loss and $y=-16295045+55231x$, $r^2=0.94$, $p=0.01$ for produced particles). Many of EPS debris in the environments directly exposed to sunlight can produce substantial number of micro- and nano-sized particles within relatively short time.

261 Leaching of additives and fragmentation of plastics in semi-terrestrial environments

T. Hüffer, T. Hofmann, C. Henkel, University of Vienna / Environmental Geosciences

The pervasive use of plastics together with inadequate waste management has led to a global contamination of ecosystems with end-of-life plastic products. Global plastic pollution has been shown to pose a planetary threat because it is causing planetary-scale exposure that is not readily reversible. Plastic particles released in the environment are subjected to various aging process including biotic (biofilm formation) and abiotic aging (UV radiation, oxidation, and physical stress). These processes lead to an alteration in the physical and chemical properties of the polymeric particle and may ultimately result in an embrittlement and fragmentation. The additive release in turn depends on the chemical compatibility of the additive with the polymer, the exposure and aging of the plastic in the environment, and the type of bonding between the additive and the polymer (chemical or physical). The aging of plastic particles under environmental conditions, the leaching of plasticizers, and the fragmentation of are among the most pressing research priorities in microplastic exposure and risk assessment. In this contribution, the current understanding of abiotic polymer aging in the aquatic environment and its role in the release of polymer plasticizers will be addressed for the example of polyvinyl chloride. While the release for example of bis(2-ethylhexyl) phthalate from polyvinyl chloride used as medical devices (e.g. blood bags) or children articles has been studied quite intensively there is very little information on the release of plasticizers from polyvinyl chloride plastics into aquatic environmental systems, and how aging influences polymer properties and additive release. Results from a recent mesocosm study within the AQUACOSM project will be presented, where these processes were investigated for polyvinyl chloride plastic test bodies containing two most commonly encountered additives using stream pond systems mimicking semi-terrestrial environments.

262 Riverine plastic inputs to global oceans

L. Mai, E.Y. Zeng, Jinan University / School of Environment

Plastic pollution has caused increasing global concern. Currently, model estimates of the riverine plastic inputs to global oceans based on the concept of Mismanaged Plastic Waste (MPW) varied substantially, and no field measurements of riverine inputs are available. We have conducted sampling at the eight major river outlets of the Pearl River Delta, South China with rapid economic growth and urbanization, to provide field measured data for developing a more objective model. Here we present a robust model for accurate estimation of riverine plastic inputs to global oceans, based on the Human Development Index (HDI), population density and water discharge. We estimate that approximately 1.73-2.46x10^6 tons of plastic waste enters the oceans annually from global rivers. Riverine plastic pollution stresses global oceans, especially the North Pacific Ocean, which receives about 0.12 million tons of plastic waste from rivers every year. Finally, we predict the future riverine plastic inputs trend. With the development of humanity, annual riverine plastic inputs will reach a peak of 0.27 million tons by 2025 and decrease gradually.
Creating Pathways to Restoration in the Great Lakes: Addressing Beneficial Use Impairments in Areas of Concern

263 Tracking Restoration Progress in the Great Lakes

B. Benson, ORISE at USEPA / GLNPO; A. Pelka, US Environmental Protection Agency / GLPO; M. Tuchman, USEPA / Great Lakes National Program Office; M. Loomis, US Environmental Protection Agency / HQ

Within the Great Lakes Restoration, significant funding has made for multiple opportunities to restore the Great Lakes. In Focus Area 1, the Environmental Protection Agency’s Great Lakes National Program Office (GLNPO) oversees the restoration of the Areas of Concern (AOCs) in the Great Lakes. There are 43 AOCs between the US and Canada and are in various stages of remediation and restoration, including sediment remediation and habitat restoration. There are a variety of metrics that have been employed to track specific projects within the AOCs. However, due to the variations and complexities of projects, habitat specific metrics are difficult to standardize and quantify. Project area size and level of degradation vary widely between AOCs. These variations along with the different restoration approaches state and local groups choose, lead to a host of issues tracking habitat restoration effectiveness in a uniform manner. The implementation of a habitat tracking matrix will allow for better tracking of environmental improvement using habitat specific metrics to assist in decision making and reporting, as well as, establishing efficacy and best practices. This presentation will describe the matrix, what measures are being tracked and preliminary analyses of projects tracked thus far.

264 Community Revitalization in the Great Lakes: assessing ecological indicators in stimulating a water-based community identity in Areas of Concern

C. Norris, USEPA GLNPO / Remediation and Restoration; A. Pelka, US Environmental Protection Agency / GLPO; K. Fritz, USEPA / ORD NHEERL; M. Mills, US Environmental Protection Agency / National Risk Management Research Laboratory

The Great Lakes region has a rich history as the “rust belt” of the U.S. This industrialization around the Great Lakes resulted in economic prosperity as well as environmental contamination. As an outcome, 43 highly degraded coastal communities throughout the Great Lakes were designated as Areas of Concern (AOCs) in the 1987 Great Lakes Water Quality Agreement. The AOC program utilizes 14 predefined Beneficial Use Impairments as indicators of ecological health, including Restrictions on Dredging Activities and Loss of Fish and Wildlife Habitat. When remediation and restoration actions have occurred such that a beneficial use impairment can be removed, this is an indication of significant environmental improvement. As remediation and restoration work is completed and BUIs are removed communities have begun to see not only environmental improvements but subsequent social and economic benefits. Communities have embraced these benefits and their newly cleaned waterways creating a new water-based identity and investing in revitalization. This is known as the R2R2R framework: Remediation to Restoration to Revitalization. Except for economic measures, measures of revitalization in AOCs and the linkage to environmental health have only been anecdotally reported. As a complex and potentially contentious topic, holistically understanding the features of revitalization is imperative. We compiled and analyzed over 15 datasets on revitalization in the Great Lakes and delineated themes and metrics representing social, economic, and environmental factors and examined their prevalence, diversity, and distribution. This will aid in normalizing the conversation on what revitalization is and means. This exploratory study then utilizes the R2R2R framework to examine how restoring beneficial use impairments in AOCs (R1+R2), leads to community revitalization (R3) as seen in the investment and community involvement in forming a sustainable water-based identity.

265 Using a weight of evidence approach and design optimization to balance remediation and restoration design goals at Spirit Lake

Spirit Lake is part of the St. Louis River Area of Concern. Under the Great Lakes Legacy Act, the U.S. Environmental Protection Agency is working with a non-federal project partner to collaboratively design environmental remediation and restoration for the lake to address chemical constituents in sediment potentially associated with beneficial use impairments. The remedy includes capping, enhanced monitored natural recovery, monitoring natural recovery, and dredging, with placement of dredged material in on-site confined disposal facilities. First, chemical analytical data and lithology were spatial modeled to determine the general extent of chemical constituents. Next, a point by point review of chemical and lithologic data was performed together with project regulators and stakeholders to better understand the conceptual site model and match remedial technologies to target areas and target depths. Target areas were then considered in light of 5 factors: minimum capping thicknesses indicated by Minnesota Pollution Control Guidance; target post-remedy depth regimes for habitat restoration which seeks to restore fisheries and wetland vegetation; total anticipated dredge volumes and capacity limitations of the confined disposal facilities; shoreline and slope stability factors that may constrain the geometry of dredge cuts. All of these factors were weighed when developing dredging prisms. The result was a multi-component design that optimized the use of each remedial technology to achieve goals for chemical concentrations while constraining CDF size and providing desirable depth regimes for habitat restoration.

266 Attention to organizational and operational processes underpins effective public engagement in environmental remediation and restoration

P. Seelbach, J. Wondolleck, University of Michigan / School for Environment and Sustainability

Community perspectives are a desired and required component of ecosystem-scale environmental remediation and restoration efforts. It is common for remediation programs to set a process for community engagement in motion, often as some form of Public Advisory Council (PAC), assuming that such processes will work effectively. However, our close examination has revealed notable variation in Michigan AOC PAC form, function, and effectiveness (and too often, ineffectiveness). Group process elements that are generally accepted and perhaps initially implemented are often forgotten in the everyday hustle to accomplish on-ground project results. PAC effectiveness requires active attention to some generally accepted organizational and operational process principles that are a required compliment to standard outcome-focused activities. PAC experiences over many years and across numerous ecosystem-scale initiatives provide insights for improved practice. Here we synthesize key lessons about effective public process from global case studies of marine ecosystem management combined with those from recent assessments in Michigan Areas of Concern. We present: (1) convergent lessons from our two ecosystem sets emphasizing that active attention to organizational and operational processes is required to achieve effective and durable public engagement; and (2) a menu of key process strategies and principles. This guidance is applicable to remediation and restoration efforts within and beyond the Great Lakes.

267 Early Stage Post-Remediation Recovery of Benthic Invertebrate and Fish Communities Within the Buffalo River, NY

K.B. Leigh, Ramboll; P.A. Leitman, Ramboll / E&H; M.T. Sorensen, Ramboll; K. Sarcy Bell, Ramboll; V.S. Magar, Ramboll US Corporation / E&H; R. Galloway, Honeywell

The Buffalo River sediment remediation was completed in 2015 under the Great Lakes Legacy Act. The 79-acre remedy included dredging 440,000
cubic yards of material, cap placement in an adjoining area, and backfill at selected locations. The remedy was designed to achieve remedial goals for PCBs, mercury, lead, and PAHs within five years following remediation. Five habitat restoration projects were also constructed within the Buffalo River Area of Concern (AOC). In agreement with USEPA’s Great Lakes National Program Office, post-remediation monitoring was required two and five years after remedy construction to assess the effectiveness of the remedy and document progress towards achieving remedial goals. In 2017, Year 2 verification monitoring was implemented, including sediment sampling, bathymetric surveys, benthic invertebrate and fish community surveys, and habitat restoration area monitoring. Benthic and fish community surveys were conducted to contribute to the data needs required for removal of Buffalo River AOC beneficial use impairments. Community survey locations were generally consistent with locations used during the 2008 baseline (pre-remediation) sampling. Benthic surveys included both sediment grab samples and multiplate samples, consistent with New York State Department of Environmental Conservation and USEPA Rapid Bioassessment Protocols. Benthic surveys were conducted at five locations within the Buffalo River, one in-stream reference location, and one out-of-watershed reference location. Fish community surveys used a boat-mounted electrofishing unit and were conducted at three locations within the Buffalo River and one in-stream reference location. Results of the Year 2 monitoring were compared to baseline conditions using a variety of species-specific metrics to determine community condition and impairment of the water body along a spectrum from no impact to severe impact. Benthic community data show modest improvement over time in some areas, while other areas show slight declines or no change over time. Overall, fish community data show no change or a very slight improvement over time. The Year 2 community survey results represent a snapshot in time during an early stage of the recovery and will be used to reassess the recovery during the next sampling event in 2020.

268 A program for assessing Beneficial Use Impairments and emerging contaminants in fish-eating birds at Areas of Concern and other Great Lakes sites

K. Grasman, Calvin University / Biology; L.L. Williams, M. Annis, C. Eakin, US Fish and Wildlife Service

Significant concentrations of persistent organic pollutants (POPs) including polychlorinated biphenyls (PCBs), chlorinated dioxins and furans, and organochlorine pesticides have contaminated the Great Lakes since their introduction during the 1940s-60s. Studies from the late 1960s onward have shown that fish-eating birds of the Great Lakes are excellent sentinel species for assessing and monitoring effects of contaminants including reproductive problems, deformities, and immune suppression. Two wildlife-related Beneficial Use Impairments (BUIs) at Areas of Concern (AOCs) are recognized by the Great Lakes Water Quality Agreement: 1) bird or animal deformities or reproductive problems and 2) degraded fish and wildlife populations. A current question under the Great Lakes Restoration Initiative (GLRI) and other federal and state AOC programs is whether these impairments continue. Furthermore, more recently bioaccumulative contaminants of emerging concern (CECs) have been found in Great Lakes wildlife, raising the question of whether these CECs are associated with reproductive, health and (or) population-level effects. This talk will present the tools and key results of a monitoring program studying fish-eating birds to reassess these BUIs and potential associations with legacy POPs and CECs. In the Saginaw Bay and River Raisin AOCs and Grand Traverse Bay during 2010-19 under the GLRI and AOC programs of the US Fish and Wildlife Service and US Environmental Protection Agency. Embryonic nonviability (elevated infertility and mortality) through late incubation in herring gulls in the Saginaw Bay (6.6%) and River Raisin (8.1%) AOCs and in Grand Traverse Bay (8.7%) was significantly higher than at the reference site (3.1%). Deformities associated with PCBs and dioxins were found in several embryos and chicks only at AOCs. Chick productivity in Caspian terns in Saginaw Bay was significantly below that of reference sites. In the River Raisin AOC, productivity of gull chicks was very poor in 4 of 9 years, with complete reproductive failure during 2010. The mean phytotoxemagglutinin (PHA) skin response for T-cell mediated immunity was suppressed 54-56% in gull chicks at both AOCs and 48% in terns and 39% in herons in Saginaw Bay and also was suppressed 50% in Grand Traverse Bay gulls. This monitoring program has demonstrated continuing wildlife BUIs at two AOCs and provides a model for assessments that could be applied at other AOCs to support management decisions.

269 Voluntary Investigation, Remediation and Restoration of a Segment of the Detroit River Area of Concern

The Monguagon Creek-Upper Trenton Channel (MCUTC) Site is located within the Detroit River Area of Concern (AOC) and is being investigated, remediated and restored under the Great Lakes Legacy Act by US Environmental Protection Agency (EPA), US Army Corps of Engineers, and Bridgestone Americas Tire Operations, LLC (BATO). Nine beneficial use impairments (BUIs) remain in this AOC. Largely channelized and culverted, MCUTC is located within an industrialized area of Riverview, MI, which had received direct discharges of manufacturing wastes for decades. BATO proposed to cooperate with EPA to ensure that the MCUTC portion of the Upper Trenton Channel would be addressed. EPA led the preparation and completion of the remedial investigation in YEAR, and BATO led the preparation and completion of the feasibility study (FS) in 2018. Of four site-specific remedial action objectives (RAOs) developed in the FS, one aimed to restore beneficial uses within the Detroit River AOC by reducing the mass, volume, and concentrations of polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), mercury, and lead in MCUTC sediment. Cleanup goals were set equal to a PAH toxic unit of 1 to 4 and remedial alternatives focused on four areas of interest (AOIs). Remedial technologies were first screened to allow detailed evaluation of only the five most feasible, effective and cost-effective remedial alternatives. Those five alternatives were evaluated with respect to overall protection of human health and the environment, attainment of RAOs, long-term effectiveness and permanence, reduction of mass, toxicity, mobility or volume through treatment, short-term effectiveness, implementability and cost. Remediation Alternative 3 (enhanced monitored natural recovery in AOI-C and dredging in AOI-D) was selected as the preferred alternative. Benefits of this remedy include its implementability, given the underground utilities in AOI-C and the steep bathymetry in AOI-D, and its short-term and long-term effectiveness. BUIs expected to benefit from this remediation project include fish tumors and other deformities, degradation of aesthetics, degradation of benthos, and loss of fish and wildlife habitat. Planning is underway to complete a pre-design investigation this year.

270 Characterizing sources, biogeochemistry, and accumulation of Hg in food webs of the St. Louis River Area of Concern

The St. Louis River Area of Concern (AOC) was designated in 1987 due to Beneficial Use Impairments (BUIs), including “Restrictions on Fish and Wildlife Consumption” (BUI 1) from historical pollutants. Minnesota and Wisconsin posted fish consumption advisories for the St. Louis River, in part, because fish have elevated mercury concentrations.
Mercury bioaccumulation in the food web can be from legacy sources in sediment and from present-day ambient sources (from both local, regional, and global sources). In 2017 a study was conducted which had four goals to support the understanding of Hg sources in the AOC: 1) Compare mercury methylation and bioaccumulation by characterizing the macroinvertebrate assemblages, geochemistry, ecosystem type, and food web structure between the AOC and a reference location (Bad River); 2) Compare age- and size-specific mercury residues in select fish species between the AOC and Bad River; 3) Trace food web pathways and identify mercury sources in select fish species using stable isotopes of carbon and nitrogen. 4) Develop a mercury-specific BUI restoration target for the AOC derived from the long-term, post-remediation projected change in fish mercury residues based on the inferred differences in mercury-source bioaccumulation between the AOC and Bad River. For each location, up to five samples each were collected for mayfly (Hexagenia) larvae, dragonfly larvae, riparian spiders, and a composite benthic invertebrate assemblage sample using multi-plate artificial substrate samplers. We deployed artificial substrates to collect macroinvertebrates in order to assess Hg accumulation and biotic condition across the St. Louis AOC and Bad River. When artificial substrates were retrieved, 12 of 14 were disassembled, scraped, sieved and then picked for biomass. The remaining two samplers were set aside for identification and metabarcoding to assess similarity in benthic communities. Macroinvertebrate assemblage (traditional identification and metabarcoding), stable isotope analyses, water, sediment and biota mercury, plus other water quality analyses will be presented and discussed.

Systematic Review for Robust Reporting and Evaluation of Environmental Toxicology Data for Risk Assessment

271 Systematic Review for Robust Environmental Assessments

J. Nichols, E. Lavoie, US Environmental Protection Agency / National Center for Environmental Assessment

Chemical and environmental assessments are the scientific basis of many policies and regulations aimed at protecting human health and the environment. As the breadth and depth of scientific evidence has expanded, the complexity of weighing, integrating and synthesizing the evidence has grown. Major elements of risk assessment development are literature identification, study evaluation and data extraction, synthesis, and integration of evidence to draw conclusions, and systematic review requires structured, predetermined and transparent process. Systematic review methodologies are being adapted and expanded in the field of environmental risk assessment and present an important opportunity for rigor in assessments. The attributes of systematic review are advantageous to assessors, decision makers and the public in being able to understand what evidence conclusions are based on and the degree of confidence in the conclusions. While the structured methods and frameworks provide transparency and consistency, expert scientists remain critical to the success of a systematic review and interpretation of the evidence. In this presentation, we will provide a succinct introduction to the systematic review paradigm with specific examples of systematic review steps in chemical and environmental assessments, including the benefits and challenges that are commonly encountered. This presentation is designed to introduce the session and set the stage for the audience.

272 SETAC Strides Towards Toxicity Data Transparency

T.H. Schlekat, J. Lynch, SETAC

Current practices in environmental management of chemicals rely heavily on human and ecological toxicity data. More specifically, chemical hazard and risk evaluations used to inform management decisions are often based on exposure and effects data related to biological pathways. There is a clear need for a global knowledge base of toxicity data that is comprehensive yet flexible. However, setting up such a database, curating data, and making it open and accessible is a daunting task due to the vast amount of chemicals currently in commerce and those entering the industrial stream every day, and the accompanying number of research studies on those chemicals. This is a global conundrum that would benefit from a global harmonized approach. SETAC, as a global society open to all stakeholders, is uniquely placed to lead the way in tackling that challenge. SETAC has the ability to reach across boundaries whether geographic or organizational, build bridges, and facilitate fruitful knowledge exchange and collaboration. SETAC staff and volunteers have teamed together to develop a roadmap for collaboration with the goal of advancing the current state of various toxicity data curation. They are identifying initiatives at every point in the cycle of developing toxicity data that should encourage data transparency and study reporting and ultimately lead to more comprehensive and flexible toxicity knowledge bases. This presentation will identify a few of those initiatives, action taken, and tasks yet to be claimed with the hopes of reaching enthusiastic volunteers willing to help SETAC lead the way.

273 Application of Systematic Review in Ecological Hazard Evaluations under the Toxic Substances Control Act

A. Nguyen, US Environmental Protection Agency / ORD; K.M. Eisenreich, US Environmental Protection Agency / Office of Pollution Prevention and Toxics

EPA’s Office of Pollution Prevention and Toxics (OPPT) is implementing systematic review for ecological hazard assessments under the Toxic Substances Control Act (TSCA) as amended by the Frank R. Launtenberg Chemical Safety for the 21st Century Act. It consists of developing a structured process to search, screen, evaluate, extract and integrate ecological hazard data to support the TSCA risk evaluations on existing chemicals that EPA designated as high priority substances. In May 2018, EPA issued guidance titled “Application of Systematic Review in TSCA Risk Evaluations.” As discussed in the guidance, OPPT leveraged EPA’s ECOTOXicology knowledgebase (ECOTOX) as a source of single chemical toxicity information. Title/abstract and full-text screening decisions were based on the modified ECOTOX minimum applicability criteria that parsed citations into “on-topic” and “off-topic” bins. The “on-topic” references were further subjected to a full-text screening step to confirm relevancy. Only citations that fulfilled the full-text screening criteria moved to the data evaluation step. Reviewers used a newly developed scoring method to assess the quality of data sources as acceptable (i.e., high, medium, or low), not applicable, or unacceptable for risk evaluation purposes. According to the “Application of Systematic Review in TSCA Risk Evaluations” guidance document, OPPT considered the ECOTOX criteria and the Criteria for Reporting and Evaluating ecotoxicity Data (CRED) along with professional judgment when developing the data evaluation criteria. Information with acceptable quality served as the basis for hazard characterization and were extracted and integrated into the TSCA risk evaluations on high priority substances. This presentation will provide details about the systematic review process for ecological hazard information using examples from the first ten TSCA risk evaluations. It will also discuss how OPPT is leveraging systematic review tools for ecological hazard data and share current challenges as well as opportunities geared towards improving the current process.
274 Using Deep Learning and Active Learning Methods to Streamline Literature Curation for the Ecotoxicology Knowledgebase

B.E. Howard, R. Shah, A. Tandon, Sciome, LLC; A. Merrick, NIEHS; J.H. Olker, US Environmental Protection Agency / Office of Research and Development / National Health and Environmental Effects Research Laboratory / Mid-Continent Ecology Division; C. Elonen, D.J. Hoff, US Environmental Protection Agency / Office of Research and Development

The ECOTOXicology Knowledgebase (ECOTOX) is a comprehensive, publicly available knowledgebase providing single chemical environmental toxicity data on aquatic life, terrestrial plants and wildlife. The ECOTOX database (as of March 2019) contains data for 11,695 chemicals and 12,713 species manually extracted from 48,464 references. The database is updated quarterly, and to identify relevant references and extract pertinent data, the ECOTOX data curation pipeline employs a methodical, multi-step process roughly equivalent to the initial stages of systematic review. This labor-intensive workflow requires human curators to regularly evaluate tens of thousands of candidate references, the majority of which are then rejected as not relevant. To streamline this process, we have recently evaluated the feasibility of using machine learning methods to automatically classify documents according to relevance, and to identify the exclusion rationale for those references that are excluded. Using a massive historical database containing hundreds of thousands of manually-screened references, we train a deep learning, neural language-model classifier to predict the relevance of new candidate references. References designated as excluded are further classified according to exclusion rationale and, using an attention mechanism built into the deep learning classifier, supporting passages are highlighted in the abstract. These models serve as a baseline classification method, subject to human intervention, which is then refined for each chemical-centric batch of new candidate articles according to user feedback within an active learning framework. Our approach is operationalized in the form of a modified version of the SWIFT-Active Screener software application, a collaborative web-based reference screening platform. We anticipate that deployment of this tool as part of the ECOTOX curation pipeline will result in more than a 50% reduction in the time spent screening references for relevance.

275 USEPA Office of Water’s Systematic Review Process for Aquatic Life Water Quality Criteria and Coordination with Environment and Climate Change Canada

The US Environmental Protection Agency (USEPA) Office of Water’s (OW) Ecological Risk Assessment Branch develops national aquatic life and aquatic-dependent wildlife Ambient Water Quality Criteria (304(a) criteria). Criteria are recommendations that states and tribes can use in developing their state water quality criteria and standards. State water quality criteria are used in setting permit limits of chemical releases in effluents under the National Pollutant Discharge Elimination System (NPDES) program, assessing water bodies, making impairment listings, and setting Total Maximum Daily Loads (TMDLs) for impaired waters. In developing robust Ambient Water Quality Criteria, OW completes systematic reviews of open literature publications, government reports and other data reports on the ecotoxicity of various chemicals. OW has recently formally documented its long-standing systematic review process in a Systematic Review Standard Operating Procedure and associated fillable Data Evaluation Record templates for various aquatic and aquatic dependent taxa. OW has been harmonizing its systematic review approach, where appropriate, with EPA’s Office of Pesticide Program and Office of Pollution Prevention and Toxics, and has initiated an effort with EPA’s Office of Research and Development to examine the feasibility of automating aspects of OW’s data quality review to streamline and expedite the process. OW has also been working with Environmental and Climate Change Canada to compare systematic review processes in order to examine opportunities to collaborate on data quality review and maximize efficient use of resources. This presentation will provide an overview of OW’s systematic review process and will describe OW’s vision and ongoing efforts to harmonize and streamline data quality review working across EPA and with external partners.

276 Separating the wheat from the chaff: objective evaluation of ecotoxicity data for use in ecological risk assessment

J.M. Guidings, C. Habig, Compliance Services International; L.W. Brewer, Compliance Services International / Department of Wildlife Toxicology; J.R. Wirtz, J.M. Stafford, Compliance Services International

While much of the progress made in ecological risk assessment has come through improvements in methodology, it has always been recognized that any assessment must be demonstrably based on sound, relevant data. Incorporating data into risk assessment involves searching for and selecting publications and reports, acquiring the selected documents, evaluating each study for relevance and reliability, extracting study data pertinent to the objectives of the assessment, and analyzing the data with a consideration of their quality. This presentation will review typical data evaluation criteria with particular attention to study relevance, test substance identification, methodological details, and exposure-response trends. Examples will be presented from aquatic, avian, and pollinator studies with pesticides. An aquatic toxicity database for pyrethroid insecticides will be discussed as a case study. The database includes data from more than 300 registrant-submitted Good Laboratory Practice (GLP) studies and a similar number of open-literature publications and reports. A large fraction of the open-literature studies were incompletely documented, making data evaluation difficult and resulting in reduced data quality scores. Some studies were considered unusable and rejected due to ambiguities (e.g., test substance identity, exposure concentration units); very rarely, data were rejected because they were evidently erroneous or (in one case) apparently fraudulent. The presentation will discuss the kinds of information that should be reported (or made available as supplementary information) in an open-literature publication to enable data quality evaluation as well as interpretation of results. We will also address the use of data quality evaluation results (e.g., scores for relevance and reliability) in a Weight of Evidence analysis.

277 Lessons learned from three systematic reviews of mercury and selenium across multiple models and use contexts

N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences

Here I outline three systematic reviews recently completed (or underway) in my research team, and focus on lessons learned. The first review was a World Health Organization (WHO)-led initiative that aimed to increase worldwide understanding of human exposures to mercury in support of the 2018 UN Global Mercury Assessment. The work captured 424,884 mercury biomarker measures taken from 336,015 individuals represented in 312 articles from 67 countries, and was recently published in Environmental Health Perspectives. The second review is underway and aims to increase understanding of mercury exposure worldwide through cosmetics. The third review is also underway and aims to assess study quality and relevance (physiological, environmental) of in vitro studies concerning selenium. I will offer a brief overview of each study, and then I will focus the presentation on lessons learned in conducting systematic reviews of environmental toxicological data. Specifically, I will highlight: a) the need to plan carefully, pilot ideas, and iterate and scale-up activities prior to conducting the definitive review; b) strategies to remain organized and document steps; c) concerns over sustaining and updating the reviews; and d) concerns of study quality in the peer reviewed literature.
278 Evidence mapping for use in human health and ecological chemical assessments

Transparent, methodologically rigorous, and rapid approaches are needed for conducting and updating human health and ecological chemical assessments. Evidence maps, also referred to as systematic maps, are useful for systematic review analysis. An evidence map includes a systematic and documented literature and/or toxicity data base search strategy and efficient review of potentially applicable toxicity data. Ideally, an evidence map also includes a quality evaluation of the applicable data, a summary of informative effect thresholds for pertinent biological endpoints and a process that encourages quality reviews. The utility of an evidence map is demonstrated by its ability to inform the scope and level of effort required for a full assessment and to reveal gaps in knowledge and/or future research needs. Data summaries are presented in a user-friendly visualization format, or a searchable database. With the use of specialized software applications and integrating results of existing data curation databases (e.g. ECOTOX Knowledge base), preparation of an evidence map can be rapid, on the order of weeks. This presentation will present examples of integrated human health and ecological evidence maps with a focus on the application of each to risk assessment. In addition, this presentation will discuss the usefulness of evidence maps in determining whether updates are needed for existing assessments. Finally, the presentation will discuss software, staffing model, and project management approaches to track and expedite systematic reviews and the development of evidence maps.

Pesticides and Pollinators: Assessing Potential Risks at Colony and Population Level

279 Challenges and successes with tiered testing for pollinator protection in a regulatory framework

With the recent development of the harmonized pollinator risk assessment framework for the U.S. and Canada, there is increased emphasis on a tiered approach for assessing risk of pesticides to bees. The Tier I level includes consideration of laboratory studies which assess both acute and chronic effects to larvae and adults at the individual level. Studies considered at higher tiers include semi-field, residue and feeding studies (Tier II), and field studies (Tier III), which are intended to provide more realistic information on exposure and include colony level effects. Tier II colony feeding studies, can provide dose related colony effects over longer observation periods. However, these studies have typically focussed on exposure through sucrose solutions rather than exposure from contaminated pollen. Tier III field studies can also provide longer observation periods, however, the amount bees forage on the test crop can be highly variable. Overall, each level of the tiered approach provides useful information in the pollinator risk assessment, however, each tier and related studies also include uncertainties which must be considered when evaluating the potential risk from pesticides. This presentation highlights the challenges and successes we have experienced from a regulatory perspective working within the pollinator protection framework, and in particular for higher tier studies.

280 USEPA’s Neonicotinoid Bee Risk Assessments

In 2016-2017, the U. S. Environmental Protection Agency (EPA) issued Preliminary Bee Risk Assessments for the neonicotinoids imidacloprid, clothianidin, thiamethoxam and dinotefuran. We present the results from the tiered risk assessment that integrates lines of evidence from individual level and colony level effects, including laboratory toxicity studies, colony feeding studies, empirical residues and incident reports. We based dietary exposures on empirical pollen and nectar residue concentrations from residue studies from crops treated via foliar spray, soil or seed applications. We compare these residues across the different active ingredients, crop use sites and application methods and consider potential sources of variability. For thiamethoxam and imidacloprid, we used a total residues of concern approach to account for exposure of the parent and degradates with similar toxicities, while for clothianidin and dinotefuran, we considered parent-only. We based honey bee colony level endpoints on large semi-field Colony Feeding Studies (CFS) which established endpoints based on consumption of spiked sucrose solution over an extended exposure period. Each assessment also quantitatively accounts for potential consumption of exposed pollen. Although the focus in these quantitative assessments is for honey bees, which we view as a suitable surrogate for assessing quantitative risk to all bee species, we also qualitatively considered risks to non-Apis bees.

281 Applying the Mechanistic Honey Bee Colony Model BEEHAVE to Inform Large Colony Feeding Study Design
E. Abi-Akar, A. Schmolke, C. Roy, Waterborne Environmental, Inc; N. Galic, Syngenta Crop Protection, Inc. / Environmental Safety; S. Hinarejos, Sumitomo Chemical Agro Europe / AgroSolutions Division International

In higher-tier studies aiming to assess pesticide exposure and effects to honey bees at the colony level, other factors can impact colonies and confound the analysis of potential pesticide impacts. Large colony feeding studies (LCFS) are sometimes affected by high losses of control colonies, indicating that stressors such as limited resource availability, weather, diseases and beekeeping activities may be influential. In the current project commissioned by the Pollinator Research Task Force, we assessed the study design and environmental conditions experienced by the untreated control colonies across seven LCFSs. Overwintering success in these control colonies differed considerably among the studies. In addition, the studies differed with respect to initial colony conditions, amount and timing of sugar feeding, landscape composition around study apiaries and weather. We applied the mechanistic colony model BEEHAVE to systematically assess the impact of study design and environmental conditions on control colonies. We first calibrated BEEHAVE to a subset of the studies, validated it with the remaining studies, and then used it to run simulations that changed only one variable at a time. The goal of the project was to inform study design that leads to increased likelihood of control colony overwintering success. From the simulations, the initial status of the colonies as well as the sugar feeding pattern were more important for fall colony condition than resource availability in the landscape and weather. Larger honey stores present in the colonies at study initiation, greater feeding amounts and earlier supplemental feedings (beginning in late summer to early fall) were the main factors that led to larger colony sizes and honey stores in the fall. This information can be used to inform the standardization of a study design, which in turn can increase the likelihood of overwintering survival in untreated controls and help ensure that studies are comparable. This project demonstrates how a mechanistic model can be used to inform study designs for higher-tier effects studies. Mechanistic models like BEEHAVE could further be applied to supplement higher-tier risk assessments, for instance, by extrapolating to non-tested exposure scenarios and environmental conditions and therefore potentially reducing the number of higher-tier studies.
282 Non-invasive metrics of honey bee (Apis mellifera) colony condition for selecting study colonies and evaluating tunnel stress

P. Moore, S. Krentz, M. Hill, J. DiMartino, Eurofins Agroscience Services; V.J. Kramer, Dow Agro Sciences, LLC / Ecotoxicology

Higher-tier studies, conducted in the field environment, present unique challenges in assessing honey bee colony impacts and in ascertaining whether a use scenario poses an unreasonable risk to pollinators. Although no guidelines for conducting semi-field studies in the U.S. have been released, the EPPO 170 document describes the basic elements that should be considered. Honey bee colonies are confined to an enclosure for a limited time and exposed to a test substance while foraging on the treated target or surrogate crop. Because confinement can only be tolerated for a limited period, due to the confinement-related stress, the colonies are moved out of the enclosure to freely forage after the exposure period ends. Typical endpoints in tunnel studies include: bee mortality, colony strength, development, food storage, flight activity, and abnormal behavior. Colony condition assessments (CCAs) involve a beekeeper observer removing each frame of a colony and estimating the number of colony constituents to calculate the total population and food reserves as colonies change over time. These measurements, however, are disruptive to the colonies, labor intensive, and subject to bias of the observer and variation in weather and time. Because of the combined tunnel stress and CCA disruption there is a need to develop metrics for hive strength and homeostasis without disturbing the hive. Here we present results of non-invasive hive assessments which were recorded in a pilot study of 5 colonies over two weeks in September 2018. Measurements identified as informative, including colony weight and entrance activity and brood nest temperature and humidity, in the pilot study, were used to evaluate colonies for study inclusion and measure tunnel stress in a conventional EPPO 170 environment. Results may warrant further research on non-invasive colony assessments in semi-field tunnel studies.

283 Fluvanilate contamination in beeswax and bioaccumulation in larval and adult honey bees

C. Fulton, K.E. Huff Hartz, Southern Illinois University, Carbondale / Zoology; R.D. Fell, Virginia Tech / Entomology; J.D. Reeve, Southern Illinois University, Carbondale / Zoology; C.C. Brewster, Clemson University / Entomology; M.J. Lydy, Southern Illinois University, Carbondale / Zoology

Insects are responsible for pollination of 70 percent of the main crops used for human consumption worldwide; a service valued over 100 billion US dollars. Honey bees in particular have been shown to increase yield of animal-pollinated crops by over 90 percent. Large-scale honey bee colony loss has led to rapid population declines in the United States and Europe, resulting in decreased availability for pollination services, increased colony replacement costs, and reduced sales of hive products. Colony loss has been attributed to anthropogenic pressures such as urbanization and pesticide use within the foraging area and the hive itself. Exposure of honey bees to pesticides can lead to behavioral changes, poor reproduction, and lethality. The current study provided a multi-pesticide residue analysis in adult honey bees, stored bee bread, and beeswax throughout Virginia, USA. The high detection frequency and concentration of miticides in wax led to an examination of fluvanilate contamination in wax from five major North American beekeeping suppliers, and fluvanilate was detected in all wax samples. A wax/pollen partition coefficient was experimentally defined to highlight the fluvanilate exposure routes from wax to the pollen food source for larval and adult honey bees. These exposure routes were confirmed by measuring bioaccumulation of fluvanilate in larval and adult bees exposed to frames with fluvanilate-impregnated treatment strips, fluvanilate-dosed foundation wax, and a combination of the two treatments. Both larval and adult honey bees had detectable concentrations of fluvanilate in all treatments, with a significant interaction between treatment type and application time in adult bees. These results indicate that fluvanilate residues were comparable between hives that only had fluvanilate-dosed foundation to those that were actively being treated, suggesting that transfer of fluvanilate from wax to honey bees is an important exposure route. Exposure of not only fluvanilate, but other pesticides that may accumulate in beeswax, must be considered when evaluating risk for colony loss.

284 Field and model-based approaches to estimate pesticide exposure and effects on bee individuals, colonies and populations

M. Rundlöf, Lund University / Department of Biology; N. Galic, Syngenta Crop Protection, Inc. / Environmental Safety; O. Jonsson, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; B.K. Klatt, J.L. Knapp, Lund University / Department of Biology; E.V. Lonsdorf, University of Minnesota, Saint Paul / Institute on the Environment; C.C. Nicholson, University of California, Davis / Department of Entomology and Nematology; U. Sahlén, Lund University / Centre for Environmental and Climate Research; C. Stuligross, N. Williams, University of California, Davis / Department of Entomology and Nematology; J.R. de Miranda, Swedish University of Agricultural Sciences / Department of Ecology

Pesticides used to control pests have the potential to expose bees and can affect their health and survival. We have limited understanding of pesticide exposure and its effects on bees, particularly for non-Apis bee species, for mixtures and in real landscapes. We aim to quantify exposure of pesticide mixtures to bees and evaluate effects on individual bees, their colonies and populations, using experiments and modelling. Pesticide exposure is estimated by quantifying residues in pollen and nectar collected by five bee species and by extending bee foraging models to include spatially explicit pesticide use. This information is used to select environmentally relevant mixtures of pesticides for laboratory experiments on individuals and on free-foraging bumblebee colonies, a potentially more sensitive social bee model than the honeybee. We use replicated landscape scale studies to capture relations between pesticide use, exposure and individual and colony level performance. Data from our experiments are used to expand bee foraging and colony models, to project population-level effects of pesticide exposure. We go beyond standard toxicity testing by evaluating from individuals to populations, from the lab to the field and from single compounds to pesticide mixtures. Understanding of potential exposure to such mixtures and possible effects is essential for the long-term safeguarding of bee populations and their pollination services. The project outcomes are relevant for monitoring pesticide residues in terrestrial environments and ecological risk assessment of chemical mixtures for bees.

285 Risk Assessment Approaches for Solitary Bees—Determining Impacts of Exposure Routes for Organosilicone Spray Adjuvants in Alfalfa Leafcutting Bees

D. Cox-Foster, USDA-ARS

Pollinators are keystones of both agricultural and natural ecosystems and vital to agriculture and food security. Over 3,600 species of bees are known to inhabit the United States. Among those, the honey bee Apis mellifera is the most used pollinator; however, several other species are managed and extensively used for orchard, field crop, and greenhouse pollination. Grave concerns over decline of bees is warranted, given that wild pollinators significantly increase crop productivity even in the presence of honey bees. Populations of honey bees and other pollinators have documented declines. In order to promote the health of pollinators, factors impacting their health need to be defined. Implicated drivers of decline include climate change, pesticides, habitat loss, parasites, diseases, competition from exotics, and interactions of these factors. Much focus has been placed on the active ingredients of pesticides; however, other agrochemicals can play a role in decreased bee health. Adjuvants are used in tank mixing to enhance pesticide efficacy; and, in particular, the use of globally-marketed organosilicone (OSS) spray adjuvants has increased in the United States. Detected in pollen, wax, and bees, OSS has been shown to impair honey bee learning, cause toxicity to honey bee workers, and synergize with viral pathogens. Data will be presented on assessing impacts of the OSS via different exposure routes (pollen/nectar sources vs. foliar exposure) for the alfalfa leafcutting bee, Megachile rotundata.
286 Effects of exposure to systemic insecticides applied to Cucurbita crops for the ground-nesting hoary squash bee (Peponapis pruinosa, Apidae)

D. Willis Chan, N. Raine, University of Guelph / School of Environmental Sciences

Seventy percent of solitary bee species nest in the ground, yet no information exists in the literature about the effects of soil-persistent systemic insecticides on this group of bees, many of which are crop pollinators. The hoary squash bee (Peponapis pruinosa) is a ground-nesting bee that provides important pollination services to Cucurbita crops (pumpkins, squash, and gourd). Because this species nests in the ground within agricultural fields and its diet comes primarily from Cucurbita crops in agricultural landscapes, it may be exposed to systemic insecticides in soil, pollen, and nectar of those crops. Here, for the first time, in a controlled, field-realistic experiment, we evaluated the effects of three crop-applied systemic insecticides (active ingredients: imidacloprid, chlorantraniliprole, and thiamethoxam) on health measures (nesting activity, number of nests/mated female, pollen harvesting, and number of offspring) for hoary squash bees foraging on those crops and on production measures (percentage fruit set, marketable yield and fruit weight of the crop) important to farmers. Few treatment-related negative effects on production measures were found. Statistically significant negative effects on nesting, pollen harvesting, and number of offspring were found for hoary squash bees exposed to imidacloprid via treated crops, suggesting that exposure to imidacloprid, although not immediately noticeable in production measures, will result in population decline over time.

Understanding Risks from Exposures to Per- and Polyfluoroalkyl Substances (PFAS)

287 Screening of PFAS in aqueous film forming foam for binding to human serum albumin and characterization of mechanisms

W. Li, University of California, Davis; T.M. Young, H. Bischel, University of California, Davis / Civil and Environmental Engineering

Aqueous film forming foams (AFFF) developed in the 1960s by the United States Navy and the 3M Company have been widely used. Exposure to poly- and perfluoroalkyl substances (PFASs) in AFFF products has been linked to elevated concentration in blood serum. Although multiple C8-PFASs (e.g., PFOS and PFOA) have been phased out of production due to toxicity, persistence in the environment, and bioaccumulative potential, PFASs with similar structures continue to serve industrial needs. Emerging PFASs with shorter perfluorinated carbon chain length were suggested to be less bioaccumulative, thus are used to replace legacy C8-PFASs in the industry. However, emerging PFASs are found more mobile and harder to treat as water contaminants. Due to the large number of commercially available and environmentally detected PFASs, the bioaccumulative potentials of PFASs are difficult to assess. In this study, a comprehensive PFAS screening library was compiled, and HPLC-Qtof-MS method was applied to identify and quantify PFASs in an AFFF product. Human serum albumin (HSA) was then exposed to a series of AFFF dilutions using equilibrium dialysis to screen for preferential associations of specific PFASs with the protein. A broad spectrum of PFASs, including C4-PFASs, exhibited strong associations with HSA. Application of non-linear binding models implied high affinity binding at specific sites. After precipitation of the protein and removal of free PFASs in solution, the hydrolyzed HSA pellet contained low levels of strongly bound PFASs. Further analysis using 19F NMR titrations provided insight into protein binding mechanisms. Different interactions with HSA were observed for PFASs in AFFF compared to individual PFAS compounds. The combination of experimental and modeling techniques applied provides value in rapidly assessing the bioaccumulate potential of emerging PFASs in commercial products.

288 Legacy and Alternative PFAS Compounds in Private Wells on Cape Cod, Massachusetts, USA

L. Schaider, Silent Spring Institute / Department of Environmental Health; A. McCann, University of Rhode Island / Department of Natural Resources Science; A. Hernandez, Silent Spring Institute; H. Pickard, P. Balcom, E.M. Sunderland, Harvard University / Harvard John A. Paulson School of Engineering and Applied Sciences

Domestic wastewater may contain per- and polyfluoroalkyl substances (PFASs) due to their widespread use in consumer products and may be a source of PFASs to drinking water wells in areas served by septic systems. In this study, we collected untreated water samples from 101 private wells on Cape Cod, Massachusetts, USA, a region where 85% of residences are served by septic systems. Samples were analyzed for 25 legacy and alternative PFAS compounds, as well as nitrate and boron, which are markers of septic system impact. Nitrate concentrations ranged from < 0.1 to 16 mg/L. Of the 25 PFAS analytes, nine were detected at least once (detection limits generally ranged from 1 to 6 ng/L), with detection frequencies up to 26% for PFOS, and 53% of wells had at least one detectable PFAS compound. Detected concentrations were generally below 10 ng/L, with maximum concentrations of 13 ng/L PFHxS, 15 ng/L PFPeA, 25 ng/L PFOA, 43 ng/L PFBS, and 51 ng/L 4:2 FTS. Total detected PFAS concentrations were correlated with nitrate (Spearman rho=0.44, p<0.001) and boron (Spearman rho=0.31, p<0.01), consistent with septic systems as a likely source of PFASs in these wells. Future analysis will also investigate associations between land use and PFAS concentrations in these wells to identify other potential sources of PFAS contamination to groundwater in this region.

289 Development of Toxicity Reference Values for Per- and Polyfluoroalkyl Substances in White-Footed Mice

A. Narizzano, US Army Public Health Center / Toxicology; M. Quinn, US Army Public Health Center / Health Effects Division

Per- and polyfluoroalkyl substances (PFAS) are compounds manufactured for use in paints, cleaning agents, fire suppressants, non-stick cookware and food containers, and water-resistant products. Concerns about PFAS stem from their ubiquitous presence in the environment, widespread reports of general toxicity, and the resistance of these compounds to degradation. Initial experiments sought to determine the rate at which steady state concentrations were reached for six PFAS [perfluorooctanesulfonate (PFOS), perfluorooctanoate (PFOA), perfluorohexanesulfonate (PFHxS), perfluorobutanesulfonate (PFBS), 6:2 fluorotelomer sulfonate (6:2 FTS), and perfluorononanoic acid (PFNA)] in the white-footed mouse (Peromyscus leucopus) following 28 consecutive days of oral exposure. Animals exposed to PFNA had increased liver weights and decreased ovarian weights. Male animals exposed to PFOS had increased liver and decreased thymus weights. Female animals exposed to PFOS has decreased uterine weights. No adverse effects were observed from exposure to 6:2 FTS, PFOA, PFHxS, and PFBS. Subsequent reproductive/developmental toxicity studies will serve to derive wildlife Toxicity Reference Values (TRVs) to assist in the development of appropriate site-specific risk assessment and decisions related to mitigation of exposures and/or future cleanup. Data from a reproductive/developmental toxicity test with PFOS suggest reduced pup survivability (0% at 5.0 mg/kg-day and ~50% at 10.0 mg/kg-day). Preliminary data from another reproductive/developmental toxicity test suggest that pup survivability is not influenced by exposure during gestation and lactation to PFNA.
290 Developing Protective Aquatic Life Values for Data-Limited Chemicals - Considerations for PFAS

USEPA’s Office of Water 1985 Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses specifies Minimum Data Requirements (MDRs) for developing national Aquatic Life Ambient Water Quality Criteria (WQC) under Section 304(a) (i) of the Clean Water Act. MDRs define minimum toxicity test data, by representative taxa, that are needed to derive WQC. The 1985 Guidelines state that data are typically needed for (at least) eight specified taxa to develop freshwater WQC, with similar requirements for the development of estuarine/marine WQC. Comparable requirements, based on taxa representation, have been established by several other countries for the development of aquatic life criteria. Although specific MDRs may differ, they have a similar objective of ensuring adequate taxa representation, consistent with the goal of protecting the broader aquatic community. USEPA’s Office of Water is in the process of developing protective aquatic life values for selected per- and polyfluoroalkyl substances (PFAS). PFAS encompass a broad suite of chemicals, representing thousands of individual compounds. Although available toxicity data are expected to achieve MDRs for some data-rich PFAS, principally perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) chemicals, data are more limited and would not achieve traditional MDRs for most PFAS. This presentation explores opportunities for addressing data limitations to achieve the underlying objectives of MDRs in the development of protective aquatic life values for data-limited PFAS chemicals. Approaches being considered include opportunities for: 1) “tailoring” toxicity data needs for the development of protective aquatic life values, when supported by applicable chemical-specific knowledge, 2) augmenting data that are available through the use of extrapolation approaches and tools, and 3) combining or “binning” chemicals for the development of protective aquatic life values.

291 Per/polyfluoroalkyl substances (PFASs) in human serum from communities impacted by contaminated drinking water in El Paso County, CO

C.A. McDonough, S. Mass, Colorado School of Mines / Civil and Environmental Engineering; K. Barton, A. Starling, University of Colorado, Anschutz Medical Campus / Colorado School of Public Health; J. Adgate, University of Colorado Denver / School of Public Health; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering

Per- and polyfluoroalkyl substances (PFASs) are a class of highly fluorinated synthetic organic compounds that have become ubiquitous water pollutants due to their remarkable persistence. More information is rapidly needed to understand health risks posed by widespread, long-term contamination of drinking water by PFAS-containing aqueous firefighting foams (AFFFs). This study investigated PFAS contamination of public water systems in El Paso County, Colorado. Wells in this area were found to be contaminated with PFASs from AFFF above EPA health advisory levels between 2013 and 2016. Raw drinking water and human serum from throughout this region were collected from April to June, 2018. Serum samples were re-collected from a subset of the initial cohort one year later to track changes in PFAS levels after exposure ended. All samples were analyzed via quadrupole-time-of-flight mass spectrometry (QToF-MS) suspect screening to understand the extent of PFAS contamination in human blood resulting from this exposure. Data were screened for >1000 previously characterized and theoretical AFFF-associated PFASs using a high-resolution mass spectral (HRMS) library and an extensive extracted ion chromatogram (XIC) list. Suspect screening of drinking water samples using HRMS libraries tentatively revealed the presence of cyclic sulfonates as well as sulfonamide precursors. Screening of human serum samples revealed that the average concentration of perfluorohexane sulfonate (PFHxS; 25 ng/mL) was elevated compared to the general population as well as most previous data from impacted communities, and showed that C5-C8 sulfonates were prominent and ubiquitous in blood from residents. Suspect screening suggests the presence of additional substituted PFASs, such as chloro- and oxy-sulfonates that have previously been seen in blood from occupationally-exposed firefighters. Relationships between composition and concentration of PFASs in drinking water and human blood will be discussed, along with changes in blood levels over time.

292 Developmental toxicity of in utero exposure to perfluoroalkyl ether acids: Comparison of GenX, Nafion byproduct 2, and Perfluoro-2-methoxyacetic acid

Perfluoroalkyl ether acids (PFEAs) are a sub-class of per- and polyfluoroalkyl substances (PFAS) and includes the compounds hexafluoropropylene oxide dimer acid (GenX), Nafion byproduct 2 (NBP2), and perfluoro-2-methoxyacetic acid (PFMOAA). PFEAs are currently used in the production of fluoropolymers following the phase-out of the legacy PFAS, perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS). Recent monitoring studies have detected GenX, NBP2, PFMOAA, and other PFEAs in a wide range of matrices including surface water, drinking water, and/or human serum. Little to no published research is available regarding the potential toxicity of these compounds compared to the legacy PFAS. We previously investigated the fetal, neonatal, and maternal toxicity of GenX in the Sprague-Dawley rat following short term (gestation day (GD) 14-18 and GD 16-20) and longer term (GD 8 - postnatal day (PND) 2) oral dosing and found that it produced similar effects, but was less potent than PFOA. Here, we assessed the in utero toxicity of PFMOAA (0.01-200 mg/kg/d, GD14-18 and GD9-13) and NBP2 (0.1-30 mg/kg/d from GD14-18 and 0.3-30 mg/kg/d from GD8-PND2) for comparison to GenX and the legacy PFAS, PFMOAA produced no adverse effects on maternal weight gain, maternal liver weight, fetal viability, or fetal liver weight at any dose in either dosing interval. In contrast, NBP2 reduced maternal weight gain (GD14-18 and GD8-PND2 dosing) and produced neonatal mortality (>=10 mg/kg) shortly after birth (< 24 hours) and reduced pup weight (GD8-PND2 dosing). Neonatal mortality and low pup weight has also been reported in the rat for PFOS and GenX following gestational exposure. Comparison of oral ED50s indicates that NBP2 is only a factor of ~4 less potent than PFOS (ED50s of 3 mg/kg versus 12 mg/kg for PFOS and NBP2, respectively); whereas, GenX is a factor of ~40 less potent than PFOS. Data collected to date indicate that the spectrum of adverse developmental effects is similar between some of the PFEAs and the legacy PFAS and that the oral potency is also relatively similar for some compounds. Ongoing research in our group is investigating the putative mechanism(s) of action and key events that lead to adverse maternal and neonatal outcomes, comparison of internal dosimetry for extrapolation to human exposures, and mixture-based effects of exposure to multiple PFAS. Abstract does not necessarily reflect USEPA policy.
Tuesday Platform Abstracts

293 Toxicological Response of Chironomus dilutus to Six Perfluoralkyl Compounds

C.J. McCarthy, Jacobs Engineering Group, Inc / Global Environmental Services; D. Wright, K. O’Neal, Jacobs Engineering Group, Inc.; M. Stanaway, B. Mickey, Test America / Applied Sciences Laboratory; C.J. Salice, Towson University / Environmental Science & Studies Biology; J. Rewerts, Oregon State University; J.A. Field, Oregon State University / Department of Environ Molecular Toxicology

A multi-faceted bioassay study was conducted on six different perfluoralkyl substances with the intent of obtaining data to evaluate relative or toxicological toxicity between the substances. The six substances were selected from the US Environmental Protection Agency (EPA) Third Unregulated Contaminant Monitoring Rule (UCMR3) list, the Health Canada (January 2017) Drinking Water Screening Values, and available Environment and Climate Change Canada guidance documents. Two of the substances, perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), are well studied. The other four substances (Perfluorononanoic Acid [PFNA], Perfluorobutanesulfonic Acid [PFBS], Perfluorohexanesulfonic Acid [PFHxS], and Perfluorohexanoic Acid [PFHpA]) are commonly detected in groundwater, particularly near aqueous film-forming foam releases (AFFF), but far less is known about their toxicological potential. 10-day acute range finding tests and 20-day chronic definitive renewal bioassays were run on all six compounds using the freshwater midge, Chironomus dilutus. Exposure doses were established above and below environmentally relevant concentrations. Measurement endpoints included: larval survival; larval growth as ash free dry weight and as biomass; and number of larvae, pupae, and emergent adults at test termination. Results from the 10-day acute survival tests were used to inform dosing for the 20-day chronic growth tests. Statistical analyses were performed with the DRC package of the R statistical software. Results are in concert with previous work showing PFOS to be the most toxic per- or poly-fluoroalkyl substance (PFAS). There is evidence of a concentration response relationship for PFOS and PFOA in both survival and growth and log-logistic models were fit to the data. Concentration responses were not apparent for single chemical exposures of PFNA, PFBS, PFHxS, and PFHpA suggesting limited toxicity, particularly at environmentally relevant concentrations. Based upon analysis of 219 surface water samples from various DoD installations that used AFFF, 81% of sampling sites included PFOS and PFHxS as the dominant PFAS. A second round of chronic testing will be performed with PFOS and PFHxS to investigate potential additive and synergistic toxicity of the most dominant PFAS in surface waters next to AFFF sites.

294 State regulatory challenges for per- and polyfluoroalkyl substances (PFAS) in the food chain

K. Fritz, Michigan Department of Agriculture and Rural Development

Environmental contaminants can migrate to food by several different routes: starting from soil, water, and air to plants and animals, plants to human food, plants to animal food, and animals and animal products to human food. Federal agencies such as the U.S. Food and Drug Administration, the U.S. Department of Agriculture, and the U.S. Environmental Protection Agency help keep the nation’s food supply safe. Additionally state agencies such as the Michigan Department of Agriculture and Rural Development (MDARD) ensure food safety at the state level. For almost two years the state of Michigan has been engaged in an intense investigation of locations and sources of per- and polyfluoroalkyl substances (PFAS) to protect drinking water and public health (www.michigan.gov/pfasresponse). MDARD is tasked with the identification of any food establishments and animal facilities in Michigan that may be impacted by PFAS sources. Also agricultural inputs such as fertilizer, soil conditioners, liming agents, biosolids, and compost are being scrutinized for possible PFAS contamination. Although MDARD has legal authorities on food safety and animal health, in this situation the lack of federal standards for PFAS concentrations in agricultural inputs, food, and feed makes decisions to use these authorities challenging. PFAS sources that MDARD has investigated thus far have included water used for home canning of human food, soil used for a community garden, and hay fed to dairy cattle. After consideration of the available literature, similar cases, and site-specific conditions, MDARD recommended 1) the canned food not be consumed by the family, 2) mitigation steps could be used for the garden, and 3) there were no food safety nor animal health concerns for the hay.

Approaches for Understanding Diversity in Species Sensitivity to Chemicals

295 Interspecific Variation in Nematode Responses to Metals

S. Glaberman, George Mason University / Environmental Science and Policy; S.M. Weir, Queens University of Charlotte / Department of Biology; A. Heaton, University of South Alabama / Biology

Nematodes are a major group of organisms that have great potential for multi-species toxicity studies due to their small size, low resource requirements, abundance of species/isolates that can be tested, and availability of molecular biology tools and mutant lines. We tested lethality of the essential trace metals, copper and zinc, on 5 different nematode species (Caenorhabditis elegans, C. briggsae, Oscheius myriophila, O. tipulae, and Pristionchus pacificus). Toxicity tests with all five species generated robust LC50 measurements using only basic laboratory space, equipment, and resources, indicating that multi-species testing with more (perhaps even dozens of) species is feasible. Results indicate that P. pacificus is the most sensitive species to both metals, fitting with its phylogenetic position as outgroup to the four other test species. The higher sensitivity of P. pacificus may be due to the absence of or higher divergence from metallothionein genes identified in C. elegans and C. briggsae, although this requires further comparative genomic examination. Patterns of sensitivity in Caenorhabditis and Oscheius species differed by metal, with C. elegans being the second most sensitive species to zinc, but the least sensitive species to copper. Together, these results suggest that P. pacificus may be a better indicator of metal lethality than the model, C. elegans, and that additional genetic, physiological, and behavioral factors may be needed to explain patterns of metal sensitivity in nematodes. The ease of testing multiple species in our study shows that nematodes are a good candidate for cross-species toxicology and adverse outcome pathway comparisons.

296 Correcting for phylogenetic autocorrelation in species sensitivity distributions

D.R. Moore, Intrinsik, Ltd.; C. Priest, Intrinsik, Ltd. / Biology; N. Galic, R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety; S.I. Rodney, Intrinsik Corp

A species sensitivity distribution (SSD) is a modeled cumulative distribution function of toxicity endpoints for a specified receptor group. SSDs are frequently used to derive environmental benchmarks or to characterize risk to hypothetical sensitive species or to entire taxonomic groups or communities. A key statistical assumption when deriving an SSD is that the toxicity data points are independent and identically distributed (iid). This assumption is tenuous, however, as closely related species tend to have similar sensitivities, whereas more distantly related species often have divergent sensitivities. When the response of one species can be at least partially predicted by the response of another species, there is a dependency or autocorrelation in the dataset. To date, phylogenetic relationships and the resulting dependencies in input datasets have been ignored in deriving SSDs. In this paper, we explored the importance of the phylogenetic signal in deriving SSDs using a case studies approach. The case studies involved toxicity datasets for aquatic autotrophic species exposed to atrazine and aquatic and avian species exposed to chlorpyrifos. Full and partial datasets were included to enable exploration of the influences of differing phylogenetic signal strength and sample size. The results indicated that the phylogenetic signal was significant for some of our toxicity datasets (i.e., the chlorpyrifos datasets for all aquatic species, all vertebrate species, all invertebrate species, and fish species) but not for others (i.e., the atrazine full and sub datasets, the chlorpyrifos datasets for...
all insects, crustaceans and birds). When a significant phylogenetic signal did occur, the result was a reduced effective sample size. The reduction was rather large when the signal was strong. In spite of the reduced effective sample sizes, significant phylogenetic signals had little impact on fitted SSDs, even in the tails (e.g., HC5 values). The lack of a phylogenetic signal impact occurred even when we artificially reduced original sample size and increased strength of the phylogenetic signal. We conclude that it is good statistical practice to account for the phylogenetic signal when deriving SSDs because many multi-species toxicity datasets do not meet the independence assumption. That said, SSDs and HC5 values appear to be robust to deviations from the independence assumption.

297 Do Daphnia magna and Ceriodaphnia dubia Acute and Chronic Tests Show Equitoxic Results?
K.A. Connors, J. Brill, Procter & Gamble Company / Environmental Stewardship and Sustainability; M.G. Barron, US Environmental Protection Agency / Gulf Ecology Division; T.J. Norberg-King, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship

Environmental risk assessments are typically based on toxicity data derived from only a handful of standard model organisms. Some standard regulatory assays limit the species in scope, others like the OECD 203 acute fish assay can be considered valid if one of seven recommended species are tested. While it is important to consider the relative sensitivity of other species, it is equally important to understand the sensitivity variation that is already contained within the standard regulatory assays. The OECD 202 Acute Daphnia Immobilization Toxicity Test requires the use of Daphnia magna or another "suitable Daphnia species (e.g., Daphnia pulex)." The daphnid species, Ceriodaphnia dubia, is not considered a standard test species for chemical registration in Europe despite the availability of ISO, USEPA, ASTM, Environment Canada standard acute and chronic test methods and its wide use and acceptance in other countries. Previous comparative work by Versteeg et al. (1997) suggests that D. magna, D. pulex, and C. dubia are acutely equisensitive. Here, we employ a big data approach to critically evaluate the comparative sensitivity between D. magna and D. pulex and contrast that to the similar species sensitivity of D. magna and C. dubia. These big data approaches will then be contrasted against the smaller, more curated web-ICE regressions. A total of 207 chemicals that had both D. magna and D. pulex acute toxicity data were identified (5,443 studies). This orthogonal regression has a slope of 0.881 and an intercept of 0.484. As both D. magna and D. pulex are accepted OECD 202 standard test species, this inherent biological difference in sensitivity is accepted under the regulatory guidelines. A total of 193 chemicals that had both D. magna and C. dubia toxicity data were identified (5,465 studies). The orthogonal regression for the acute toxicity studies has a slope of 0.919 and an intercept of 0.599. The relative species sensitivity differences between D. magna and D. pulex and D. magna and C. dubia are of the same magnitude and have nearly identical slopes. D. magna and C. dubia chronic toxicity (83 chemicals, 1062 entries), also showed similar sensitivity with a slope of 0.841. Interspecies modeling demonstrates similar sensitivity for Daphnids and C. dubia and the interchangeability of these taxa is recommended for chemical testing.

This presentation does not necessarily reflect the views or policies of the US Environmental Protection Agency.

298 PhyloTox: A Phylogenomic Approach to Predicting Species Sensitivity Across the Tree of Life
J. Shaw, Indiana University / O’Neill School of Public and Environmental Affairs; M. Bondesson, Indiana University / Department of Intelligent Systems Engineering; J. Coral, Indiana University; S. Jacobson, Indiana University / Department of Chemistry; J. Klaunig, Indiana University / Department of Environmental Health Sciences; J. Tennesen, Indiana University / Department of Biological Sciences; J. Colbourne, M.R. Viant, University of Birmingham / University of Birmingham Enterprise; B. Brown, Lawrence Berkeley National Laboratory / Department of Molecular Ecosystems Biology

Knowledge of the evolutionary reasons for why genes are functionally bound to one another is needed to extrapolate from laboratory models to humans and decode their health functions, including their responses to chemical pollutants. However, this puzzle remains largely intractable due to three major obstacles. (1) Many of gene are not expressed under standard laboratory conditions to reveal what traits they encode. (2) Genetic tools that break gene functions or genome scans that identify associations between genes and phenotypes are designed for interrogating single genes rather than coordinated gene networks. (3) Functional studies of genomes often do not account for their evolutionary origins. To address these needs, we developed PhyloTox, a novel predictive toxicology approach, that identifies the functions of evolutionarily conserved groups of interacting genes, while simultaneously delineating molecular toxicity pathways that are critical to solving the enormous public health crisis caused by human exposure to chemical pollutants. PhyloTox draws insights on gene functions by disrupting entire networks via chemical ablation, just as genetics does with individual genes. To demonstrate the utility of PhyloTox, we are exposing a group of six model species/cells, i.e., human cell lines, zebrafish, frog, fruit fly, water flea, worm, which together represent major branches of animal evolution and are recognized biomedical model systems, across dose and time to a panel of four chemicals, arsenic, cadmium, ethoprophos, wyeth 14,643. By applying fit-for-purpose computational, statistical, phylogenetically driven analyses of data that integrate biomolecular information (i.e., transcriptomes and metabolomes), we identify core networks of interacting genes and reveal their toxicological functions. These results will be discussed in their ability to identify the evolutionary origins of toxicity pathways and improve cross-species extrapolations. Presented on behalf of the Environment Care Consortium (https://www.environmentcareconsortium.org/).

299 Glucuronosyltransferases in Lower Vertebrates: Phylogenetic Signals and Implications for Species Sensitivity to Pollutants
P. van den Hurk, Clemson University / Biological Sciences

Now that completely sequenced genomes are rapidly becoming available for a wide variety of organisms, information can be gathered about the presence of genes that are involved in the detoxification of environmental pollutants in these species. This allows for the analysis of phylogenetic signals in closely related taxa, and may be used to predict the sensitivity of species to pollutants. However, annotation of genes found in lower vertebrates, like in alligators, but do not have the same activity. In fish taxa, the primitive jawless lamprey and hagfish species appear to be missing the phenol-type UGTs, while in the bony fish, isoforms that are distinctly different from mammalian ones are widespread, but appear to have comparable substrate specificity. Recent studies have analyzed the UGTs in bird species and found several unique sequences for the UGTs. Among the birds, top predators like birds of prey and vultures have less
UGT isoforms than omnivores and herbivores, indicating that ecological niche plays a role in the presence and expression of UGT isoforms. This pattern is also seen in some hyper carnivores among mammalian species. All these observations indicate that the phylogenetic history of UGTs in vertebrate species is a complicated story, driven by a variety of factors. This may make it complicated to use phylogenetic signals to predict species sensitivity to environmental pollutants or their metabolites that need to be conjugated by UGTs for detoxification and excretion.

300 Are we looking close enough? Genetic diversity despite morphological uniformity affects cryptic species’ sensitivity towards stress

A. Feckler, Swedish University of Agricultural Sciences (SLU) / Department of Aquatic Sciences and Assessment; J.P. Zubrod, A. Thieltsch, K. Schwenn, R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Department of Aquatic Sciences and Assessment

Over the last decades, genetically distinct but morphologically uniform lineages within nominal species (i.e., cryptic lineages complexes) have been uncovered for many species, including those used as standard test species in environmental risk assessment (ERA) such as Lumbricus variegatus, Eisenia fetida, and Hyalella azteca. From an applied perspective, it remains uncertain whether and to which extent the genetic differentiation - which is comparable to an interspecific level - affects cryptic species’ sensitivity and therefore ERA on the basis of a single assessed lineage. We therefore tested for potential sensitivity differences between chemical stress between the two cryptic lineages A and B found for the sentinel species Gammarus fossarum (Crustacea: Amphipoda) using the fungicide tebuconazole (up to 600 µg/L), the insecticide thiacloprid (up to 50 µg/L), and ammonia (up to 1.3 mg/L) as model stressors. Test organisms were exposed individually towards the stressors (n=15-20) for 5-7 days applying their feeding rate on leaf discs as a measure of sensitivity. Cryptic lineage A showed a biologically meaningful and statistically significant higher sensitivity towards the applied chemical stressors compared to cryptographic lineage B, with up to six-fold (pesticides) and two-fold (ammonia) sensitivity differences between lineages. As we either actively controlled for or observed only marginal deviations between lineages in potential confounding factors that could have influenced the outcome of the studies - namely the season of collection, gammarids’ life stage, parasitism, and physiological fitness - we presume the considerable genetic differentiation between cryptic lineages A and B to be the driving factor for the observed sensitivity differences. Although we only concentrated on one single trait of species (i.e., sensitivity), our studies indicate that it seems to be adequate to assume traits of individual species to only vary around one mean value. Environmental monitoring and ERA should therefore proactively consider the discussed genetic heterogeneity in terms of cryptic lineage complexes by including a correct genetic differentiation to avoid implications in their reliability and quality.

301 Transcriptomics explains differential sensitivity to pesticide exposure through a novel off-target mechanism

D. Spurgeon, Centre for Ecology & Hydrology; S. Short, University of Cardiff; A. Robinson, Centre for Ecology & Hydrology; A. Green Etxabe, CEH Wallingford; E. Lahive, Centre for Ecology & Hydrology (NERC); P. Kille, Cardiff University

In silico tools that use omics data-sets to ‘flag’ sensitive species can improve risk assessment. However, to achieve such insights, we need to know how both toxicokinetics (TKs) and toxicodynamics (TDs) contribute to differential species sensitivity. As a case study in the use of such data, we investigated the TK and TD characteristics underlying differences in sensitivity for five earthworm species for the widely used neonicotinoid pesticide imidacloprid known to inhibit neuronal synaptic function by targeting Nicotinic Acetylcholine receptors (nAChRs). We identify that earthworms have a lower sensitivity to imidacloprid than a soil arthropod (Folsomia candida) and that there is a large-magnitude (>30-fold) within earthworm taxa variations from Eisenia fetida and Lumbricus rubellus (least sensitive) to Amythys gracilis (most sensitive). Species sensitivity was not linked to TK traits that determine either total body imidacloprid concentrations or rates of uptake or loss. Analysis of TD traits by characterisation of the known insect nicotinic acetylcholinesterase receptor (nAChR) orthologue targets of imidacloprid through genome sequencing and transcriptomics identified a greatly expanded gene family in earthworms, including numerous highly expressed AChRs and also multiple nicotinic acetylcholinesterase binding proteins (AChBP). Splicing implied by gene architecture, a mainly nervous system expression and ligand binding domain analysis indicated that earthworm nAChRs have similar sub-unit structure and potential for imidacloprid and acetylcholine binding as the insect receptors. Thus, nAChRs structure could not explain the differences in sensitivity. AChBP are also highly expressed in earthworms. Their potential to bind imidacloprid off-target away from the synapse may explain the lower sensitivity of earthworms compared to springtails in which these genes are absent. Ligand binding domains of expressed AChBPs in low sensitivity E. fetida and L. rubellus dominantly have high imidacloprid affinity YPPC ligand binding domains. A. gracilis predominantly show low-affinity ligand binding domains that provide lower protective off-target imidacloprid binding in this sensitive species. Our work, thus, defines a predictive model for imidacloprid sensitivity based on off-target AChBP presence, expression and especially off-target ligand binding that advances beyond the state-of-the-art of primary receptor target sequence analyses only.

302 Study on taxon-toxicity sensitivity of fish to representative transition metals

Y. Wang, Beihang University / School of Space and Environment; W. Fan, Beihang University / Environmental Science and Engineering

Transition metals, an important class of metals, are a group of elements in groups IIIB to IIB of the Periodic Table of the elements. The last electron of the transition metal is often filled in the d orbital of the outer layer of the atomic orbital, which leads to a variable valence state for transition metals. As a result, transition metal plays a transitional role during the periodic characteristic change of elements. Transition metals widespread in aquatic environments that can seriously affect the species diversity and species distribution of aquatic organisms when concentrations exceeding threshold values. For example, cadmium, a representative toxic metal, can affect the embryonic development, the larvae survival and the reproduction of aquatic organisms. The United States and many other countries/organizations have worked on water quality criteria (WQC) of metals to protect aquatic life since the 1960s. However, different taxa are protected by use of unified WQC thresholds, which are derived to protect most creatures and rarely considers the ecological status and economic value of different species. At present, there are lots of experimental researches of aquatic toxicity of metals to different taxa, especially fish. It is the time to study taxon-toxicity sensitivity to metals through the dose-effect relationships and massive bioaccumulation data obtained from laboratory exposure experiments. The present study established the species sensitivity distributions of nine representative transition metals (Cr(VI), Mn, Fe, Ni, Cu, Zn, Ag, Cd, Hg) for protecting Chinese fish based on non-parametric kernel density estimation models and then derived their HCS values. The results showed that Ag has the lowest HCS value, which has the highest toxic potency to fish; Ni has the largest, the least. Moreover, it suggested that the toxic potency of the transition metals to fish may be periodic and Cyprinidae is more sensitive to these nine metals than other fish. The study will provide some reference for future research on the toxicity sensitivity of fish to other transition metals.
Adverse Effects of Chemicals on the Microbiome

303 Challenges and opportunities for microbiome analysis in toxicology

E. Brinkman, B. Jia, R. Lo, Simon Fraser University / Molecular Biology and Biochemistry; R. Beiko, Dalhousie University / Faculty of Computing Science; M.A. Croxen, Public Health Laboratory (ProvLab) University of Alberta / Department of Laboratory Medicine and Pathology; C.C. Helbing, University of Victoria / Biochemistry & Microbiology; C. Kennedy, Missouri Department of Conservation / Department of Biological Sciences; V. Lau, Simon Fraser University / Department of Molecular Biology and Biochemistry; F. Maguire, Dalhousie University / Faculty of Computing Science; P.K. Tang, University of British Columbia; N.A. Prystajecky, M. Uyaguari-Diaz, British Columbia Centre for Disease Control Public Health Laboratory; J. Verreault, University of Quebec, Montreal / Sciences Biologiques; T. Van Rossum, EMBL Heidelberg / Structural and Computational Biology Unit

Microbiome analyses are growing in popularity, with broad applications in biomedical, agricultural and environmental research. We have been performing analyses relevant to these areas, including toxicological applications such as: Characterizing the bullfrog skin microbiome over their life cycle and when exposed to endocrine disrupting chemicals; Investigating the utility of skin microbiome analysis as a non-invasive method of contaminant monitoring in endangered St. Laurence estuary belugas (vs more invasive skin/blubber biopsies currently performed); Identifying riverine bacteria potentially involved in aquatic copper bio-remediation at a proposed northern Canadian mine site; Characterizing western Canadian watershed microbiomes over time and space in agricultural- and urban-impacted environments to identify new biomarkers of water quality (viral, bacterial and protist). Through this array of studies, we have identified components of microbiome analysis methodology that are critical for robust analysis, and common pitfalls to watch out for. These will be presented along with fundamental insights/common themes identified from these studies regarding microbial community changes over time and location that must be considered for toxicology-based analyses. We also report the development of new computational tools, named PSORTm and AMRTime, for metagenomics-based analyses of potential microbial cell surface diagnostic targets, and prediction of antimicrobial resistance (AMR) genes, respectively. The utility of Metagenomics Assembled Genomes (MAGs) for microbial community analysis, versus direct sequence read-based analysis, has also been compared, and we present our recent simulated data analyses, showing how both approaches are important, and complement each other. Analyses of the impacts of chemicals on microbiomes is one key component of more holistic assessments in environmental toxicology, so collectively a framework will be presented for the mitigation of common challenges, that will help researchers fully capitalize on the opportunities that microbiome analysis provides for toxicology.

304 Acidic rock drainage and remediation induce shifts in sediment bacterial community composition at the Callahan Mine superfund site

K. Thompson, Harvard School of Public Health / Biostatistics; J.E. Wilkinson, T. Hsu, Harvard University / T.H. Chan School of Public Health, Department of Biostatistics; G.D. Mayer, Texas Tech University / Department of Environmental Toxicology

The production of acid rock drainage (ARD) results in an increased release of metals and metalloids into the environment. ARD is generated naturally as a result of the oxidation of sulfide minerals; however, the process is accelerated at active and abandoned mine sites where increased rock surface area results in increased oxidation of sulfur, which results in lowered pH that hastens demineralization of metal ores. The Callahan Mine (CM) Superfund Site has been impacted by ARD over nearly a century of interspersed mining operations for copper (Cu) and zinc (Zn). Currently, the EPA is attempting to remediate two classes of contaminants, metals and polychlorinated biphenyls (PCBs), that were prioritized after an initial investigation. Previous studies have identified a seepage site at the base of a waste mine tailings pile, which drains into an adjacent marsh site. This study aims to characterize the spatial and temporal changes of free-living bacterial community compositions in sediments and commensal communities in fish gut and gill samples within CM’s marsh and between CM and a clean reference marsh, Horseshoe Cove (HC). Here we show that in each of four sampling years, the locations closest to the seepage site had vastly different sediment community structures and lowered alpha diversity compared to sampling sites farther seaward. In the fish gut microbiome samples, we identified no significant differences in the composition of the gut microbiome by site, but large differences by year of sampling. We also identified the presence of a genus of bacteria in the sediment that naturally remediates PCBs in the environment, Dehalococcales. This suggests a novel contamination event of PCBs within the marsh, most likely related to the relocation of PCB contaminated soil to an impoundment site at the freshwater end of the Superfund Site. Thus, as of 2015, leachate from a metal laden waste tailings pile continues to modify sediment-borne bacterial community structures towards inclusion of metal tolerant bacterial taxa. Additionally, PCB-contaminated soil relocation resulted in a correlative appearance of PCB degrading bacteria into the marsh sediment microbiota.

305 Is Biosynthesis of OH-BDEs an Adaptation Strategy for Bromobacteria?

J. Sun, H. Peng, University of Toronto / Department of Chemistry

Hydroxylated polybrominated diethers (OH-BDEs) are naturally produced as secondary metabolites by marine microbes, including Marinomonas mediterranea MMB-1. But the biological function of OH-BDEs in marine bacteria remains elusive. 6OH-BDE47, the major natural OH-BDE was discovered in our recent study to kill bacteria by inhibiting enoyl-acyl carrier protein reductase (FabI). This study further confirmed this result by testing the antibacterial potencies of 15 OH- or MeO-BDEs, and found that E. coli could be only inhibited by the natural OH-BDEs with MICs 1 - 33 μM, which were further rescued by overexpression of FabI protein. In vitro FabI activity inhibition was in accordance to the growth inhibition, confirmed that all natural OH-BDEs targeted FabI. However, the natural OH-BDEs producer, MMB1, could tolerate 6OH-BDE47 as high as 50 μM, about ~25 fold less sensitive than E. coli. The genome of MMB1 as well as two other bromobacteria was sequenced, and another functional homologue FabV presented in all three bromobacteria. Function of FabV of MMB1 was illustrated by restoration of fatty acid synthesis in E. coli fabI (Ts) mutant strain, JP1111, by transformation with a plasmid carrying genes encoding MMB1-FabV. JP1111 containing MMB1-FabV was also more resistant to 6OH-BDE47 (MIC 25 μM) compared to JP1111 with vector only (MIC 3.1 μM). The binding affinity of 6OH-BDE47 to FabV is much weaker than FabI, as evidenced by in vitro assays. In TILS (target identification by ligand stabilization) plus SDS-PAG and western blot assay, FabI was stabilized by 6OHBDE47 while precipitated in DMSO at 65 °C, while no change was observed in FabV. In affinity pulldown assay, 6OH-BDE47 was remarked pull-down by FabI, but not FabV. When the natural lysates of E. coli and MMB1 incubated with 7 OHBDEs, 6OH-BDE47 was detected in HPLC-co fractions 14, 16, 18, and 20 of E. coli lysate, while no OHBDEs were detected in any fractions of MMB1 lysate. FabI protein also presented in fractions 14, 16, 18, and 20 with the same concentration trend of 6OH-BDE47. This the first study to clarify that OH-BDEs may be a natural adaption strategy for marine bromobacteria to kill other bacteria in the high-dense space (i.e., sponge). It is also evidenced in field studies that 16s rRNA gene diversity profiles were significantly impacted by high concentrations of OH-BDEs in sponge.
306 The gut microbiome of invertebrates upstream and downstream wastewater treatment plants on the Grand River
E. Millar, McMaster University / Biology; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division
The composition of the gut microbiome is being increasingly linked to overall organismal health and function. Gut microbiota can influence various physiological traits (e.g. weight, immune function, disease), and is sensitive to a variety of factors (e.g. diet, environment, pharmaceutical use). Effluents from the Kitchener and Waterloo wastewater treatment plants (WWTPs) in Ontario contain antibiotics and other pharmaceuticals that could negatively impact the gut microbiome of aquatic biota living in the Grand River. To assess this, in the Fall of 2018 we collected mussels (Lasmigona costata), several species of macroinvertebrate larvae (rimed with ethanol), and riparian spiders (Tetragnathidae) that consume emerging insects from sites upstream and downstream of the Waterloo WWTP, as well as sites downstream of the Kitchener WWTP along the Grand River. The microbiomes of mussel and invertebrate gut contents, as well as whole spiders, were analysed following the extraction, nested PCR amplification, and sequencing of bacterial genomic DNA using the V3-V4 hypervariable region of the 16S rRNA genetic barcode. Mussels samples (n=43) had a total of 10,664 unique bacterial taxa. Alpha diversity varied significantly among locations (one-way ANOVA; Simpson F=6.258, df=2, p=0.004), and decreased from upstream to downstream Kitchener locations (Tukey HSD: Simpson p=0.005) as well as from the downstream Waterloo to downstream Kitchener locations (Tukey HSD: Simpson p=0.026). Bray-Curtis beta diversity was significantly different between locations (Permanova, F=4.1586, df=2, p=0.001). Spiders (n=98) had a total of 3,553 unique bacterial taxa. Alpha diversity indices varied significantly among locations (one-way ANOVA; Simpson F=6.783, df=2, p=0.002), and increased from the downstream Waterloo to the downstream Kitchener locations (Tukey HSD: Simpson p=0.001). Bray-Curtis beta diversity was also significantly different between locations (Permanova, F=3.2068, df=2, p=0.001). At present, the composition of the gut microbiome and factors affecting it are still poorly understood in aquatic organisms, but these initial results suggest some effects of contaminant exposure on their microbial community.

307 Dietary exposure to bis(2-ethylhexyl) phthalate on the zebrafish (Danio rerio) microbiome-gut axis: A multi-omics approach
C.J. Martyniuk, University of Florida / Physiological Sciences; A.N. Buerger, University of Florida / Department of Environmental and Global Health, College of Public Health and Health Professions; A. Hanlon, S. Sohag, University of Florida / Department of Physiological Sciences, College of Veterinary Medicine; H. Vespalova, S. Smatana, E. Budinska, Masaryk University / Research Centre for Toxic Compounds in the Environment RECETOX; S.L. Craft, P. Ginn, University of Florida / Department of Comparative, Diagnostic and Population Medicine / College of Veterinary Medicine; J.H. Bisesi, University of Florida / Environmental and Global Health; O. Adamovsky, Masaryk University, RECETOX
Diethyylhexyl phthalate (DEHP) is an endocrine disrupting chemical and a commonly used plasticizer, notably in polyvinyl chloride. As such, DEHP is relatively ubiquitous, and it is detected in aquatic environments. Microplastics are also a concern, and DEHP can leach directly from these small plastic fragments in the water column. To better quantify risk to aquatic organisms, this study aimed to determine the impact of dietary DEHP exposure in the zebrafish (Danio rerio) gastrointestinal system by (1) assessing histopathology of the gut; (2) assessing the effects of DEHP on the host microbiome (16S RNA sequencing) and host gut transcriptomics; (3) targeting expression levels of transcripts related to Gl hormone signaling and nutrient uptake. We hypothesized that DEHP would shift the microbiome to a state of dysbiosis, leading to pathological changes in the tissue. A two-month dietary exposure was conducted in which male zebrafish were fed DEHP (3 ppm). There was no discernible pathology nor evidence of inflammation in the GI tract. DEHP significantly affected the composition of microbiome and Fusobacteriaceae and Enterobacteriaceae, both disease causing bacterial genera, were increased in relative abundance while the abundance of Verrucomicrobiaceae was decreased with DEHP. In zebrafish gut tissue, a peroxisome proliferator-activated receptor gene network was altered in expression, consistent with reports of DEHP acting as a lipid regulator. Host transcriptome changes included genes of the immune system, metabolism, gut integrity and homeostasis (cell-cell communication). Using real-time PCR, we measured a number of key gut hormones and peptides. There were no changes in the expression of gastro-intestinal hormones (cck, ghrelin, sst1, sst2), nor were there any changes in neuropeptides active in the brain-gut axis (opn, cattl, grp) with DEHP treatment. These data suggest the microbiome-gut axis is a target for metabolic disruptors and emphasizes the value of multi-omics approaches to study microbiome-host interactions.

308 Influences of life stage at first exposure on the disruption of the gastrointestinal microbiome by a phthalate plasticizer
A. Buerger, University of Florida / Environmental and Global Health; D.T. Dillon, University of Florida / Department of Anthropology; C.J. Martyniuk, University of Florida / Physiological Sciences; J.H. Bisesi, University of Florida / Environmental and Global Health
Phthalate plasticizers, such as diethylhexyl phthalate (DEHP), have become ubiquitous in the environment due to their leaching from products including food containers, personal care products, and PVC pipes. These chemicals are suspected to contribute to the global obesity epidemic in conjunction with poor diet and lack of exercise. One possible mechanism by which exposure to DEHP may contribute to obesity is through dysbiosis of the gastrointestinal (GI) microbiome. We hypothesized that life stage at exposure to DEHP will impact the alterations observed in the GI microbiome profile of zebrafish (Danio rerio), and that an earlier, more prolonged exposure will have more pronounced effects on this dysbiosis. Two feeding studies were conducted to examine this hypothesis. In the first, adult zebrafish (~6 months old) were fed ad libitum with either control or DEHP (3 mg/kg) food for 60 days. In the second study, zebrafish were fed ad libitum for 6 months, starting at 3dpf, to control of DEHP (3 mg/kg) food. At the end of each exposure period, zebrafish were euthanized and gut and fecal matter were excised for gene expression analysis and microbial sequencing, respectively. In the adult study, 16s sequencing revealed significant changes in b diversity, increases in Bacteroidetes, and decreases in Fusobacteria and Tenericutes in Overfed + DEHP zebrafish compared to Overfed fish. Additionally, PICRUSt functional analysis revealed significant changes in carbohydrate, galactose, inositol phosphate, and taurine and hypotaurine metabolism, which suggests alterations in nutrients available to the host from the microbiome. RNAseq analysis and qPCR of adult zebrafish guts revealed alterations in functions related to host metabolism and gut function. These alterations will be compared to 16s data forz ebrafish exposed to DEHP in the 6 month study for to assess microbial diversity and function, as well as expression of genes related to lipid metabolism and gut function in the host. Thus far, evidence suggests that DEHP does alter zebrafish microbial diversity and function, which is paralleled by metabolic alterations in the host. We expect that earlier and prolonged DEHP exposure will increase dysbiosis and further altered host gene expression related to lipid metabolism and gut physiology than a shortened adult exposure, highlighting the importance of life stage during exposure in toxicology studies.

309 The Effect of Wastewater Effluent on the Gut Content Microbiome of Rainbow Darter (Etheostoma caeruleum)
V. Restivo, McMaster University / Biology; M.G. Sature, McMaster University / Department of Biochemistry and Biomedical Sciences; J.Y. Wilson, McMaster University / Department of Biology; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute
The microbiome represents a community of bacteria integral in maintaining host health. At present little is known about the gut content
microbiome of fish, but emerging research suggests that it is influenced by environmental stressors, diet, and habitat. This study evaluates how exposure to wastewater treatment plant (WWTP) effluent in the central Grand River, Ontario, Canada, affects the diversity and composition of the gut content microbiome of the rainbow darter (Etheostoma caeruleum), a sentinel species common in this system. In October 2018, gut content was steriley collected from rainbow darter at 10 sites (n=15/site) located at varying distances upstream and downstream of two major WWTPs. Genomic DNA was extracted, and PCR amplification of the 16S rRNA gene V3-V4 region and Illumina sequencing were performed. Amplicon sequence variants (ASV) were mapped back to bacterial species using the SILVA database and DADA2 pipeline. Diversity of the gut content microbiome increased significantly downstream of both WWTP outfalls (Shannon Diversity, ANOVA, F=4.829, p<0.001) when compared to upstream samples. There was an increase in dominance (Berger-Parker Dominance) at upstream locations compared to locations downstream (Tukey, p<0.05). There was a change in microbiome composition, with dominant bacteria in upstream samples belonging to the phyla Proteobacteria, and Firmicutes, while downstream samples had higher relative abundances of Proteobacteria and Cyanobacteria, and decreased abundances of Firmicutes. Mammalian literature suggests that an increased abundance of Proteobacteria is indicative of dysbiosis between the host and its gut microbiota and leads to a decline in host health. However, much of the functionality of bacteria in the fish gut is unknown and cannot yet be linked to fish health outcomes. Bray-Curtis beta diversity and principle coordinate analysis showed that individuals within and between sites were significantly dissimilar (Permanova, F=5.422, p<0.001). This research suggests that the fish gut content microbiome is affected by exposure to complex mixtures of emerging and legacy contaminants found in WWTP effluent. Laboratory exposures are underway to assess the magnitude of WWTP effluent effects on the gut content microbiome of the rainbow darter, and for comparison to the field results.

310 Gut microbiota in fishes from the North Saskatchewan River following an oil spill
A. DeBofsky, Y. Xie, University of Saskatchewan / Toxicology Centre; P.D. Jones, University of Saskatchewan; T. Jardine, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences

The gut microbiota of animals has been described as an additional host ‘organ’ with beneficial roles. However, little is known about the impact of chemical exposures on the structure and function of gut microbiota of fishes. In July 2016, a Husky Energy pipeline spilled 225,000 liters of diluted bitumen (dilbit), with much of the dilbit entering the North Saskatchewan River near Maidstone, SK. This event provided a unique opportunity to assess the shifts of gut microbiota in native fish species following exposure to dilbit. In summer 2017, goldeye (Hiodon alosoides), walleye (Sander vitreus), and shorthead redhorse (Moxostoma macrolepidotum) were collected at six locations upstream and downstream of the spill, and in summer 2018, these same species were collected at four sites. Muscle and bile were sampled from each fish for chemical measurements, and intestinal contents were collected for gut microbial analyses. Gut contents from these species were also collected at additional sites within the province as controls for the North Saskatchewan River. Gut microbiota were assessed using 16S rRNA metagenetics. Results suggest that host species are a significant driver in determining gut microbiota, with significant differences among the species across sites (p = 0.01). Furthermore, increased concentrations of polycyclic aromatic hydrocarbons (PAHs) in fish muscle tissues are negatively correlated with alpha diversity of fish gut microbiota (p = 0.003). This research is one of the first studies to investigate the community composition of fish gut microbiota from wild species in response to chemical stressors.

Advances in Contaminant Bioaccumulation

311 Biotransformation of benthic invertebrates impacts persistence and bioaccumulation of sediment-associated cyclic siloxanes (D4, D5, D6)
H. Selec, R. Windfield, Roskilde University / Department of Science and Environment; K. Dinh, Roskilde University / Section for Marine Ecology and Oceanography, DTU Aqua

Concerns regarding the environmental fate and effects of cyclic volatile methyl siloxanes (cVMS) have been raised due to their hydrophobicity. Generally, regulatory frameworks assess risk of hydrophobic organic chemicals (HOCs) based on their persistence, bioaccumulation and toxicity using water exposure setups and microbial degradation only. This study assessed the impact of dietary uptake (i.e., via sediment ingestion) and benthic invertebrate biotransformation for risk assessment of cVMS. A radiotracer technique was employed to examine uptake- and depuration kinetics as well as biotransformation of sediment-associated cVMS (octamethylcyclotetrasiloxane, D4; decamethylcyclopentasiloxane, D5; dodecamethylcyclohexasiloxane, D6) by a freshwater oligochaete ( Tubifex tubifex) and a marine polychaete (Capitella teleta). Overall, sediment-associated D4, D5 or D6 did not adversely affect the benthic invertebrates, uptake, depuration and biotransformation was dependent on compound, BSAF was low due to biotransformation and fast elimination of parent and metabolites; and especially presence of C. teleta, reduced sediment concentrations of compared to microbial degradation due to biotransformation and flushing. It, thus, appears that cVMS have little impact on sediment-dwelling organisms at environmentally realistic concentrations, and that a focus on water-only setup alone and ignoring invertebrate biotransformation will misjudge risk and increase uncertainty in B and P assessment of HOCs, like cVMS.

312 Bioconcentration of cationic surfactants in rainbow trout
M. McLauchlan, A. Kierkegaard, M. Strandell, B. Yuan, C.L. Chen, Stockholm University / Environmental Science and Analytical Chemistry (ACES); J.M. Armitage, AES Armitage Environmental Sciences, Inc / Physical and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting; S. Droge, University of Amsterdam/ IBED Institute

Cationic surfactants are an important class of environmental contaminants, given that they are released to the environment in large quantities. In vitro experiments have shown that they have a strong tendency to partition into membranes, which suggests that they may bioaccumulate strongly. There is, however, a dearth of bioaccumulation data. Here we report on in vivo experiments to determine the bioconcentration factors of a series of methyl alkyl amines in rainbow trout. The test chemicals included primary, secondary, tertiary and quaternary amines ranging in chain length from C9 to C16. In an initial set of experiments we explored the tissue distribution of the test chemicals in ~130 g rainbow trout. All of the alkyl amines except for the two quaternary amines were quantified in blood, muscle, liver, gills, skin and skin mucus, and it was concluded that all of these tissues must be included when assessing the bioconcentration of these substances. In a second set of experiments we measured uptake and depuration of mixtures alkyl amines in ~11 g rainbow trout and determined bioconcentration factors (BCFs). The experiments were conducted at 2 different pHs (7.8 and 6.3), with an exposure phase of 14 days and a depuration phase of 28 days. The concentrations of the test chemicals in water were relatively constant during the exposure experiment, with relative standard deviations ranging from 2-9%. The BCFs ranged from <1 to ~9000 L kg⁻¹. There were clear positive relationships between alkyl chain length and BCF for the methyl alkyl amines, while the permanently charged quaternary amine cations showed markedly lower bioconcentration than amines of similar alkyl chain length. Marked lower BCFs were measured at pH 6.3 than pH 7.8 for the alkyl amines, but not for the quaternary ammonium cations. The results will be valuable for developing a quantitative understanding of how chemical properties such as pKa, membrane-water partition coefficients and biotransformation rate constants influence the bioaccumulation of cationic surfactants.
Toxicokinetic (TK) processes such as chemical absorption, distribution, biotransformation and excretion are fundamental to better understand relationships between external and internal exposures, and to assess bioaccumulation in various organisms, i.e., fish, mammals. The biotransformation rate can be estimated using in vitro tests to obtain the in vitro intrinsic clearance (CL\text{int}). Then in vitro-in vivo extrapolation (IVIVE) and Quantitative Structure Activity Relationship (QSAR) models can be used to maximize the information available from in vitro measurements. Unfortunately, the quality of existing data is not always adequate and critical information may not be available. Moreover, there is a high degree of variability in the assay methods that may negatively impact the biotransformation rate estimates. This presentation describes new methods to address data gaps in biotransformation rates through the development of validated QSARs. More than 30 years of existing in vitro TK data for mammals (i.e. rodents approximately 9000 data, human approximately 12000 data) are assimilated and critically evaluated. A scoring system to evaluate the confidence and consistency of existing in vitro data with new standardized guidelines is developed and applied to all the in vitro data to address variability and uncertainty in the datasets. This data confidence scoring method seeks to identify high quality data that are most appropriate for QSAR development and for other potential applications (e.g., bioaccumulation screening, prioritization). Multi-variate analysis is applied to evaluate the statistical distribution of experimental responses, correlations, and to investigate the presence of structural patterns. In addition, QSAR models are generated using multiple training sets created on the basis of similar reactivity patterns. Case studies are presented to illustrate how the variability in the existing experimental data can be addressed to improve the quality of QSAR models. These results demonstrate that QSAR methods can predict biotransformation rates for mammals to improve bioaccumulation assessment and optimize other chemical hazard and risk assessment objectives.

**314 Bioaccumulation kinetics of model pharmaceuticals in the freshwater Unionid Pondmussel, Ligumia subrostrata**

*S.R. Burket, Baylor University / Environmental Science; J.L. Sims, Baylor University / Biology; B.W. Brooks, Baylor University / Department of Environmental Science*

Though biomonitoring of in situ biological tissues for pharmaceutical accumulation has increased over the last decade, most reported tissue concentrations in wildlife from the field or laboratory experiments are from fish. Few studies have examined bioaccumulation of pharmaceuticals by freshwater bivalves; however, our laboratory’s recent field studies of effluent dependent wadable streams indicate bioaccumulation of multiple pharmaceuticals in bivalves. In addition to being important priorities for conservation biology (~70% of freshwater mussel species in North America are endangered or threatened), the presence of robust bivalve populations provides important ecosystem services by improving water quality and clarity in lotic systems. Unfortunately, factors influencing bioaccumulation of pharmaceuticals by bivalves are not well understood. In the present study, we investigated bioaccumulation kinetics of model acidic and basic pharmaceuticals in the freshwater pond mussel, *Ligumia subrostrata*. Specifically, when compared to fish, we have observed some of the highest levels of antidepressants in bivalves in the field. Reasons for these marked differences are unclear. In this laboratory study, we evaluated bioaccumulation kinetics following exposure to a weak acid, acetaminophen (mean measured (±SD) = 4.66 ± 0.32 µg/L), and a weak base, sertraline (mean measured (±SD) = 2.89 ± 1.14 µg/L) during a 14-day uptake experiment. Following exposure, mussels were transferred to contaminant free water to measure depuration for 7 days, which supported derivation of bioaccumulation kinetic parameters. Pharmaceutical concentrations were evaluated in water and tissue at 11 time points, and samples were analyzed via isotope dilution LC-MS/MS. By day 14, mussels accumulated orders of magnitude higher concentrations of sertraline (31.72 ± 8.17 µg/g) compared to acetaminophen (0.32 ± 0.05 µg/g).

Considering these laboratory observations and our recent field studies, bioaccumulation differences between fish and bivalves potentially result from differences in exposure, biotransformation, and elimination.

**315 Evaluating polymeric sampling as a tool for predicting the bioaccumulation of hydrophobic organic contaminants by fish and shellfish**

*S.N. Schmidt, R.M. Burgess, US Environmental Protection Agency / Atlantic Ecology Division*

Predicting the bioaccumulation of hydrophobic organic contaminants (HOCs) by aquatic organisms is often labor and cost intensive. However, recent research has shown that polymeric sampling can reduce costs and accurately predict the bioaccumulation of HOCs by benthic and sessile organisms (within a factor of 10). Research is now needed to evaluate polymeric sampling as a tool for predicting the bioaccumulation of HOCs by pelagic and mobile organisms. In the current study, scientific literature on polymeric sampling (i.e., equilibrium sampling and passive sampling) and bioaccumulation by fish and shellfish was reviewed to investigate (1) the strength of the correlations between lipid-normalized concentrations and equilibrium polymer concentrations, (2) the ability of polymeric sampling techniques and data to predict bioaccumulation, and (3) the advantages, limitations, applicability domains, and data gaps associated with this approach. Data on a wide range of HOCs, polymers, fish, and shellfish were retrieved from scientific studies. Polymeric sampling data was expressed as the polymer concentration at assumed, adjusted, or confirmed equilibrium with the water column or sediment interstitial water (ng HOC/g polymer) while bioaccumulation was expressed as the lipid-normalized concentration in fish or shellfish (ng HOC/g lipid). Coherent data were then plotted in a log-log system and fitted with a linear regression. Generally, strong log-log linear regressions existed between lipid-normalized concentrations and equilibrium polymer concentrations across non-degradable HOCs, polymers, fish, and shellfish. Further, for non-degradable HOCs the regressions were generally within a factor of 10 from the 1:1 relationship, suggesting that the polymers accumulated a concentration comparable to the actual body residue (i.e., lipid-normalized concentration). These findings support using equilibrium polymer concentrations as surrogates for lipid-normalized concentrations of non-degradable HOCs and thus using polymeric sampling as a tool for predicting fish and shellfish bioaccumulation. Interestingly, the findings suggest that bioaccumulation models may not be necessary for predicting body residues when using polymeric sampling data. Ideally, this research will provide a tool for regulatory agencies to assess the risk associated with contaminated sediments and waters in terms of their potential to contaminate commercially and recreationally important fish and shellfish.

**316 Hydrodynamics May Influence Field Bioaccumulation of Organic Contaminants - a Meta-analysis on Bivalves Data**

*D. Kuo, City University of Hong Kong / Architecture and Civil Engineering; C. Xin, City University of Hong Kong*

Prediction and understanding of bioaccumulation of organic contaminants in aquatic environments have been hampered by substantial variability in field measurements. This study examined the variability in field bioaccumulation sediment accumulation factor (BSAF) in bivalves in various water bodies and investigate the role of flow condition on BSAF measurements. Over 3000 field BSAFs for close to 40 species of bivalve for some 100 PCBs, PAHs, and legacy organochlorine pesticides were compiled
from existing field sampling literature. Analysis of compiled bivalves bioaccumulation shows that field BSAFs vary by 4 to 6 log units for the selected chemicals. Both the BSAFs and their variation appear to exhibit little correlation with physicochemical properties of the compound or the sediment (i.e., log KOW, log KOC, and log KBC). Then, BSAFs were classified into three types based on the hydrodynamic condition or nature of the waterbodies: (i) low flow environment (e.g., lake), (ii) high flow environment (e.g., river), and (iii) complex hydrodynamic environment (e.g., intertidal zone). BSAFs measured at low flow sites are generally closer to the theoretical value prescribed by equilibrium partitioning (EqP). BSAFs reported at high flow sites, however, are substantially lower than those predicted by EqP. The greatest variability and unpredictability are observed in BSAFs from the complex hydrodynamic environment. Field BSAFs from low flow and high flow sites were found to exhibit a strong dependence on mean flow velocity of the waterbody such that at low velocities BSAFs converge toward the EqP limit while they decline dramatically with increasing velocity at high flow conditions. The observed BSAF-velocity dependence could be adequately derived and explained by considering hyporheic or benthic mass exchange using a simple box model. Findings from this work are expected to have major implications on bioaccumulation monitoring practices and the modeling of field bioaccumulation and biomagnification behavior.

317 Bioaccumulation and Trophodynamics of Substituted Diphenylamine Antioxidants and Benzotriazole UV Stabilizers in Aquatic Food Webs

Z. Lu, University of Quebec, Rimouski / Aquatic Contaminants Research Division Canada Centre for Inland Waters; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; C. Stewart, W. Zhou, Environment and Climate Change Canada / Aquatic Contaminants Research Division; G. Tetreault, Environment and Climate Change Canada / Aquatic Contaminants Research Division; S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Substituted diphenylamine antioxidants (SDPAs) and benzotriazole UV stabilizers (BZT-UVs) are anthropogenic additives widely used in industrial and commercial products such as plastics, rubbers, fuels, lubricants, and personal care products. They are very persistent in the aquatic environment, and chronic exposure to these contaminants may lead to adverse effects in organisms. Recent in vitro studies have reported that some BZT-UVs are associated with the aryl hydrocarbon receptor-mediated effects in human and fish, indicating the dioxin-like toxicities of these contaminants. Despite an increasing number of reports on the occurrence and distribution of SDPAs and BZT-UVs, the knowledge of their bioaccumulation and trophodynamics remain extremely limited. Thus, the present study collected water, sediment and various organisms such as plankton, insect, mussel and fish to investigate the fate of SDPAs and BZT-UVs in food webs from Hamilton Harbour (HH) and Lake Joseph (LJ), Ontario, Canada. Field-based partitioning data such as bioaccumulation factors (BAFs) and biota–sediment accumulation factors (BSAFs) of these chemicals will be reported in this study. Organisms from HH generally showed higher detection frequencies and concentrations of SDPAs and BZT-UVs compared with samples from LJ. This is the first time to report the levels of SDPAs and BZT-UVs in insects. SDPAs such as 4,4’-bis(a,a-dimethylbenzyl)-diphenylamine(diAMS) and dinonyl-diphenylamine (C9C9), as well as BZT-UVs 2-(2H-benzotriazol-2-yl)-4,6-bis(1-methyl-1-phenylethyl)phenol (UV234) and 2-(2H-benzotriazol-2-yl)-4,6-di-tert-pentylphenol (UV328) were frequently detected in insects (e.g., dragonfly (Anisoptera)) with concentration up to 22 ng/g for UV328 (wet weight). Biodilution of SDPAs was found in both food webs from HH and LJ. The levels of SDPAs were positively correlated with δ13C, indicating benthic species had higher exposure to SDPAs compared to pelagic species. In contrast, UV234 showed biomagnification in the HH food web, suggesting greater exposure risks of higher trophic level organisms to this contaminant. Such variations of trophodynamics indicate the differences in accumulation and elimination pathways of SDPAs and BZT-UVs and require further elucidation of underlying mechanisms.

318 Quantifying the Biomagnification Potential of Polychlorinated Biphenyls in Arctic Wolf and Domestic Dog by Equilibrium Sampling

Y. Chen, University of Toronto, Scarborough / Chemistry; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; Y. Lei, University of Toronto / Physical and Environmental Sciences

Biomagnification is the process through which organisms can have higher lipid-normalized concentrations of hydrophobic contaminants in their bodies than are prevalent in the food that they eat. The underlying mechanism is the decrease in the fugacity capacity (Z) of the food for the biomagnifying contaminants during digestion and assimilation in the gastrointestinal tract. Traditionally biomagnification is quantified by measuring contaminant concentrations in tissues collected from dead animals. Here we propose a non-invasive way to quantify the Maximum BioMagnification Factor (MBMF) by determining the ratio of the Z-values of the undigested and digested food using equilibrium sampling. We quantify the Z-values by equilibrating homogenized food and feces samples with silicone films of variable thickness coated on the inside of glass vials that are being rotated for several days. Contaminants that have migrated to the silicone are extracted and quantified using gas chromatography-mass spectrometry. Equilibration is confirmed if the amount of contaminant in the film is proportional to the volume of silicone in a vial. The content of contaminants in food and feces samples is also quantified. We demonstrate the feasibility of this method for wolf (Canis lupus hudsonicus) and domestic dog (Canis lupus familiaris). For adult wolf eating a relatively lean meat diet, MBMFs of approximately 3 were observed, whereas the MBMFs reached 10 for a juvenile domestic dog eating a lipid-rich diets. Beside the dietary lipid content which strongly affects the Z-value of the diet, the capability of an animal to digest its diet also influences the MBMF by influencing the Z-values of their feces. Cooperating with the Toronto Zoo, we have the opportunity to study the impact of an organism’s assimilation capability on the MBMF by feeding the same diet to a wide range of carnivores (e.g. Felidae, Canidae and Ursidae) with different physiological properties.

319 Effects of diluted bitumen exposure on seawater tolerance of salmon smolts

S. Alderman, S. Avey, University of Guelph / Integrative Biology; C. Kennedy, Simon Fraser University / Department of Biological Sciences; A.P. Farrell, University of British Columbia / Zoology; T.E. Gillis, University of Guelph / Department of Integrative Biology

Diluted bitumen, a heavy type of crude oil, is the main export product from Canada’s oil sands, which are the third largest crude oil reserve in the world. Millions of liters of diluted bitumen travel across North America every day in a vast network of railways and pipelines, posing a real and continuous risk for spill and environmental contamination. Yet surprisingly little is known about the specific sub-lethal toxicity of diluted bitumen, particularly in native Canadian species and in the context of critical life history stages. This study tested the hypothesis that diluted bitumen exposure would impair the ability of salmon smolts to transition between freshwater and seawater, a key event in their natural life history. Atlantic salmon smolts were exposed in freshwater to one of three environmentally relevant concentrations of the water soluble fraction of diluted bitumen for three weeks, and then transferred directly to seawater for up to seven days. The capacity for smolts to acclimate to seawater...
was assessed across a suite of standard endpoints related to osmoregulatory capacity and tissue integrity. In the gills, diluted bitumen exposure did not affect gill morphology, nor were seawater-induced changes in Na+/K+ ATPase expression or activity altered; however, the transient increase in gill *cytochrome p450 1a* expression after one day in seawater was abolished in fish exposed to diluted bitumen. In the kidney, there was a dose-dependent effect of diluted bitumen exposure on *aquaporin 3a* expression before and during seawater acclimation, and mild histopathological changes in tubule morphology. There was no effect of diluted bitumen exposure on plasma osmolality or sodium concentrations. Results of this study show that sub-chronic exposure to realistic concentrations of diluted bitumen do not adversely impact the ability of Atlantic salmon smolts to acclimate to seawater. This research is funded by the National Contaminants Advisory Group at Fisheries and Oceans Canada.

320 Effects of weathered diluted bitumen on early-life stages of zebrafish (Danio rerio)
K. Fujita, S. Everitt, G.G. Pyle, University of Lethbridge / Biological Sciences; S. Wiseman, University of Lethbridge / Biology

Due to the potential of spills, transport of diluted bitumen (dilbit) in pipelines poses a risk to aquatic ecosystems. Although previous research has assessed the toxicity of fresh dilbit to aquatic vertebrates, few studies have investigated effects of dilbit that has been weathered by evaporation and sedimentation. The objective of this study was to determine the effects of weathered dilbit to early-life stages of zebrafish (Danio rerio) as a more accurate representation of a spill of dilbit in aquatic environments. Embryos were exposed, from 30 minutes post-fertilization to 120 hours post-fertilization, to one of two water accommodated fractions (WAFs) of weathered bitumen, referred to as the SD-WAF (sediment derived WAF) and WAF. Exposure to either WAF caused a concentration-dependent increase in mortality and malformations in early-life stages of zebrafish. Exposure to the WAF at 10, 50 and 100% concentrations resulted in 17.5, 100, and 100% mortality respectively. Exposure to the SD-WAF at 10, 50 and 100% concentrations resulted in 32.3, 23.1 and 99.3% mortality respectively. Malformations and gene expression were only assessed for embryos exposed to the control, WAF 10%, SD-WAF 10% and SD-WAF 50% treatments due to high mortality in the other exposures. Prevalence of yolk sac edema was 33.8, 2.2 and 86.7% when exposed to WAF 10%, SD-WAF 10% and SD-WAF 50% treatments, respectively. Prevalence of pericardial edema in the same treatments was 59.9, 3.5 and 95.1%, respectively and prevalence of uninflected swim bladder was 75.2, 170 and 100%, respectively. Analysis of mRNA abundance of glutathione S-transferase (GST), glutathione peroxidase (GPx), glutamate cysteine ligase catalytic subunit (GCLC) and superoxide dismutase (SOD) suggest that the observed effects are not a result of oxidative stress. Greater mRNA abundance of CYP1A1 indicated presence of dioxin-like compounds in weathered dilbit that might have contributed to the observed effects. Overall, the results show that weathered dilbit has adverse effects on early-life stages of zebrafish. Currently, transcriptomic and metabolomic analyses are being used to identify potential mechanisms of toxicity of weathered dilbit.

321 Exposure to Diluted Bitumen Affects Cardiac Output, Metabolism and Swim Endurance in a Freshwater Fish Species (Pimephales promelas)
D. April, D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; V. Palace, IISD-Experimental Lakes Area; L.P. Weber, University of Saskatchewan / Veterinary Biomedical Sciences

Transport of diluted bitumen (dilbit) is becoming an increasing public and political concern due to the potential for impacts on aquatic ecosystems as a result of oil spills. Further study is required, as the current understanding of dilbit toxicity is limited. Much existing research focuses on early-life-stage developmental toxicity, however limited evidence suggests that there may be sublethal effects in other life stages. The focus of this study was to assess effects of dilbit exposure on cardiac function, metabolism, and swim endurance of sub-adult Fathead Minnows (*Pimephales promelas*). Fish were exposed to concentrations of either 0% (Control) 3%, 10%, or 30% of dilbit water accommodated fraction (WAF) for 7 days. Following the exposure period, one group of fish (n=16/treatment) were assessed for cardiac function using ultra-high frequency ultrasound. A second group (n=12/treatment) were assessed for critical swim speed (Ucrit) and active metabolic rate (AMR) using swim tunnel respirometry. A third group (n=4-6/treatment) was assessed for standard metabolic rate (SMR) using intermittent flow respirometry. Dilbit exposure was shown to significantly increase heart rate and cardiac output in the highest dose group. The high dose group also showed greater increases in AMR in response to increasing swim speeds (p<0.001, 2-way ANOVA with repeated measures), and lower Ucrit. SMR was significantly reduced in fish exposed to high doses of dilbit WAF. The physiological data from this experiment will be compared to physiological data from fish exposed to conventional heavy crude oil in the future. The results of this research will add to our understanding of sublethal toxicities of complex petroleum mixtures to advanced life stage fishes in a freshwater environment.

322 BE-SPME (Biomimetic Extraction Solid Phase Microextraction) as an Analytical Tool for Predicting Toxicity in Oil Sand Process-affected Water
A.J. Smith, B. Hedgpeth, ExxonoMobil Biomedical Sciences, Inc. / Environmental Science; H. Bailey, L. Clothier, Nautilus Environmental Company, Inc.; A. Bekele, Imperial Oil; T. Parkerton, ExxonMobil Biomedical Sciences, Inc. / Environmental Science; A. Redman, ExxonoMobil Petroleum and Chemical / Toxicology and Environment Science Division

Oil sands operational activities lead to the production of oil sands process-affected water (OSPW) which will eventually be treated and returned to the environment. The constituents of OSPW make up a complex mixture which varies by source and producer, with challenges in determining risk for exposure and toxicity. Biomimetic extraction with solid phase microextraction fibers (BE-SPME) coated with polydimethylsiloxane (PDMS), have been used as a measurement of bioavailable organics in OSPW and as a predictor for toxicity in prior work where critical threshold values were derived. Here we present new toxicity data from exposures to OSPW, single constituents, and simple mixtures with accompanying BE-SPME analysis using algae, daphnids, chironomids, blackworm, zebrafish, fathead minnows, and rainbow trout. An updated species sensitivity distribution (SSD) that includes these species is provided. BE-SPME continues to be a valuable analytical tool to predict toxicity accounting for bioavailability of complex organic compound mixtures and as a tool for predicting toxicity of OSPW. Additionally, we discuss applicability of a BE-SPME-derived SSD as an exposure metric to predict toxicity, and decrease the need for traditional toxicity endpoints to evaluate acceptable levels for safe release of treated OSPW.

323 Monitoring Ecological Responses to Air Quality and Atmospheric Deposition in the Athabasca Oil Sands Region
K. Foster, Owl Moon Environmental, Inc.

The expansion of oil sands resource development in the Athabasca Oil Sands Region in the early 1990’s led to concerns regarding the potential ecological and health effects of increased emissions and deposition of acidic substances. Conditions attached to a 1994 approval for an oil sands facility expansion led to the creation of the Wood Buffalo Environmental Association, and its Terrestrial Environmental Effects Monitoring committee. This multi-stakeholder body was tasked with development and operation of an environmental (forest health) monitoring program for the detection of ecological responses to atmospheric emissions and deposition. Initially focused on acid deposition monitoring, jack pine forest, growing on sandy soils with limited acid buffering capacity, was selected as the receptor system. An initial set of 10 monitoring locations was established using the Canadian Acid Rain Network Early Warning System methodology (since increased to 27, with three lost to development). Ecological monitoring is on a 6-year cycle, with concurrent measures of soil, needle and lichen chemistry, and tree and understory condition,
together with ongoing measurements of air quality and atmospheric deposition. Because jack pine forest edges facing the emissions sources were expected to be more exposed to acidic emissions, evaluation of stand edge monitoring locations began in 2008. Monitoring of a targeted suite of indicators began in 2012 at 25 jack pine stand edge monitoring sites. The virtual special issue presents the results derived from biophysical sampling campaigns (1998 to 2013), coupled with ongoing ambient atmospheric, deposition and epiphytic lichen monitoring (data through 2017) and source apportionment studies, as well as papers contributed by others engaged in regional research and monitoring programs. The Forest Health Monitoring Program provides data supportive of regulatory and stakeholder evaluations of environmental quality, and is adaptive to new needs, extreme environmental events and technological development while providing continuity of monitoring.

324 Forest Health Effects due to Atmospheric Deposition: Findings from Long-Term Forest Health Monitoring in the Athabasca Oil Sands Region

C. Davidson, Endeavour Scientific, Inc.

Oil sands development releases acidifying compounds [sulphur dioxide (SO2), nitrogen dioxide (NO2)] leading to concerns from stakeholders regarding the potential for acidifying deposition. Recent modeling results have suggested that acidic deposition is widespread and should exceed critical loads to forest health. The Wood Buffalo Environmental Association’s Forest Health Monitoring (FHM) Program has been in operation since 1996 to address concerns about acidifying deposition. The program is guided by a clear conceptual model of the stressor-response relationship and is recognized by the International Cooperative Programme on Assessment and Monitoring of Air Pollution Effects on Forests operating under the UNECE Convention on Long-Range Transboundary Air Pollution. It has expanded to include metal and organic deposition, more robust air quality measures, deposition monitoring programs, and source apportionment studies. Assessment of data from multiple campaigns reflects the dynamic nature of deposition in this landscape. Key program findings include: deposition of sulphur, nitrogen, base cations, polycyclic aromatic compounds and trace elements decline exponentially with distance from emission sources; there is little evidence for acidification of forest soils or acidification effects on understory plant communities or tree growth, but there is evidence of fertilization effects on jack pine needles and understory plant communities on sites within 25km of oil sands operations. Source apportionment studies suggest fugitive dust is a key driver of base cation, trace element, and organic compound deposition, confirming earlier work suggesting that base cation deposition may be neutralizing acidifying deposition. While better dust management practices are important and highly desired by local communities like Fort McKay, better control may reduce this apparent neutralization effect and contribute to acidification. The FHM Program is guided by a clear conceptual model of the source to effect pathway of acidifying deposition. Given that the FHM Program has detected effects of eutrophying emissions in the receiving environment via a pathway other than acidification, it suggests that the FHM Program is well placed to adapt its conceptual model and guide future forest health monitoring.

325 The oil sands, not just surface mines. An assessment of potential risks to aquatic health and resources from Solvent Assisted SAGD operations

M.L. Olsgard, University of Alberta / Biological Sciences

The Peace, Cold Lake and Athabasca Oil Sand deposits in Alberta comprise 167.2 billion barrels of crude oil and the 3rd largest reserve in the world. The oil sands consist of crude bitumen suspended in an ore that is a mixture of sand, clay and water found beneath boreal forest, prairie and muskeg. Reserves that are within 80 meters of surface are considered mineable and represent most images the public equate with the oil sands. Since the late 1960s, only 3.6% (4.5 billion barrels) of the total reserve has been extracted through mining. The other 80% of oil sands reserves (~100 billion barrels) are too deep for mining and require external stimulation to decrease bitumen viscosity and allow reserves to flow to surface through wells. This process, commonly referred to as Steam Assisted Gravity Drainage (SAGD). However, recent technological advances have increased the efficiency of this process by adding the same hydrocarbon-based solvents and diluents used to dilute bitumen. The solvent/diluent is a complex mixture of propane, butane, benzene, toluene, ethylbenzene, xylene, and other hydrocarbons. Many of these chemicals are associated with adverse effects in both humans and aquatic life as evidenced by federal and provincial drinking water and protection of aquatic life guidelines. The chemicals used in solvent injection are not well understood and at the discretion of individual operators not fully reported to the regulator, much like the regulatory process for hydraulic fracturing. A review of regulatory applications and environmental impact assessments (EIAs) for pilot and commercial scale solvent assisted-SAGD applications identified gaps in the assessment of releases of these chemicals to groundwater and subsequently interconnected surface water. In order to understand the risk of this emerging solvent-based technology to contamination of groundwater and hydraulically connected surface water a screening level aquatic health risk assessment was conducted. The modelling and risk assessment methods, regulatory gaps, key learnings, and potential risks of this emerging technology based on the independent risk assessment will be presented.

326 Exposure to airborne and waterborne oil sands chemicals of concern can cause immediate or latent effects on amphibians in field-based experiments

D.M. Orihuela, Queens University / Department of Biology / School of Environmental Studies; S.A. Patterson, Queens University / School of Environmental Studies; J.M. Blais, University of Ottawa / Biology; C.M. Davy, Ontario Ministry of Natural Resources and Forestry / Wildlife Research and Monitoring Section; J.V. Headley, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; B. Pauli, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; S. Robinson, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; V. Trudeaux, University of Ottawa / Biology

Whereas the spatial extent of pollution from Canadian Oil Sands mines has received considerable attention, the ecological implications on aquatic biota, and especially amphibians, remain poorly understood. Our team investigated the chronic effects of airborne and waterborne oil sands chemicals of concern on early life stages of the wood frog (Lithobates sylvaticus) using controlled outdoor mesocosm experiments. Here, we present the findings from two experiments conducted at the Queen’s University Biological Station using environmental samples collected in Alberta. In the first experiment, we exposed wood frog embryos to melt waters from snowpack collected from near-field sites in close proximity (< 50 km) to major bitumen upgrading facilities or from more distant far-field sites. Contaminants in snow near industrial facilities are likely derived from atmospheric emissions from bitumen upgraders as well as fugitive dust from petroleum coke piles. In another experiment, we exposed wood frog embryos to environmentally-relevant concentrations of naphthenic acids extracted from oil sands process affected water - that is, the waste water currently stored in large tailings ponds - and then caged the animals in a natural wetland until metamorphosis. In both experiments, we observed immediate and latent effects of exposure to oil sands chemicals of concern on the growth, development, and survival of wood frogs, an amphibian species that is native to the Canadian oil sands region.
New and Existing Chemical Contaminants in Changing Arctic and Antarctic Environments - Part 2

327 Effects of changes in species composition and distribution on contaminant accumulation in an Arctic marine food web

J. Giebichenstein, University of Oslo / Department of Biosciences; i Varpe, The University Centre in Svalbard / Department of Arctic Biology; G. Gabrielsen, The Norwegian Polar Institute / Fram Centre, Tromsø; T. Andersen, K. Borgå, University of Oslo / Department of Biosciences

Arctic marine organisms are susceptible to multiple stressors, including climate change, contaminant exposure and increased human activities such as fisheries and tourism. Combined, these stressors are expected to alter food web composition and the transport, fate, and effect of contaminants within it. Contaminants in the Arctic derive predominately from range-long transported contaminants originating at lower latitudes, as well as from local sources of pollution, e.g. human settlements, petroleum activities and shipping. Contaminant availability, uptake, and transfer are influenced by several factors characteristic of the Arctic environment, such as high seasonality in irradiation, sea ice cover and thus, primary production. But the Arctic is altered by climate change and thereby contaminant dynamics in the food web, by influencing water temperatures, sea ice distribution and thickness and consequently species distribution and composition, as well as lipid dynamics and energy transfer within the food web. This study is part of the Nansen Legacy project which promotes holistic research to identify, investigate and predict the underlying mechanisms of the changing Arctic. To better understand and predict these climatic changes, understanding of seasonal dynamics is needed. Seasonal food web data from the Arctic is difficult to obtain, and so far, mostly available from fjords rather than the productive Arctic shelf seas with its marginal ice zone, which is the focus of the Nansen Legacy project. The present study aims at identifying and comparing bioaccumulation and biomagnification processes of legacy and emerging contaminants (e.g. persistent organic pollutants and mercury) related to energy use and availability between an Atlantic-influenced and an Arctic marine food web in the Barents Sea throughout the year. Four research cruises in different seasons are undertaken, and key species of zooplankton, fishes, and seabirds are collected. Chemical and dietary descriptors are analyzed to determine how seasonal changes in energy acquisition and allocation affect annual dynamics of species composition, contaminant accumulation and transfer in the food web.

328 Avian wildlife: contaminant temporal trends and the bipolar perspective

K. Borgå, University of Oslo / Department of Biosciences; N. Eckbo, University of Oslo; N.A. Warner, Norwegian Institute for Air Research / Fram Centre; C. Le Bohec, CNRS/University of Strasbourg; D. Herzke, NILU-Norwegian Institute for Air Research / Environmental Chemistry; V. Planas-Bielsa, Centre Scientifique de Monaco / Département de Biologie Polaire; G.W. Gabrielsen, Norwegian Polar Institute; S. Descamps, Norwegian Polar Institute / Fram Centre; J.O. Bustnes, Norwegian Institute for Nature Research / Fram Centre

After decades of research in the Arctic, recent years’ research on contaminants in Polar Regions has shifted focus to the Antarctica and southern polar region. Here, we summarize results from our recent project, which aimed at comparing avian wildlife contaminant occurrence between the two Polar Regions, to assess temporal trends in Antarctic avifauna, and to identify relations between temporal trends and climate, ecological and physiological drivers. By comparing contaminant occurrence between the Polar Regions and differentiating between migratory and resident species (Arctic: great skuas and black guillemots; Antarctica: south polar skuas and Adelie penguins, respectively), we found generally higher levels of most contaminants such as polychlorinated biphenyls in Arctic wildlife compared to Antarctica. In both regions, we find generally higher contaminant levels of e.g. per- and polyfluoroalkyl substances in migratory species (great skuas and south polar skuas) compared to year-round polar residents such as black guillemot and Adelie penguins. The exception is the organochlorine pesticides Mirex and hexachlorobenzene (HCB), which are found in high levels, dominating the profile in the Antarctic birds. Levels of chlorinated paraffins and new brominated flame retardants were below detection limit in both Polar Regions. Cross-sectional temporal trends in King penguin chicks (11 months) in the sub-Antarctic Crozet archipelago show declining levels of Mirex and no changes in HCB over a 16-year period. Rather than a chronicologic signal, the levels of other contaminants are explained by years with additional stress on penguin parental care and energetic constraints caused by a prolonged distance to the polar front when moving into sub-Antarctic water, reflected in sea surface temperature and shifting δ13C signal. The polar front is an important foraging area for the adult King Penguins during chick rearing. Contaminant levels were not related to any indicators of toxicological effects, neither oxidative stress, nor survival, growth and reproduction. A longitudinal study, following the King penguin chicks in two adult years, indicate an increase in contaminant levels from chick to adult, but only minor differences in levels between the two adult years. Our results provide important knowledge on contaminant temporal trends in the changing Antarctic ecosystem, and emphasize the importance of understanding of climate, ecological and physiological drivers.

329 The Arctic tundra and its soil-dwelling springtails (Collembola) reflect nitrogen and contaminants biotransported by seabirds

S. Kristiansen, H. Leinaas, University of Oslo / Department of Biosciences; D. Herzke, NILU-Norwegian Institute for Air Research / Environmental Chemistry; K. Høyland, University of Oslo / Department of Biosciences; G.W. Gabrielsen, Norwegian Polar Institute; M. Harju, NILU Norwegian Institute for Air Research; K. Borgå, University of Oslo / Department of Biosciences

Arctic-breeding seabirds contain high levels of many anthropogenic contaminants, which they deposit through guano to the tundra near their colonies. The resulting nutrient-rich soils in the vicinity of seabird colonies are favourable habitats for soil invertebrates, such as springtails (Collembola), and may expose the springtails to seabird-derived contaminants. We quantified a wide range of lipid-soluble and protein-associated environmental contaminants in two springtail species (Megaphorura arcticae and Hypogastrura viatica) and their respective habitats (soil/moss) collected underneath different seabird cliffs. Although springtails are commonly used in laboratory toxicity tests, this is to the best of our knowledge the first study to measure concentrations of persistent organic pollutants (POPs) and mercury (Hg) in springtails from natural habitats, and the first to document biotransportation of contaminants by seabirds to soil fauna. We categorised the study sites a priorias having low, medium or high influence of seabirds based on colony composition regarding seabird species and their density. This ranking was reflected in increasing δ15N values with increasing seabird influence in the springtails’ habitat (soil and/or moss) and springtails themselves. We found clear indications of seabirds impacting the terrestrial soil environments with organic contaminants, and the contaminant concentrations were higher in soil sampled close to the bird cliff, compared to further away.

330 Elucidating Emerging Perfluoroalkyl/Polyfluoroalkyl Substances (PFAS) in Arctic Beluga Whales in Canada

A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; K. Spaan, L. Schultes, Stockholm University / Department of Environmental Science and Analytical Chemistry; M.M. Plassmann, J.P. Benskin, Stockholm University / ACES. Y. Son, South China Sea Institute of Oceanology, Chinese Academy of Sciences / Aquatic Contaminants Research Division; S. Catingan, Environment and Climate Change Canada; C. Spencer, Environment and Climate Change Canada / Water Science Technology Directorate; C. Watt, Department of Fisheries and Oceans; S. Ferguson, Fisheries and Oceans Canada; L.L. Loseo, Fisheries and Oceans Canada / Central and Arctic Region

Many Inuit living in the Arctic value subsistence foods for nutrition and culture, which include harvested beluga whales (Delphinapterus

96 | SETAC North America 40th Annual Meeting
leucas). Common dietary preparation includes maktaaq (fresh, fried, frozen, boiled, fermented blubber with skin), nikuk (dried meat/intestines), throat/trachea, misarq (fermented and liquefied blubber), and cartilage. Contaminant monitoring in traditional foods is a priority of the Northern Contaminants Program in Canada and includes assessment of Arctic temporal trends and long-range transport of contaminants. Biomagnification of certain PFASs has been confirmed in Arctic marine and freshwater food webs. In this study, we quantified 23 PFASs (including perfluorooalkylcarboxylates (PFCAs), perfluoralkylsulfonates (PFSA$s), and perfluorooctanesulfonamide (FOSA) and extractable organic fluorine (EOF) in beluga livers from three different areas of Arctic Canada: Hendrickson Island (HI) in the Beaufort Sea, Sanikiluaaq (SQ) in eastern Hudson Bay, and Pangnirtung (PG) in Cumberland Sound, Baffin Island. Samples found to have unaccounted EOF were subjected to additional suspect screening using high resolution mass spectrometry (HRMS). Total targeted PFAS (ΣPFAS$_{targ}$ = ΣPFCA$s$+ΣPFSA$s$+FOSA) corresponded to 81±9 ng/g wet weight in HI, 62±8 ng/g in PG, and 88±8 ng/g in SQ. Approximately 40–60% of PFAS$_{targ}$ was accounted for by perfluorodiacetate (PFUnDA) and perfluorooctane sulfonate (PFOS). Ratios of PFOS:PFUnDA concentration were 0.47±0.03 in HI, 1.16±0.06 in PG, and 1.21±0.18 in SQ. Emerging PFAS including monochloro-perfluorooctane sulfonate (Cl(CF$_2$)SO$_3$-, 8Cl-PFOS) and the major monochloro-perfluorooctyl ether sulfonate component in F53B (Cl(CF$_2$)OCF2CF2SO$_3$-, 9Cl-PF3ONS) was site-specific: 0.64±0.27 ng/g 8Cl-PFOS in HI and 0.11±0.01 ng/g 9Cl-PF3ONS in PG. The fraction of EOF accounted for by PFAS$_{targ}$ corresponded to 50±4% in HI, 42±5% in PG and 87±11% in SQ, suggesting that further study of the unknown organosulfonamide in HI and PG beluga is warranted. Using high resolution Orbitrap mass spectrometry, several fluorotelomer acids and perfluoro-butanesulfonamide were identified demonstrating the exposure of beluga to PFCA$_s$ and PFSA$_s$ precursors. The authors gratefully acknowledge the provision of beluga samples by participating Indigenous communities and the Northern Contaminants Program funded by the federal department, Crown-Indigenous Relations and Northern Affairs, in Canada.

331 Blubber persistent organic pollutant levels in Icelandid killer whales (Orcinus orca), 2014-2016

A. Remili, McGill University; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; R. Dietz, C. Sonne, Aarhus University / Department of Arctic Environment; F.I. Samarra, G.A. Vikingson, Marine and Freshwater Research Institute; D. Blair, Environment Canada; I. Eulaers, Aarhus University (AU), Arctic Research Centre / Bioscience; J. Desforges, Aarhus University (AU) / Bioscience; M.A. McKinney, McGill University / Department of Natural Resource Sciences

Killer whales (Orcinus orca) are among the most heavily polluted animals in the world. In particular, recent studies have highlighted the critical threat posed by persistent organic pollutants (POPs). POPs biomagnify, and cetaceans show limited biotransformation and elimination capacities, thus top-trophic feeding killer whales are highly exposed. The main risks associated with these high POPs levels are altered immune system function, reproductive impairment, and carcinogenicity. Although tissue concentrations of POPs are reasonably well documented for North Pacific killer whales, considerably less is known for North Atlantic conspecifics regarding POP concentrations, especially for more recent/current-use chemicals including brominated flame retardants. In the present study, a broad suite of POPs were determined in beluga biopsies of 51 killer whales (16 females, 33 males and two of unknown gender) sampled between 2014 and 2016 around Vestmannaeyjar, Kolgrafafjördur and Grundarfjörður, Iceland. The POP groups analyzed include polychlorinated dibenzo-p-dioxins (PCBs), organochlorine pesticides (OCPs) including dichlorodiphenyltrichloroethane and its metabolites (DDTs), hexachlorobenzene (HCB), lindane (HCHs) and chlordane (CHLs), and polybrominated diphenyl ethers (PBDEs), and 23 other flame retardant compounds, including hexabromocyclododecane (HBCDD) and polybrominated biphenyl (PBB) congeners. We hypothesize that there will be high levels of these POPs in the killer whale blubber. PCBs especially will be at the highest concentrations, followed by DDTs, and CHLs. As some killer whales in Iceland appear to be hering-specialists, while others show a mixed diet including fish and higher trophic level prey, such as seals, we nonetheless hypothesize that POPs concentrations will be lower than in some other North Atlantic killer whales, which may feed to a greater degree on marine mammals. We also hypothesize that concentrations will vary between males and females due to maternal transfer. Results from this study will be interpreted in combination with POPs data from other North Atlantic locations to provide insight into differential exposures and risks posed by POPs for North Atlantic killer whales, likely related to a combination of region-specific POPs contamination and foraging strategies. Knowledge on differential exposures among North Atlantic groups will be useful for more targeted conservation strategies across the North Atlantic.

332 Distribution of Short-Chain Chlorinated Paraffins in Ringed Seal Blubber from Eight Arctic Sites Using Gas Chromatography-Orbitrap Mass Spectrometry

R.B. Young, K. Vorkamp, Aarhus University / Environmental Science; F.F. Riget, Aarhus University / Bioscience; D.C. Muir, M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; G.W. Gabrielsen, Norwegian Polar Institute; H. Routti, The Norwegian Polar Institute

Chlorinated paraffins are complex mixtures of polychlorinated n-alkanes used in various commercial and industrial applications, including as plasticizers, flame retardants, and metal working fluid additives. Since 2017, short-chain chlorinated paraffins (SCCPs), whose carbon numbers range from C10 to C13, have been listed in Annex A of the Stockholm Convention on Persistent Organic Pollutants (POPs) due to their persistence in the environment, their long-range transport and bioaccumulation potential, and their toxicity to many laboratory model organisms. SCCPs are challenging to quantify in environmental and biological samples because they comprise dozens of congeners and possibly thousands of unique chemical structures which vary in amount, degree of chlorination, and detectability. As a result, the extent of SCCP pollution in Arctic environments and elsewhere is not well understood. Data from the Arctic is invaluable for assessing the long-range transport and bioaccumulation potential of SCCPs and other POPs. For example, other persistent chlorinated pollutants are known to bioaccumulate in ringed seals (Pusa hispida), an important food source for polar bears, killer whales, and indigenous people in the Arctic. This study examines the bioaccumulation and spatial distribution of SCCPs in ringed seal blubber samples from four Arctic locations in Canada during 2016 (Arviat, n = 4; Nain, n = 5; Resolute Bay, n = 4; Sachs Harbour, n = 5), two Arctic locations in Greenland during 2016 (Ilulissat, n = 7; Qeqertarsuatsiaq, n = 5), two Arctic locations in Norway during 2017 (Ekmannfjorden, Svalbard, n = 1; Yoldiabukta, Svalbard, n = 3), and one (1) Arctic location in Greenland during 2018 (Qaanag, n = 5). The study uses a selective sample fractionation process to remove possible interferences, gas chromatography-electron capture negative ionization-Orbitrap mass spectrometry to detect and distinguish SCCP congeners at trace levels, and a chlorine content-dependent calibration approach to quantify total SCCP amounts. The initial total SCCP concentrations range from ~50 to 1000 ng/g ringed seal blubber (w/w) and vary with location. This study will provide new insights into the spatial distribution and bioaccumulation of SCCPs in ringed seals, and help to provide a baseline for future temporal studies of SCCPs in the Arctic, including studies to examine the effects of climate-related change.
333 Profiling the hepatic metabolome of High Arctic versus Subarctic polar bears and ringed seals to investigate relationships with contaminants and diet

A.D. Morris, Northern Contaminants Program / CIRNAC; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M. Houde, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.A. Rand, Carleton University / Chemistry; T.M. Brown, Fisheries and Oceans Canada / Department of Biochemistry and Microbiology; D. Blair, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M. Dyck, Government Of Nunavut / Nunavut Department of the Environment

Environmental metabolomics have been applied to identify relationships between endogenous metabolites and contaminants in a range of species, including polar bears (Ursus maritimus) and ringed seals (Pusa hispida). Here, a targeted metabolomics approach was used to identify differences in hepatic, endogenous metabolite profiles in polar bears from Western Hudson Bay (WHB, Subarctic) and Baffin Bay (High Arctic, HA) and in nearby populations of ringed seals. Relationships were assessed between these metabolites and hepatic concentrations of legacy and new persistent organic pollutants (POPs) as well as total mercury (THg). Tissue samples were collected from the populations of both species by subsistence hunters in 2015-2016. Metabolites (239, e.g., fatty acids (FAs), amino acids, bile acids, phospholipids and their metabolites) and POPs such as polychlorinated biphenyls, organochlorine pesticides, flame retardants, perfluoroalkyl substances (PFASs) and total mercury (THg) were determined in the liver. Stable isotopes of carbon and nitrogen, quantitative FA profiles, and oxidized lipids (oxylipins) were also quantified in muscle, fat/blubber and liver (respectively) to evaluate diet. The stable isotope signatures were more variable in WHB than HA populations of both species, likely due to influxes of inland nutrients from the massive catchment of the bay, and regional shifts in food web composition and diet. Differences in POP and THg concentrations created unique exposure profiles as expected, but these were inconsistent between species; e.g., the PFASs and THg were greater in HA over WHB bears, but were greater in WHB over HA seals. The hepatic metabolite profiles for the HA and WHB seals and bears were distinct, and were differentiated using a three component, partial least squares discriminant analysis model (46.8 % of the total variation). Assessed across all samples, the PFASs were correlated with FAs, amino acids, some phospholipids, bile acids and acylcarnitines, while THg was weakly correlated to phospholipid metabolites. These contaminant and metabolite groups were also correlated with stable isotopes in both species, indicating complex interactions between metabolites, contaminants and diet. Species-specific statistical analyses on the bears and seals separately, and on location-specific predator-prey interactions will be performed once profiles of POPs and FA-based dietary indices are complete and can be included in the analytical profiles.

334 Metabolomic and transcriptomic signatures reveal PCB related effects in ringed seals (Pusa hispida) in Labrador

T.M. Brown, Fisheries and Oceans Canada / Department of Biochemistry and Microbiology; J. Cosgrove, Eurofins Eaton Analytical, LLC; B. Chandramouli, SGS AXTYS Analytical Services, Ltd.; H. Butler, SGS AXTYS Analytical Services, Ltd. / Metabolomics; C.C. Helbing, University of Victoria / Biochemistry & Microbiology; K. Reimer, Royal Military College; A. Fisk, University of Windsor / Great Lakes Institute for Environmental Research

Causal evidence linking PCBs to adverse health effects in free-ranging marine mammals is generally confounded by the highly complex contaminant mixtures to which they are exposed. A local PCB “hotspot” on the Labrador coast provided a rare opportunity to evaluate the effects of PCBs on the health of a marine mammal as this chemical dominated their persistent organic pollutant (POP) burdens. The release of approximately 260 kg of PCBs by a military radar facility over a 30 year period (1970-2000) contaminated some local marine biota, including 60% of the ringed seals (Pusa hispida) along the coast. In order to assess the implications for ringed seal health, we evaluated the abundance profiles of eight health-related gene transcripts in liver. The mRNA transcript levels of five gene targets, including aryl hydrocarbon receptor (Ahr), interleukin-1 β (Il1b), estrogen receptor α (Esr1), insulin like growth factor receptor 1 (Igf1), and glucocorticoid receptor α (Nr3c1) correlated with increasing levels of blubber PCBs. Threshold values were calculated for these five genes, with the most conservative value being 1,370 ng/g lw for Il1b. Approximately 14% of the seals in the region exceeded this threshold. We further examined 254 metabolites to add insight to the consequences of PCBs on their health. These included 18 energy metabolism metabolites, 18 endogenous steroid metabolites, 21 amino acids, 22 biogenicamines, 40 acylcarnitines, 89 phosphatidylcholines, 15 sphingomyelins, 2hexose, 13 bile acids, and 18 fatty acids in liver, plasma, and serum samples collected from 43 ringed seals in the affected area. Preliminary metabolomics results suggest that variability between metabolites is attributed to PCB concentrations and year of collection with those collected during 2010, an unfavourable ice condition year, differing from the other years. The dominance of PCBs in the seals studied enabled an assessment of the effects of this chemical on gene transcripts and metabolites involved in regulating the health of a highly mobile predator, something that is rarely possible in the world of complex mixtures.

Sequencing the Exposome Using Nontarget Mass Spectrometry: Aims, Perspectives and Challenges - Part 2

335 Identifying bioaccumulative per/polyfluoroalkyl substances (PFASs) in complex mixtures using a mouse model and nontarget mass spectrometry

C.A. McDonough, Colorado School of Mines / Civil and Environmental Eng.; S. Choyke, Duke University / Environment; L. Ferguson, Duke University / Civil and Environmental Engineering; J.C. DeWitt, East Carolina University / Pharmacology and Toxicology; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering

Per- and polyfluoroalkyl substances (PFASs) are a global research priority because they have been found at levels exceeding health advisory limits in the drinking water of millions of people. Aqueous firefighting foams (AFFFs) are a common source of complex mixtures containing hundreds of PFASs to drinking water. Understanding the full extent of human exposure to PFASs via these complex mixtures requires innovative analytical methodologies, including high-resolution mass spectrometry for suspect screening and nontarget analysis. In this study, a mouse model was dosed with a commercial AFFF mixture. Serum and urine samples from dosed mice were analyzed by quadrupole time-of-flight mass spectrometry (QToF-MS). Suspect screening was conducted using an extensive in-house extracted ion chromatogram (XIC) list and fragmentation library for hundreds of AFFF-associated PFASs. Screening of serum revealed that several substituted perfluoroalkyl sulfonates, for which no toxicological data is available, were enriched in blood from AFFF-dosed mice. Screening of urine revealed a mixture of PFASs distinct from those accumulating in the blood, with normalized peak areas increasing over the exposure period. Additionally, non-target analysis of mouse serum revealed the presence of fluorinated compounds that were not included in the original suspect screening list and had not been detected previously in the AFFF product. This highlights the use of in vivo models as an effective tool for prioritizing novel bioaccumulative PFASs that may be overlooked because they are minor components in drinking water and AFFF products.
336 Development of a database infrastructure for analytical reference data for the identification of per- and polyfluoroalkyl substances

B. Place, J. Reiner, J. Ragland, National Institute of Standards and Technology / Chemical Sciences Division

There have been numerous news reports and peer-reviewed research regarding the presence of per- and polyfluoroalkyl substances (PFAS) in the environment. The detected compounds include known PFAS (such as perfluorooctanoic acid [PFOA] and perfluorooctane sulfonate [PFOS]), and now there is emerging evidence regarding the environmental presence of novel PFAS (such as the hexafluoropropylene oxide dimer acid, HFPO-DA). Recently, novel PFAS have been identified using non-targeted analysis (NTA) approaches with liquid chromatography and high-resolution mass spectrometry (LC-HRMS). The greatest hindrance to confident identifications of novel PFAS by LC-HRMS is the accessibility of compound-specific analytical data, specifically mass spectral data, especially without the broad availability of analytical standards. Meanwhile, researchers across the world are producing quality mass spectral data for these novel PFAS from technical mixtures, synthesized compounds, and limited/expensive stocks of analytical standards. Often these produced data are used for internal mass spectral libraries that are not easily communicable between laboratories. To address this data need, researchers at NIST are designing a database structure that is specifically built to store, manage, and analyze mass spectral data regarding historically-known and novel PFAS. The database, based in an open-sourced SQL format, includes the management of mass spectra, their associated analytical metadata (such as instrument parameters), sample information, and annotated fragments for similarity searching. Included in this database will be a system for submitting data with a confidence level determination, and the statistical assessment of mass spectral uncertainty. The database is currently in a prototype format, but the functions and concepts will be presented. With the data in a publicly-accessible, open-sourced format, PFAS researchers across the world will be able to utilize the data for the identification of PFAS in environmental and other samples.

337 Characterizing Azobenzene Disperse Dye Occurrence in House Dust via Non Targeted Analysis

Disperse dyes are a class of substituted anthraquinone- or azobenzene-based dyes used to color synthetic fabrics such as polyester, nylon, and acrylic. Many of these dyes are chlorinated or brominated, and account for roughly 70% of the 9.9 million tons of industrial colorant used annually. Azobenzene dyes are well-characterized as electrophilic mutagens and contact allergens in clothing, but little is known about occurrence of these dyes in the indoor environment, nor their health implications following exposure. Furthermore, no comprehensive chemical database of disperse dyes exists. Here, we report tentative and confirmed identifications of numerous azobenzene disperse dyes in house dust samples collected from 190 homes in the Toddlers Exposure to SVOCs in Indoor Environments (TESIE) study in central North Carolina. House dust samples were collected in 2014-2016 by research investigators from homes with small children. We used a data-dependent, suspect-screening analytical strategy with HPLC-ESI-HRMS/MS analysis to annotate azobenzene-class disperse dyes in organic house dust extracts. A substructure search in CAS was used to assemble a suspect list of compounds containing p-aminoazobenzene as the core structure of disperse dyes. Extracted dust samples were then analyzed using an Orbitrap Lumos mass spectrometer in positive and negative modes with data-dependent MS/MS selection. Tentative identifications were assigned using a weight-of-evidence non-targeted analysis approach with multiple open-source, in silico fragmentation algorithms combined with curated data source, scientific reference, and patent information for each candidate compound. Based on our preliminary data, we have tentatively identified approximately 90 features in house dust as azobenzene compounds at environmentally relevant concentrations (area counts greater than or equal to 10^{5}); many of these compounds are halogenated. More than 30 of these tentative identifications appear to be significantly (p = 0.05) enriched in the homes of Hispanic and non-Hispanic black children relative to homes of non-Hispanic white children. We report the first comprehensive analysis of azobenzene compounds in house dust in the United States. Ongoing analysis will confirm tentative identifications with authentic reference standards, and will continue to investigate associations of tentatively identified azobenzene compounds with additional metadata available (e.g. age of home, square footage, etc.).

338 Towards Confident Identification of Organic Pollutants Without Authentic Standards

S. Schreckenbach, University of Toronto, Scarborough / Department of Chemistry and Department of Physical and Environmental Sciences; J. Koopman, University of Bonn / Mulliken Center for Theoretical Chemistry; J.S. Anderson, National Autonomous University of Mexico / Institute of Chemistry; S. Grimme, University of Bonn / Mulliken Center for Theoretical Chemistry; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences; K.J. Jobst, McMaster University / Department of Chemistry and Chemical Biology

One aim of nontargeted screening (NTS) is to identify new environmental pollutants prior to their emergence as global contaminants. Suspected pollutants are typically identified using the time-honoured approach of comparing their electron ionization (EI) mass spectra with those compiled in libraries or obtained from authentic standards. Nevertheless, such libraries are incomplete, and standards may be unavailable or too costly. This study evaluates the performance of competitive fragment modeling (CFM-ID) and quantum chemical electron ionization mass spectrometry (QCEIMS) for suspect screening and identification of unknowns. EI mass spectra of 35 compounds, including halogenated organics, brominated and organophosphorus flame retardants, and disinfection by-products were computed and compared with the NIST Library using standard matching algorithms. The computational results were also compared to collision-induced dissociation (CID) experiments with authentic standards as well as an indoor dust sample containing flame retardants and other pollutants. QCEIMS generally performed equivalently or better than CFM-ID. Average match factors were 628 vs. 542 for the halogenated organics, and on average 55% of CID products were accurately predicted by QCEIMS compared with 17% by CFM-ID. For the organophosphorus flame retardants, CFM-ID predicted 58% of CID products whereas QCEIMS predicted 48%. When applied to the indoor dust sample, QCEIMS performed comparably to routine combinatorial methods for suspect screening, identifying 19/20 target compounds. The challenge of identifying unknown pollutants presents a cyclic problem: by virtue of being unknown, these pollutants are not found in any database, and there are no authentic standards available for confirmation. Herein, two cases are presented of previously unreported pollutants. The close match between the experimental and QCEIMS predicted spectra raises the tantalizing possibility that an unknown pollutant can be confirmed in hours, as opposed to days or months required to obtain an authentic standard.

339 Nontarget Profiling of Organic Compounds in a Temporal Series of Hydraulic Fracturing Flowback and Produced Waters

C. Sun, University of Alberta / Laboratory Medicine & Pathology; Y. Zhang, University of Alberta / Department of Laboratory Medicine & Pathology; D. Alesi, University of Alberta / Earth and Atmospheric Sciences; J.W. Martin, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES and Science for Life Laboratory

Horizontal drilling coupled with hydraulic fracturing (HF) is a widely-used technology to enhance the release of oil and natural gas from tight reservoirs. Large volumes of water are mixed with HF fluid additives and
propellant which is pumped into the wells at high pressure to fracture the target geologic formation. When HF pressures are released, a fraction of the injected water along with natural formation water return to the surface, which we refer to here as flyback and produced water (FPW). FPW is often brackish and contains a mixture of organic compounds originating from HF fluid additives, geogenic substances, and possibly transformation products. HF-FPW is toxic to aquatic life, but its chemical content is largely unknown, variable and complex. In this study, seven FPW samples were collected from a HF operation in the Duvernay Formation (Alberta, Canada) over 30 days of flyback and characterized by a nontarget workflow based on high performance liquid chromatography - high resolution mass spectrometry (HRMS). A modified Kendrick mass defect plot and MS/MS spectral interpretation revealed seven series of homologous compounds of ethylene oxide, among which a series of aldehydes was proposed as degradation products of polyethylene glycols, and two series of alkyl ethoxylate carboxylates could be proprietary HF additives. Many other ions were confidently assigned a formula by accurate mass measurement and were subsequently prioritized for identification by matching to records in ChemSpider and the USEPA's CompTox Chemistry Dashboard. Quaternary ammonium compounds, amine oxides, organophosphorous compounds, phthalate diesters and hydroxyquinoline were identified with high confidence by MS/MS spectra (Level 3), matching to reference spectra in MassBank (Level 2) or to authentic standards (Level 1). Temporal trends showed that most of the compounds declined in abundance over the first nine days of flyback, except for phthalate diesters and hydroxyquinoline that were still observed on Day 30 and had disappearance half-lives of 61 and 91 days, respectively. All the compounds followed first-order disappearance kinetics in flyback, except for polyoxygenated acids which followed second-order kinetics. This analysis and the workflow, based largely on public on-line databases, enabled profiling of complex organic compounds in HF-FPW, and will likely be useful for further understanding the toxicity and chemical fate of HF-FPW.

340 Using suspect screening to determine Hurricane Florence’s impact on chemicals of concern at a forested water reuse site

M.L. Hedgespeth, North Carolina State University / Department of Forestry and Environmental Resources; D. Rashash, North Carolina State University / NC Cooperative Extension; D. Shea, Statera Environmental, Inc. / Biological Sciences; M.J. Strynar, US Environmental Protection Agency / ORD/NERL/EMMD; J.A. Delborne, E.G. Nichols, North Carolina State University / Department of Forestry and Environmental Resources

The city of Jacksonville, North Carolina, currently utilizes a forested water reuse system to treat and repurpose its municipal wastewater. Forested water reuse systems provide an alternative means of wastewater discharge in which treated effluent is applied to forest soils via slow-rate irrigation. Although these systems have been utilized for decades in the US, they have only recently been investigated in terms of their roles as a source of emerging contaminants into the environment. The entire forested watershed at the Jacksonville site covers 7200 acres (2900 ha) for which 2000 acres (810 ha) are irrigated with wastewater. The irrigated area of the site contains multiple streams throughout its forest, is bordered by agricultural land use, and also receives leachate input from a nearby landfill. The site was impacted in September 2018 by Hurricane Florence, receiving approximately 760-990 mm rainfall over the entire month (whereas 2007-2017 September rainfall values range from 38-310 mm). The purpose of this study was to assess changes in organic chemical contaminants of concern related to the impact of the hurricane both on and directly off site. A previous study at this site examining a smaller scale storm event found that storm events send pulses of chemical contaminants into surface waters with high initial concentrations that are then rapidly diluted. Surface, ground-, and wastewater samples from the site collected prior to and after the hurricane’s impact were analyzed via a suspect screening approach to determine differences in numbers of chemical features and changes in chemical feature composition. We believe this will provide valuable information as to how tropical storm events impact emerging contaminants not only within such forested water reuse systems, but also the potential for their transport to surrounding areas.

341 Combining and multiplexing novel online sampling techniques to widen coverage of non-targeted analysis in water

T. Anumol, Agilent Technologies, Inc.; L. Tölgyesi, Agilent Technologies Sales & Services GmbH and Co.KG / Global Laboratory Solution Sales (LSS) Marketing

Water safety and quality are fundamental to human development and well-being. Yet, we are exposed to several thousand chemicals in our water daily. Safe and readily available water is important for public health, whether it is used for drinking, domestic use, food production or recreational purposes. Environmental regulations throughout the world currently focus on monitoring a limited number of well-known compounds that are assumed to be responsible for significant ecological and human health related risks. However, the quantum of chemicals we are exposed to in the environment is significantly greater. Hence there is a growing interest to extend the well-defined fraction of anthropogenic chemicals, the priority pollutants declared by the regulations, to allow the surveillance screening for contaminants of emerging concern and thus provide comprehensive data on the chemical quality of drinking and surface waters. Contamination of environmental samples with harmful chemicals can be detected with high-resolution mass spectrometry (HRMS), which provides accurate mass data on the compounds found with broad range of physicochemical properties and allows retrospective analysis to look for known and newly identified contaminants in a single sample. Targeted analytical methods are increasingly complemented by untargeted acquisition methods using high resolution accurate mass (HRMS), which provides accurate mass data on the compounds found with broad range of physicochemical properties and allows retrospective analysis to look for known and newly identified contaminants in a single sample. Targeted analytical methods are increasingly complemented by untargeted acquisition methods using high resolution accurate mass Q-TOF LC/MS due to comprehensive screening requirements in current environmental regulations as well as increasing interest in the occurrence of contaminants of emerging concern. However, coverage of chemicals that can be accurately identified by HRMS is a function of the sample preparation technique and is often not investigated thoroughly. The determination of polar and semi-polar compounds in a single analytical run is difficult due to their inherently different physicochemical properties. It is challenging to analyze polar compound with conventional SPE setup as they rapidly pass through the SPE cartridge, but they have successfully been used for increasing the sensitivity of an LC/MS system due to the enrichment of semi-polar compounds on the cartridge. Issues with time, labor and reproducibility though led us to investigate a novel online SPE approach in the first phase that will be discussed. The aim of the current work was the development of a target and suspect screening LC/MS method using HRMS for the determination of contaminants of emerging concern with broad range of physicochemical properties in drinking water by leveraging a customized online SPE setup for polar and non-polar analytes in a single injection to ensure their high quality. This coupled with direct large column aqueous injection in the same analysis helps with recovery and identification of other compounds that would be lost on the SPE cartridge due to non-retention. This unique approach of using online SPE and direct injection simultaneously allows for broader range of analysis of chemicals present in the sample. This study will present data on less frequently considered issues with sample preparation that are not considered when looking into HRMS analysis too.

342 Toxic Contaminant Identification in Wastewater Effluent using Gas Chromatography High Resolution Mass Spectrometry

S. Nieto, T. Anumol, Agilent Technologies Inc.; T.M. Young, University of California, Davis / Civil and Environmental Engineering

In order to identify the source of toxicity in wastewater effluents a conventional targeted analysis approach may not always be sufficient, due to significant limitation of the scope and possibility of unknown chemicals causing the toxicity. A more comprehensive screening and/or non-targeted analysis is often be required. The use of liquid chromatography coupled with a high-resolution mass spectrometer has gained in popularity for these kinds of analysis in the last few years. Yet, many
Microplastics in the Environment: Transport, Fate and Ecological Effects - Part 2

343 Measuring Microbead and Microplastic Trends in Wastewater Treatment Plant Effluents Before and After Regulation

P.A. Helm, Ontario Ministry of the Environment, Conservation and Parks / Environmental Monitoring and Reporting Branch; A. Marquez, Ontario Ministry of the Environment, Conservation and Parks; M. Talelishojaieion, University of Toronto, Mississauga; J. Abraham, University of Guelph / School of Environmental Science; A. Sims, Ontario Ministry of the Environment, Conservation and Parks / Laboratory Services Branch

Microplastics enter waters such as the Laurentian Great Lakes from a wide variety of sources and pathways, including wastewater treatment plant effluents. Microbeads, which have been used in personal care products such as exfoliating face and body washes, are one source of microplastics that received considerable attention, and were subsequently regulated in both Canada and the United States, banning their use in such products. Three wastewater treatment plants (WWTPs) from the Greater Toronto and Hamilton Area, with effluents that reach Lake Ontario, Canada, were sampled to characterize the types of microplastics present, the relative contributions of microbeads, and to track changes in microbead abundances following their removal from personal care products. Sampling began in 2014 at one WWTP and 2016 at the other two and continued into spring 2019, bracketing the dates bans took effect in Canada and the US. Two sampling strategies, net grabs and 24-hour composites, were employed and compared, ensuring a range of particle sizes were captured. Personal care products containing exfoliating materials were purchased from retail outlets in the Toronto, Ontario in 2015 prior to companies removing polyethylene microbeads and in 2018 after the ban in Canada. Microplastic particles were counted and categorized according to particle morphologies using a microscope to reflect source types, ensuring both irregularly-shaped and spherical microbeads could be appropriately measured and tracked. Microbead abundances declined over the sampling period reflecting removal from the marketplace. The abundance of spherical microbeads increased relative to irregular microbeads due to the continued use of multicolored spherical beads, which are typical composed of synthetic wax or cera microcrystalline as confirmed by FTIR spectroscopy. The composition of microplastics in the effluents varied among the WWTPs, with industrial-based sources representing a significant fraction of one plant, demonstrating the presence of other manageable microplastic sources that are not captured under initiatives to address litter and single-use plastics.

344 Assessing blue jeans as a major microfiber source to global aquatic systems

J. Adams, S. Athey, University of Toronto / Earth Sciences; L. Erdle, University of Toronto / Department of Ecology & Evolutionary Biology; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; P.A. Helm, Ontario Ministry of the Environment, Conservation and Parks / Environmental Monitoring and Reporting Branch; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology; S.A. Finkelstein, University of Toronto; M.L. Diamond, University of Toronto / Department of Earth Sciences

United States consumers purchase ~450 million pairs of blue jeans per year, with global sales increasing annually. Approximately 75% of consumers strongly prefer denim produced using 100% cotton or cotton blends. Cotton is a natural fiber and is commonly considered more environmentally friendly than synthetics, however cellulose fibers (including cotton) are among the most common types of anthropogenic particles observed in the natural environment. Risks associated with processed cotton microfibers in the environment, including persistence and toxicity, are unknown. We analyzed samples for microplastics and microfibers (MFs) from several stages along the microfiber aquatic pathway, including in-home washing machines, waste water treatment plants (WWTPs), freshwater lakes of southern Ontario, aquatic organisms inhabiting Lake Ontario, and marine sediment from the Canadian Arctic Archipelago. Cellulose-based cotton fibers were identified using a combination of Raman spectroscopy and morphology. Further detection of a dye or chemical additive indicated anthropogenic origin. Cellulose fibers that did not contain a dye or additive were considered cellulose of ‘unknown origin’. However, there are no natural sources of cotton within >1000 km of our study sites. Microfibers, and among those, cellulose fibers, were the dominant particle type in all samples. WWTP final effluent analysis showed that 80% of particles discharged into Lake Ontario were MFs, and 11% of MFs were identified as anthropogenic cellulose. Lake Ontario and Lake Huron sediments also showed that 90% of particles were MFs, and ~50% of all MFs were identified as anthropogenic cellulose. Microparticles recovered from Rainbow smelt from the Great Lakes also indicated a dominance of MFs, at ~97%. Raman analysis is still to be conducted on a portion of these particles. Widening the geographic scope, our findings from sediment taken across the Canadian Arctic Archipelago were congruent with other ecosystems, as 90% of particles were MFs, and ~35% of all MFs were anthropogenic cellulose. Approximately 75% of anthropogenic cellulose fibers found across ecosystems contained blue indigo dye. The prevalence of anthropogenic cellulose fibers with indigo dye are consistent with the microfibers shed from washed blue jean denim. Our results show the extensive footprint of our current blue jean culture that extends throughout aquatic ecosystems.
345 Microplastics and contaminants: Field experiments to assess the role of microplastics as a vector for contaminants
K. Vorkamp, Aarhus University / Environmental Science; A. Karlsson-Drangsholt, Bellona Foundation; E. Burgerhout, V. Puvanendran, H. Teiten, Nofima AS; N.J. Diepens, Wageningen University; A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management; I. Rannestad, University of Bergen / Biological Sciences; A.S. Bogevik, Nofima AS

Microplastics (MP) are polymer particles with a diameter of less than 5 mm, originating from commercial use (primary MP) or degradation of larger plastic debris (secondary MP). The presence of large amounts of MP in the sea is a significant pollution issue. Besides the risk of physical damage to marine organisms that ingest MP, concern has been expressed about exposure to contaminants sorbed to MP from seawater. The sorption process is known from passive sampling studies using plastic polymers such as polyethylene (PE) to accumulate contaminants from seawater. The project PlastiCod has studied the contaminant sorption to MP in the sea and the subsequent uptake by Atlantic cod (Gadus morhua). In the field experiments, PE particles (0.3-0.6 mm) were deployed alongside sheets of polydimethylsiloxane (PDMS) and polyoxymethylene (POM), commonly used passive samplers. The polymers were placed in the sea at nine locations along the coast of Norway for about four months and subsequently analysed for polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), hexabromocyclododecane (HBCD), chlordane-related pesticides and toxaphene. The contaminant concentrations sorbed to PE were generally low, but higher than in the virgin PE. The ΣPCB concentrations (CB-28, -52, -101, -118, -138, -153, -180) ranged from 0.09 to 2.9 ng/g dry PE, with highest average concentrations for CB-52 and CB-101. Amongst the PBDEs, BDE-47, -49, -99, -100 and -209 were detectable in most samples, with highest concentrations for BDE-47 (0.007-0.06 ng/g PE) and BDE-209 (not detected-0.8 ng/g PE). The maximum ΣHBCD concentration was 0.09 ng/g PE. The PDMS concentrations ranged between 0.07-0.9, 0.04-0.2 and 0.003-0.05 ng/g for ΣPCB, ΣPBDE and ΣHBCD, respectively. Data for chlordane-related pesticides and toxaphene are still being processed for PE and PDMS, as well as data for all contaminants in POM. Comparisons between PDMS and PE indicate higher concentrations in PDMS for the most hydrophobic compounds and will be analysed further. Duplicate samples from the same location showed better agreement for PDMS than for PE. The highest concentrations were generally found in samples near the capital Oslo. However, elevated concentrations of specific compounds occurred in some locations, indicating local phenomena. The results can be compared with food-chain associated contaminant exposure and contribute to our understanding of the significance of MP as a vector for contaminants.

346 Microplastics in San Francisco Bay: Abundance, Transport, Fate, and Policy Recommendations
R. Sutton, M.D. Sedlak, San Francisco Estuary Institute; D. Lin, San Francisco Estuary Institute / Department of Civil and Environmental Engineering; A. Gilbreath, San Francisco Estuary Institute / Watershed Program; C. Box, 5 Gyres; R.C. Holleman, University of California at Davis; X. Zhu, University of Toronto / Department of Ecology and Evolutionary Biology; K. Munno, University of Toronto / Ecology & Evolutionary Biology; L. Werbowski, J. Bikker, A. Ho, C.M. Rochman, University of Toronto / Department of Ecology and Evolutionary Biology

The San Francisco Bay Microplastics Project has characterized microplastics and other microparticles in a variety of media to determine sources, pathways, and loadings to San Francisco Bay, a densely populated urban environment, as well as to the adjacent Cordell Bank, Greater Farallones and Monterey Bay National Marine Sanctuaries. Field staff collected samples of stormwater runoff, wastewater effluent, open Bay and Sanctuary surface waters, Bay sediment, and two species of prey fish. All samples were analyzed for microparticles using visual techniques; a subset of the particles was examined via Raman or FTIR spectroscopy to identify whether they were composed of plastic polymers or other materials. The concentrations observed were used to validate a process-based particle transport model for the Bay and Sanctuaries that can be used to predict the transport and fate of microplastics in the region. Findings further informed a collaborative, multi-stakeholder process to develop data-driven region-specific policy recommendations to reduce microplastic pollution.

347 Weathering impacts on the fate of plastic debris in the marine environment
A. Jahnke, Helmholtz Centre for Environmental Research - UFZ GmbH / Cell Toxicology; H.H. Arp, Norwegian Geotechnical Institute (NGI); D. Kuehnel, UFZ - Helmholtz Centre for Environmental Research; M. Schmitt-Jansen, UFZ - Helmholtz Centre Environmental Research / Bioanalytical Ecotoxicology; A. Potthoff, Fraunhofer Institute for Ceramic Technologies and Systems IKTS; E. Gorokhova, E. Toorman, KU Leuven; M. MacLeod, Stockholm University / Department of Environmental Science and Analytical Chemistry

The marine environment is the final sink for a large fraction of the plastic waste that we generate on land. As soon as plastic is emitted to the environment, it is subject to factors influencing its yet poorly characterized weathering. This presentation will highlight some of the major research outcomes of the JPI Oceans-funded project WEATHER-MIC (www.jpi-oceans.eu/weather-mic, 2016-2019). The overall goal was to assess how weathering impacts the transport, fate and toxicity of plastic material in the marine environment. A major topic was to characterize the chemicals that are liberated from plastic into artificial seawater under strong UV light irradiation. Several breakdown products of the polymer backbone were identified, and the leachates were tested for mixture effects in cell-based, algal and daphnid bioassays. At the same time, changes in particle properties were characterized, and the weathered particles were tested along with their pristine counterparts in the algae and daphnid test systems. We also addressed the impact of weathering on the sinking rates of plastic particles and incorporated the outcomes into a mathematical model. Future work will also be presented, including a glimpse on the results of a scientific expedition on the German research vessel "SONNE," crossing the North Pacific Ocean between Vancouver (Canada) to Singapore in summer, 2019. During the cruise, we will both collect and generate field-weathered plastic in the Great Pacific Garbage Patch and along gradients to less polluted areas. Sampling will consider both plastic debris and the surrounding media (water and sediment) at the sea surface, in the water column and in the seabed, to determine if the plastic is a source or sink for organic environmental pollutants. The results are expected to contribute to our understanding of the transport and fate of plastic debris in the marine environment, and to help test the hypothesis that the majority of plastic debris emitted to the marine environment sinks to the seabed, where it is stored for an undetermined time.

348 Synthesis of metal doped nanoplantastic particles and microplastic fibers and their utility for investigating plastic fluxes in complex matrices
S. Frehland, R. Kaegi, Eawag - Swiss federal Institute of Aquatic Science and Technology / Process Engineering; R. Hufnens, Empa Swiss Federal Laboratories for Materials Science and Technology; D.M. Mitran, Eawag - Swiss Federal Institute of Aquatic Science and Technology / Process Engineering

Reports on the occurrence of particulate plastics (nano- and microplastic particles and fibers) in the environment emerge on a weekly basis, but quantitative data are still limited due to analytical difficulties and inconsistencies of the methods applied to detect particulate plastics in complex environmental matrices. While progress is still ongoing to develop analytical methods to measure particulate plastic in field studies, researchers who study the fate, transport and biological interactions and effects of nano- and microplastics in bench top or pilot scale studies can take advantage of an entirely different approach. In this work, we synthesized a variety of particulate plastics (nanoplastic particles, fibers) with an embedded inorganic fingerprint (Pd or In; approx. 0.5% metal/wt) which can be used to detect plastic by common analytical techniques
for metals analysis, such as ICP-MS. This allows us to more quickly and quantitatively assess plastic in complex matrices than is currently possible with other analytical techniques. To highlight the utility of this approach, here we used these materials to investigate the fate and transport of particulate plastic in a pilot-scale WWTP representing the activated sludge process. Triplicate samples were taken from the mixed liquor and effluent at least twice a week for the entire length of the experiment, which lasted five weeks. With a recovery rate of plastics over 90%, our findings show that in discrete grab samples 98% of plastics (both nanoplastic particles and microplastic fibers) were in the activated sludge, with a high correlation between TSS concentration and plastic concentration. However, when assessing the total mass balance (i.e. including respective volumetric flows of the sludge and effluent), only about 70% of the plastic is retained in the activated sludge. As our test system boundaries did not include the primary clarification stage of WWTP, a further reduction of plastic in full scale WWTP may be expected. Nevertheless, by using these metal-doped plastics, benchscale and pilot-scale studies can be used as a bridge to understand (particulate) plastic in complex matrices until analytical techniques to measure particulate plastic in solids, in trace concentrations, and in wastewater applications of UV-based AOPs for potable water reuse will be addressed. Prof. Dionysiou will elucidate the advantages and challenges for the treatment of emerging contaminants for water reuse.

350 Microplastics in biosolids and agricultural soils: A Canadian case study
J. Crossman, University of Windsor; R. Hurley, Norwegian Institute for Water Research; M. Futter, Swedish University of Agricultural Science / Aquatic Sciences and Assessment; L. Nizzetto, Norwegian Institute for Water Research NIVA
Here, we report on microplastics (MPs) detected in biosolids and in the soils to which they were applied in Ontario, Canada. MPs in biosolids from three waste water treatment plants, three agricultural fields receiving biosolid application and a fourth control field were examined. Composite samples were collected at three depths (0-5, 5-10 and 10-15 cm) over the course of a growing season. Approximately 10K MP particles were detected per kg biosolid (dry weight). Fragments and fibers were the most common form of MP, beads were a minor component of all biosolid samples and glitter was detected in one biosolid sample. Polyethylene, polypropylene, and polyester were the dominant polymer types across all biosolids samples. MPs concentrations in the top 15 cm of soils receiving biosolid amendments averaged 170 MP particles per kg soil (dry weight) versus 7 MP particles per kg soil (dry weight) in the control soil where no biosolids were applied. In contrast to the biosolid samples, fibers were the dominant MP type in all fields. MPs were detected in the deepest samples at all sites, in lowest concentrations in the control field. The three study sites demonstrate significant differences in microplastics transport behaviour over time, with evidence of vertical migration in some with lower permeability. There is no evidence that the MPs detected were associated with agricultural plastics (e.g. use of plastic mulches). These results are likely to be extremely useful for modelling studies of MP fate and transport and can support a stakeholder dialogue about the risks and benefits of biosolid application.

349 Characterizing Microplastics in Bottom Sediments from US Waterways
B. Suedel, J.L. Wilkens, US Army Engineer Research Development Center; A.D. McQueen, J. LeMonte, US Army Corps of Engineers ERDC / EL
The US Army Corps of Engineers uses dredging to excavate shoaled sediments from federal navigation channels to maintain safe and navigable waterways. Given the reported extent of microplastics in the aquatic environment, environmentally relevant exposure information is needed for bottom sediments targeted for dredging to lend context to the potential risk of the presence of these materials. Therefore, the objective of this research was to measure the occurrence and abundance of microplastics in sediments collected from waterways where dredging is performed and characterize exposure parameters (i.e., size, shape, composition) that are likely to influence ecological risks. Sample locations included sites dredged within the Great Lakes, Gulf of Mexico, Long Island Sound, Atlantic Ocean, and the Mississippi River (n=9) and both freshwater and marine reference sites (n=2) where no dredging occurred. The number of particles for all samples ranged from 162 to 6,110 particles/kg dry wt., with a mean of 1,636 particles/kg dry wt. Microplastic particle shapes observed in the sediments examined included fibers, films, foams, fragments, and spheres. Fragments occurred most frequently, present in all sample sites (100%, n=11), followed by fibers (81%), spheres (75%), foams (38%) and films (34%). Based on analyses of chemical composition of the particles using Fourier transform infrared spectroscopy (FTIR), polyethylene:propylene was the most common polymer type observed. Microplastics varied considerably among sites with respect to abundance and shape. The occurrence of microplastics at every sample site in this study (including freshwater and marine reference sites) was consistent with microplastic occurrence and abundance reported by investigators in other regions, and provides evidence that microplastic particles are abundant in both marine and freshwater bottom sediments and therefore should be anticipated in dredged sediments. These data provide additional insight and context to key parameters (e.g., particle concentration, shape, and chemical composition) necessary to inform ecological consequences of microplastic exposures during dredging operations.

351 Advanced technologies to remove contaminants of emerging concern for water reuse
D. Dionysiou, University of Cincinnati / Department of Biomedical, Chemical and Environmental Engineering (DBCEE)
With the increasing public attention to health risk associated with environmental pollution, introduction of newly synthesized chemicals into the environment, and the rapid development of analytical instruments, a wide variety of contaminants of emerging concern (CECs) were detected in recently years. Various treatment technologies are developed to remove these CECs from wastewater for water reuse applications, including filtration, membrane separation, reverse osmosis, activated carbon adsorption, ozonation, and advanced oxidation processes (AOPs). In this presentation, Prof. Dionysiou will elucidate the advantages and challenges for the treatment technologies for the removal of CECs. Work from his group on the applications of UV-based AOPs for potable water reuse will be addressed. Special attention will be given to the transformation products and cytotoxicity of treated CECs.

352 Using UV/chlorine as drinking water barrier in Harmful Algal Bloom events: Effects and concerns
M. Kong, X. Duan, University of Cincinnati / Department of Chemical and Environmental Engineering; D. Dionysiou, University of Cincinnati / Department of Biomedical, Chemical and Environmental Engineering (DBCEE)
The widespread occurrence of harmful algal blooms (HABs) in drinking water sources poses great threat to the drinking water safety. During HABs, certain cyanobacteria could produce cyanotoxins which are potent hepatotoxins, and besides they could release algal organic matter, which as the primary source of dissolved organic nitrogen (DON) can serve as a nitrogenous disinfection byproduct (N-DBP) precursors.
UV/chlorine process has been evaluated as a potentially practical and effective process to degrade frequently detected cyanobacterial toxins in drinking water. Meanwhile the N-DBP formation need to be studied to fully evaluate the impact of UV/chlorine process on the quality of finished water. In this study, degradation of MC variants, including MC-LA, MC-RR, MC-YR, and MC-LR, by UV/chlorine process and chlorination and were evaluated. The combined UV and chlorine oxidation showed a significant synergistic effect on the degradation of all studied MCs. Rapid degradation of MCs was observed even at high pH 8-10, which indicated the UV/chlorine could be employed to treat water from several lakes contaminated with HABs after proper pre-treatment in engineered water treatment plants. The formation of nitrogenous disinfection byproducts (N-DBPs) from microcystin, arginine, or algal organic matters can be enhanced by UV/chlorine compared with chlorination only. The UV/chlorinated cyanotoxins also showed quantitatively less cytotoxicity than treated by chlorination.

353 Microbial Communities as Drivers of Non-Target Chemical Change and Contaminants of Emerging Concern Degradation

G. Mahadwar, Oregon State University; G.D. Jones, Oregon State University / Biological and Ecological Engineering; B. Crump, Oregon State University

Microbial communities in aquatic systems act as drivers of chemical change, including the degradation of contaminants of emerging concern (CECs). This study investigated the ability of microbial communities to alter the surrounding chemical environment, and to degrade a suite of 21 known CECs across time and space. A series of four streams and a wastewater treatment plant were sampled across three seasons. Microbial community composition was identified using 16S Illumina sequencing, non-target chemical analysis was performed using high resolution time-of-flight mass spectroscopy, and future work includes a target analysis of the 21 CECs. Using hierarchical clustering and multidimensional scaling, chemical and microbial communities have been grouped to find the most important variables. Microbial variables will be used to predict chemical signature changes over time. The key microbial species will be compared against CECs degradation to determine the core microbiome most important to CEC removal. Identification of such a core microbial community can be utilized to seed wastewater treatment plants such that CECs removal can be improved prior to wastewater discharge into surface water.

354 Evaluation of waterborne estrogenic activity at a land-based, water recirculation aquaculture facility using E-screen

N.W. Shappell, USDA-ARS / Edward T. Schafer Agricultural Research Center; C.M. Good, The Conservation Fund Freshwater Institute; S.B. Harper, ARS-USDA / Office of National Programs; J. Davidson, The Conservation Fund Freshwater Institute; C.E. Harrison, Formerly Conservation Fund Freshwater Institute, currently Michigan State University

Land-based, closed-containment production of Atlantic salmon Salmo salar using recirculation aquaculture system (RAS) technologies could prove a viable avenue for aquaculture industry expansion, given the limited coastal locations worldwide that are suitable for raising this species in tradition sea cage systems. At present, certain hurdles remain regarding RAS Atlantic salmon production; these include early maturation, which can result in decreased product quality through reduction in normal flesh coloration. It is hypothesized that accumulating steroid hormones in RAS water can influence early maturation. We therefore sought to investigate waterborne estrogenic activity at a land-based RAS facility raising Atlantic salmon, utilizing the highly sensitive in vitro assay E-screen. Water samples were collected from replicated (n=3) RAS treatment with or without ozone, +O3 or - O3, as well as influent spring water and combined facility effluent water, over a 4-month sampling period. Samples were also collected from the facility spring pond, receiving both spring water and facility effluent, and a nearby duck pond (presumed positive control). E-screen results indicated that estrogenic activity of influent RAS water from +O3 or -O3 was never greater than 0.008 ng/L of estradiol equivalents (E2Eq), with 75% of intake samples either ≤ solvent method blanks or below the limits of quantitation. Concentrations of all water samples collected were 10-fold lower than the predicted No Effect Concentration for E2 in fish (2 ng/L). While culture tank water from +O3 RAS tended to be lower in E2Eq than those from -O3 RAS, there was some inconsistency across all RAS culture tanks. On one sampling date the ozonated culture tanks had higher E2Eqs than two of the non-ozonated RAS tanks. Liquid chromatography, tandem mass spectrometric (LC-MSMS) analysis of samples from this date confirmed the presence of estrone in all RAS tank samples, with quantitation valid only in the three RAS with higher E2Eqs. Estradiol glucuronide was present in the same three RAS, and in spring and duck pond samples. Estrone concentrations were ~ 3 times higher in the duck pond than in the RAS tank waters. The extremely low concentrations of E2Eqs in tank waters indicate there would be no threat to aquatic life by release of tank effluents to environmental surface waters. While estrogenic activity of water from ozonated RAS tanks tended to be lower, ozonation treatment had no significant effect on Atlantic salmon early maturation, which was high in both +O3 or - O3 RAS. Further investigation is therefore required to assess the role of accumulating steroid hormones in RAS, alone and in combination with other important environmental variables, on the development of early sexual maturation in Atlantic salmon.

355 Transcriptome response of Danio rerio and Promelas pimephales to complex pharmaceutical mixtures in a WWTP effluent-impacted stream

E. Meade, University of Wisconsin, Milwaukee / School of Freshwater Sciences; H. Zhi, G.H. LeFevre, University of Iowa / Civil and Environmental Engineering; D.W. Kolpin, S.M. Meppelink, US Geological Survey / Central Midwest Water Science Center; L.R. Iwanowicz, US Geological Survey / Leetown Science Center; R. Lane, US Geological Survey / Organic Geochemistry Research Laboratory; R. Klaper, University of Wisconsin, Milwaukee / School of Freshwater Sciences

Pharmaceuticals are an important class of contaminants that have been documented release into the environment by wastewater treatment plants (WWTPs). The incomplete removal of pharmaceuticals during treatment within WWTPs poses potential risk to aquatic organisms in streams receiving effluent, particularly during low-flow conditions that elevate concentrations of complex mixtures of pharmaceutic. Although the endocrine disrupting potential of select individual pharmaceuticals has been studied, less is known regarding mixtures of pharmaceutical compounds which are known to be present in WWTP effluent and receiving water bodies. To characterize the potential risks of adverse effects that pharmaceutical mixtures pose to aquatic organisms, Muddy Creek, a small (22.5 km2) stream receiving effluent from the North Liberty WWTP in Iowa, was selected as a field laboratory for study. Four sampling sites were chosen to capture the spatial and temporal variability of pharmaceutical mixtures: (1) 100 m above the WWTP outfall, (2) the WWTP outfall, (3) 100 m below the WWTP outfall, and (4) 5 km downstream of the WWTP outfall. From September 2017 to August 2018, monthly water samples were collected during low-flow conditions and analyzed by the U.S. Geological Survey for 110 pharmaceuticals and total estrogenicity. Corresponding monthly water samples were also sent to the University of Wisconsin-Milwaukee for zebrfish (Danio rerio) exposure and gene expression studies. Zebrfish embryos were exposed to all monthly water samples for 3- and 6-day durations. The expression of five genes along pathways in the hypothalamus-pituitary-gonadal (HPG) axis: Vitellogenin, CYP19a2, GnRH, and ER-alpha were analyzed using quantitative polymerase chain reaction (qPCR). Next generation sequencing and RNAseq were used to identify approximately 700 genes with significant differential expression (p< 0.05) in larval fish (6 days post-fertilization) exposed to water from the outfall and from the site 100 m below the outfall. The transcript-level impacts of exposure to complex mixtures of pharmaceuticals in wastewater effluent are also being investigated in laboratory-created pharmaceutical
mixture exposures with zebrafish and an in-stream exposure with juvenile fathead minnows (*P. pimephales*). Ultimately, the gene expression results from this study will inform a predictive model to correlate real-world mixtures of pharmaceuticals.

**356 Significant improvements to effluent discharged into the Grand River as a result of infrastructure upgrades at the major wastewater treatment plants**

N. Srikanthan, L. Bragg, E.K. McCann, H. Dhiyebi, P. Law, Region of Waterloo; M.R. Servos, University of Waterloo / Biology

Wastewater treatment plants (WWTPs) are traditionally designed to remove contaminants such as total suspended solids, phosphorous, and ammonia. Pharmaceuticals and personal care products (PPCPs) and endocrine disrupting compounds (EDCs) are widely prevalent in wastewater but are not targets for removal in Canada, causing them to be discharged into surface waters. As a result, municipal wastewater is one of the largest contributors to surface water contamination. The Kitchener and Waterloo wastewater treatment plants (WWTPs) are the two largest WWTPs along the Grand River watershed in southern Ontario. The effluent discharged from both of these plants has been analyzed for various nutrients, PPCPs, and EDCs since 2010. Recently both plants underwent major infrastructure and treatment process upgrades. Effluent quality has been measured in pre, during, and post upgrade time periods, allowing for an evaluation of effluent quality as a result of upgrades. Grab samples were collected and extracted using solid phase extraction. The samples were analyzed using a biological assay (yeast estrogen screen) for total estrogenicity and chemical analyses for pharmaceuticals and specific hormone concentrations (LC-MS/MS) as well as nutrients. Results show a significant decrease in ammonia concentrations which is a major indicator of improved effluent quality (e.g. nitrification). Analysis of total estrogenicity and select hormones and pharmaceuticals (e.g. estrone, ibuprofen, and naproxen) also showed decreases corresponding to upgrades at both treatment plants despite these compounds not being specific targets of the upgrades. These compounds are removed through biodegradation and respond well to treatments with good nitrification and long solids retention times. However, many compounds remain detectable and some are recalcitrant to secondary treatment (e.g. venlafaxine, carbamazepine). Overall the upgrades implemented at these two plants have had a positive impact on the quality of the final effluent discharged. A corresponding improvement in indicators of exposure and health in fish populations downstream of the treatment plants have also been reported. This data will aid in developing relationships between contaminant exposure and secondary stressors, and validating predictive models linking contaminants to specific biological endpoints.

**357 Identification of Predominant Antibacterial Pollutants in Wastewater Treatment Plant (WWTP) Sludge by an Unbiased Chemical-Genetics Platform**

H. Barrett, University of Toronto / Chemistry; H. Peng, University of Toronto / Department of Chemistry

Antibiotic resistant bacteria (ARB) have been found in wastewater treatment plants (WWTPs), and recent studies have focused on their potential as hotspots for ARB development. It is necessary to identify the major chemicals in WWTPs that kill bacteria and lead to antibiotic resistance, but identification of the causative antibacterial chemicals remains elusive for current methods-- chromatographic and effects-directed analyses approaches have limitations in terms of specificity, recovery efficiency, and accuracy. We hypothesize that identifying the key protein(s) mediating the antibacterial potencies will enable us to apply pull-down untargeted chemical analysis (PUCA) to identify the causative chemicals. To achieve this goal, a hybrid workflow is applied wherein the key protein is first identified via chemical genetics screening. We have constructed His-tagged overexpression and SPA-tagged ‘knock-down’ libraries for all 300 essential genes in *E. coli*. This chemical genetics platform was tested for antibiotics with different modes of actions. His-tagged strains were effectively rescued in the presence of antibiotics targeting enzymes (e.g., trimethoprim-FolA, trimclosan-FabI) and membrane proteins (e.g. ampicillin-PbpG) but not larger ribosomal complexes (e.g. tetracycline-rpsA). To overcome this challenge, SPA-strains were tested and found to be susceptible to antibiotics targeting enzymes, membrane proteins, and ribosomal proteins while having increased sensitivity to antibiotic effects, making them ideal for real sample applications wherein antibiotics are present at low concentrations. Notably, a significant response was observed for a SPA-FabI strain at 4 µg/L of trimclosan, which is comparable to the sensitivity of mass spectrometry. The established platform was applied to identify the predominant antibacterial reagents in sludge samples from Ontario WWTPs. Initial screening has demonstrated that several SPA strains, such as SPA-FabI, are susceptible to sludge extracts which indicates that FabI may be the key protein mediating antibacterial potencies in WWTPs. PUCA methods established in our previous work were adopted to identify the exact chemicals physically targeting FabI proteins. This study is expected to establish an unbiased chemical genetics platform to identify antibacterial reagents in WWTPs, and the susceptible *E. coli* strains established in this study will provide a cost-effective method to bio-monitor antibacterial potencies in diverse environmental samples.

**358 The interactions of azole compounds with an anammox enrichment culture: Toxicity and biotransformation**

N. Lakhey, R. Sierra-Alvarez, J.A. Field, University of Arizona / Chemical and Environmental Engineering

Azole (five-membered heterocyclic aromatic compounds) are prominent emerging contaminants frequently detected in water and wastewater streams. This study investigates the effect of the presence of the azole compounds towards the anaerobic ammonium oxidation (anammox) process, which is an emerging and efficient biotechnology for nitrogen removal during wastewater treatment. The toxicity of eight widely used azole compounds, namely, 1H-benzotriazole, 5-methyl-1H-benzotriazole, 1H-benzotriazole-5-carboxylic acid, 3,5-dimethyl-pyrazole, 1-methyl-pyrazole, 1H-pyrazole, 1H,1,2,4-triazole and 1H-imidazole towards an anammox enrichment culture (AEC) was tested using batch bioassays. The key finding of the toxicity study was that the azole compounds were for the most part mildly toxic to the anammox process except for 1H-benzotriazole and 5-methyl-1H-benzotriazole. Amongst the azole compounds tested for their toxicity, 1H-pyrazole (PA) and 1H,1,2,4-triazole (TA) were found to be biotransformed when incubated with the AEC along with the usual anammox substrates, ammonium (NH4+) and nitrite (NO2-). Substrate scope experiments revealed that the presence of nitrate (NO3-) along with glucose significantly promoted the biotransformation process. Process optimization and kinetic studies were carried out. The AEC was found to bring about the biotransformation of PA and TA at a high rate of 0.22 mmol PA gVSS-1 d-1 and 0.24 mmol TA gVSS-1 d-1 respectively, under the optimal conditions. The uncultured heterotrophic microorganisms coexisting with the anammox bacteria in the AEC are hypothesized to be responsible for the biotransformation. Ongoing work includes characterization of the biotransformation products using LC-MS/MS techniques, and determination of the microbial diversity in the AEC. The results of the toxicity study provide a better understanding regarding the use of the anammox process in the treatment of both municipal and industrial wastewaters containing azole compounds. This study also highlights the ability of the AEC to biotransform and potentially degrade the azole compounds that were previously considered to be non-biodegradable.
Tuesday Platform Abstracts

Estimating Environmental Hazard and Risks from Exposure to Perfluorinated and Polyfluorinated Alkyl Substances (PFAS): Outcome of a Focused Topic Meeting

M.S. Johnson, US Army Public Health Center / Toxicology; I. Cousins, Stockholm University / Department of Environmental Science and Analytical Chemistry (ACES); R.C. Buck, The Chemours Company / Fluoroproducts; C. Weis, National Institutes of Health/NIEHS

Per- and polyfluorinated alkyl substances (PFAS) are largely surfactants and were historically used in multiple industrial applications, such as fire-fighting foams, anti-stain products for carpet and upholstery and heat-resistant, nonstick cookware and are increasingly found in biota and media within the environment. Together, these classes of compounds represent over 3,000 chemicals that can be persistent in the environment and in biota. A focused topic meeting/workshop was held in August 2019 to gather the latest science in chemistry, environmental fate, ecotoxicity, human health effects and risk characterization and to address how to best interpret these data and formulate a roadmap towards improving our understanding of risks. Specific charge questions were developed on this topic each set specific to one of the breakout session areas to include: analytical chemistry, exposure analysis, ecotoxicity, human health concerns, and risk characterization. The products of these breakout groups will be presented relative to the general trends discussed in these groups. Other outcomes will be summarized regarding trends in the available science and areas for further research for these unique substances.

359 Estimating Environmental Hazard and Risks from Perfluorinated and Polyfluorinated Alkyl Substances (PFAS): Outcome of a Focused Topic Meeting

360 Per- and Poly-Fluoro Alkyl Substances (PFAS): Environmental Sources, Chemistry, Fate and Transport - Report from the 2019 SETAC Focused Topic Meeting

M. Mills, US Environmental Protection Agency / National Risk Management Research Laboratory; S. Korzeniowski, BEC; J.L. Guelfo, Texas Tech University / Civil, Environmental, and Construction Engineering

The overall objectives of the SETAC focused topic meeting (FTM; August 2019) were two-fold: 1) to review new and emerging information on PFAS chemical classification and grouping, environmental chemistry, detection technology, fate and transport, exposure potential, human health toxicity, and ecological toxicity and 2) to harness the expertise of eminent scientists from around the globe with the goal of developing a risk assessment approach that considers mechanistic (including computational) approaches for extrapolating exposure and effects across different scenarios/species and compounds within environmental pathways for exposure. Our workgroup included 7 major presentations and a subsequent breakout group that identified fundamental aspects of the current state of the science, critical knowledge gaps, and future research needs. The seven major workstreams in our workgroup (sources, chemistry, fate & transport) were as follows: Key challenges and strategies for source-pathway evaluation and prioritization; Existing analytical techniques and areas of need for detecting and measuring PFAS; Identification of PFAS in the environment; Physical-chemical properties of PFAS, patterns that can be used to develop empirical models of environmental fate and transport, and application of physical-chemical properties towards defining source zones and source strength; Addressing long-term transformation of PFAS precursors in the environment; Current state of the science and advances in the systematic characterization and categorization of PFAS; Classification and grouping of PFAS for environmental risk assessment. This platform presentation will highlight workgroup outcomes and frame these findings within the broader scope and output of the PFAS FTM.

361 Research Needs for Better Understanding Pathways of Human and Ecological Exposures to Poly- and Perfluoroalkyl Substances (PFAS)

This presentation will provide a summary of presentations and discussions convened by the Exposure Assessment breakout group as part of the SETAC Focused Topic Meeting on environmental risk assessment of PFAS. Topics include current understanding of the global distribution of PFAS, exposures from drinking water and diet, the role of contaminated sites for elevated exposures, bioaccumulation in food webs, and toxicokinetics of PFAS in humans and wildlife. The focus of the presentation will be to highlight key gaps in knowledge identified in the breakout session that affect exposure and risk assessments for PFAS. We will also provide an overview of the state-of-the-science understanding in each topical area discussed.

362 Assessing the Ecological Effects of PFAS: Current Knowledge, Existing Uncertainties, and a Path Forward

G.T. Ankley, US Environmental Protection Agency / Mid-Continent Ecology Division; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. Kumar, CSIRO / Land and Water; Program- Environmental Contaminant Mitigation and Biotechnology; J.L. Newsted, Ramblel / Environmental and Health Sciences; R.P. Lanno, Ohio State University / Department of Evolution, Ecology, and Organismal Biology; C. Salice, Towson University / Biology; B.E. Sample, Ecological Risk, Inc.; M.S. Sepulveda, Purdue University / Department of Forestry and Natural Resources; S. Valsecchi, Water Research Institute - Italian National Research Council IRSA-CNR

This talk will provide an overview of the state-of-the-science and forward-thinking recommendations by an international group of experts tasked with considering assessment of the potential ecological effects of per- and polyfluoroalkyl substances (PFAS). While there have been hundreds of peer-reviewed publications examining different facets of the toxicity of PFAS in plant, invertebrate, and vertebrate species relevant to ecological risk assessment, most of this work has been conducted with only a small number of individual high-visibility PFAS and a few species. For example, a reasonable amount of data exist concerning the effects of perfluorooctane sulfonate (PFOS) on model aquatic invertebrate and fish species, but much less information is available concerning possible toxicological effects in plants, terrestrial invertebrates, and vertebrates such as amphibians, reptiles, birds and mammals. Also, there are little or no toxicity data for any species for most of the hundreds to thousands of PFAS that theoretically may enter and persist in the environment. Since testing resources are limited, there is a need to prioritize those PFAS of greatest concern in terms of possible ecological effects, and to identify/develop standardized, cost-effective approaches for testing when required. These approaches should employ, to the extent possible, a mechanistic understanding of biological pathways impacted by different PFAS so that likely susceptible species and endpoints are emphasized. A pathway-based understanding of toxicity would enhance the ability to extrapolate potential PFAS effects from tested to untested species and across different PFAS structures. Species-specific assay selection and experimental design also need to consider unique physico-chemical attributes of individual and PFAS mixtures that can be challenging in execution and interpretation. Similarly, there is a need for efficient analytical and biomonitoring tools to detect occurrence and possible effects of complex PFAS mixtures in the field. The contents of this talk do not reflect organizational policies of the coauthors.

106 | SETAC North America 40th Annual Meeting
363 Human Health Effects from Exposure to Perfluorinated and Polyfluorinated Alkyl Substances (PFAS)

J. Smith, Navy and Marine Corps Public Health Center / Environmental Health; A. Boobis, Imperial College London / Centre for Pharmacology & Therapeutics; S. Roberts, University of Florida / Department of Environmental and Global Health

Per- and polyfluorinated alkyl substances (PFAS) are classes of compounds that have been used extensively in household products and in multiple industrial applications, such as fire-fighting foams, anti-stain products for carpet and upholstery and heat-resistant, nonstick cookware and are increasingly found in biota and media within the environment. Data from epidemiological studies are suggestive of many toxic endpoints; however, studies conducted in animals are varied and not consistently corroborated by the human data. This presentation will summarize the outcome of a focused topic meeting on this subject to include a synopsis of the outcome of specific charge questions involving the effects in humans from exposure to these substances. Additionally, uncertainties associated with the available database will be discussed to include areas of further research for these unique substances.

364 Characterizing the Risks from Exposure to Perfluorinated and Polyfluorinated Alkyl Substances (PFAS)

M. Dourson, Toxicology Excellence for Risk Assessment; A. Hinwood, EPA Victoria / Office of the Chief Environmental Scientist; T.I. Halldorsson, University of Iceland / Faculty of Food Science and Nutrition, School of Health Sciences

Characterizing the risk from exposure to per- and polyfluorinated alkyl substances (PFAS) has been varied between various jurisdictions. Data from epidemiological studies, studies conducted in experimental animals, and mechanistic data are varied and subject to different degree of uncertainty. As a result, interpretation of those data to safeguard public health and the environment is complex. Here we present the outcome of a SETAC Focused Topic Meeting and workshop on this subject and provide a summary of how various jurisdictions have interpreted the available experimental and observational data to develop health benchmarks. This presentation will also summarize the outcome of a breakout group session where experts in academia, government, and industry have worked together to address several target questions on moving forward towards the goal of consistently evaluating toxicity data for risk characterization. Additionally, uncertainties associated with characterizing risk from various lines of evidence and the relative importance of various exposure routes will be discussed.

365 Assessment of Potential Mercury Toxicity to Native Invertebrates in a High-Gradient Stream

J. Flanders, EHS Support, LLC; G. Long, EHS Support; B.J. Reese, AECOM / DHS Remediation; N.R. Grosso, Corteva / Environmental Remediation; W.H. Clements, Colorado State University / Fish, Wildlife and Conservation Biology; R.G. Stahl, DuPont (retired)

We recently presented the results of a study that evaluated the potential effects of mercury (Hg) on benthic macroinvertebrates in the South River, Virginia, USA (Flanders et al., 2019; IAM 15 (3): 374-384). This study, evaluated spatially and temporally matched sediment chemistry, population-level community metrics, and toxicity testing (Sediment Quality Triad), exposure and effect analysis in bulk and interstitial sediment and interstitial water, and critical body residue analysis. The results of this comprehensive evaluation of exposure and effects and illustrates the inadequacy of literature-derived screening benchmarks for sediment and body residue exposures. Ten-day Chironomus dilutus and Hyaletta azteca toxicity tests established site-specific no-effect concentrations (NOEC) at 18.9 mg/g total Hg (THg) and 102 ng/g methylmercury (MeHg). However, the benthic community at these locations was impaired, with lower mayfly and caddisfly composition. Few locations had concentrations of THg and MeHg that exceeded the NOEC in bulk or interstitial sediment. The THg concentrations in interstitial water were far below concentrations expected to reduce survival in benthic invertebrates, and only a low percentage of samples exceeded sublethal (growth) low-effect concentrations (LOEC) for THg or MeHg. The THg concentrations in invertebrate tissue did not exceed the NOEC or LOEC in the South River, and MeHg concentrations exceeded the LOEC at all locations, including those with no evidence of benthic impairment, illustrating the uncertainty associated with this line of evidence. Finally, statistical modeling that evaluated diversity of sensitive invertebrate species as a function of Hg exposure, geomorphological parameters, and physicochemical variables indicated that physicochemical and geomorphological parameters were most predictive of benthic community; where Hg was indicated, we were unable to distinguish between models with or without interstitial water Hg. Overall, the lines of evidence indicate that Hg, while clearly toxic to invertebrates at sufficiently high exposure concentrations, is not negatively impacting invertebrate communities in the South River. This study illustrates the difficulty of assessing risks to invertebrates using traditional tools of risk assessment and identifies critical gaps in knowledge that complicate the management of Hg risk.

366 Lines of evidence within risk characterization designed to evaluate the likelihood of adverse ecological effects

J.L. Peterson, Oregon Department of Environmental Quality / Northwest Region, Portland Harbor Section

Risk characterization is a critical but often underrepresented component of the ecological risk assessment process. Ecological risk assessment guidance proposed by the Oregon Department of Environmental Quality identifies qualitative and quantitative lines of evidence to evaluate the likelihood of adverse effects at cleanup sites. Lines of evidence focus on the adequacy of exposure and effects assessments to characterize those parameters that represent the greatest reducible uncertainty. The guidance identifies specific methodologies to ensure a clear presentation of the nature, magnitude, spatial distribution, and relevance of the risk estimates. These components are used to evaluate the likelihood of adverse effects in support of a risk determination, guide additional data collection to improve accuracy, or inform remedial decisions. Risk characterization lines of evidence will be presented along with real world examples.

367 Lessons Learned for Ecological Risk Assessment at a Legacy Chromalloy Plant

A baseline ecological risk assessment (BERA) was conducted for an 333-acre site which includes an abandoned ferrochromium alloy processing plant and legacy slag in the eastern US. The BERA for the site included upland, floodplain and in-stream aquatic habitat. COPCs include heavy metals, notably chromium. There are many lessons learned for this site, specifically regarding bioavailability of metals to ecological receptors and the way in which this site-specific information impacted the findings of the BERA. While there is a plethora of scientific research on lead and arsenic bioavailability for human health risk assessment since the passage of CERCLA in 1980, there is less attention paid to use of bioavailability to support ecological risk assessment. In vitro tests identify the bioaccessible fraction of a constituent which is the fraction that dissolves from its matrix (e.g., soil) in the gastrointestinal tract and is available for absorption. USEPA developed in vitro bioaccessibility methods for arsenic and lead exposure in humans. The Framework for Metals Risk Assessment (USEPA 2007), however, provides guidance for both human health and ecological risk assessment. In order to effectively evaluate exposure risk due to metals, the USEPA says: “risk assessors should adjust bulk metal concentrations by appropriate bioavailability factors to achieve comparable, actual uptake of metals by organisms.” That said, agencies often do not accept use of bioavailability for soil, sediment or prey items for ecological risk assessment because the analytical methods were developed
for humans, not ecological species, and this site was not an exception. Soil, sediment and invertebrate tissue were analyzed for 18 metals for bioaccessibility based on the USEPA Method 1340, with some modifications to reflect physiologic conditions of a bird and/or small mammal. The BERA was finalized to include the empirical bioaccessibility data in the upper trophic level receptor hazard indices, but also evaluated 100% bioaccessibility in the uncertainty section. Additional lines of evidence were generated including three biocriteria studies for the creek. The lines of evidence converged to indicate there was unlikely risk for receptor exposure to media at the site as well as Cross Creek.

368 Assessment approaches for data-poor substances: A walkthrough using examples from risk assessments under Canada’s Chemicals Management Plan

T. Francis, K.L. Potter, S. Gordon, Environment and Climate Change Canada

Under the Canadian Environmental Protection Act, 1999, Environment and Climate Change Canada and Health Canada assess and manage, where appropriate, risks of chemical substances to the environment and to human health. The Chemicals Management Plan (CMP) is a Government of Canada initiative to address approximately 4300 substances identified as priorities for assessment. This presentation will focus on risk assessment approaches used in the evaluation of substances that are lacking empirical data. Different assessment approaches that can be used to characterize physical-chemical properties, environmental distribution, bioaccumulation and ecotoxicity will be explored using specific examples from risk assessments currently being developed under the CMP. These examples may include substances such as naphthalene sulfonic acids, aliphatic amines, and benzothiazoles. Approaches discussed will include in silico, read-across and weight of evidence approaches.

369 Development of Ecological Risk-based Thresholds for Cs-137 Using Log-Linear Regression-based Bioaccumulation Models

R.E. Sample, Ecological Risk, Inc.; C. McCarthy, Jacoby; D. Wright, Jacobs Engineering Group, Inc.; S. Robinson, INTERA Incorporated / Toxicology Risk Assessment; A. Aly, INTERA Incorporated

Cs-137 is a radionuclide fission product from nuclear reactors and nuclear weapons. Nuclear fuel and weapons manufacturing, accidents, and above-ground weapons testing have resulted in elevated Cs-137 concentrations in some terrestrial environments. Risk from Cs-137 in soil to terrestrial biota is evaluated using models such as RESRAD-BIOTA. Bioaccumulation factors (BAFs) are a ratio of tissue-to-soil concentration used to estimate internal radionuclide concentrations. BAFs assume uptake is represented by a single, constant value over all soil concentrations. Analyses of metals and organics show non-linear uptake, with rates varying by concentration. Similar uptake relationships were expected for radionuclides. A dataset was developed from published measures of Cs-137 in terrestrial invertebrates, small mammals, shallow-rooted plants, and co-located surface soil. Regression analyses were performed on natural-log transformed tissue and soil data. Statistically significant regressions (with soil concentrations associated sensitivity analyses allow risk assessors to consider and predict effectiveness of remedial actions to reduce such risk. Even when model results are not documented in an ecological risk assessment, key areas of uncertainty on which to focus during the risk assessment. Additionally, population models often help explain why field observations of abundant wildlife populations seemingly differ from predicted adverse effects from laboratory toxicity studies. Examples of population modeling we conducted include evaluating lead shot ingestion effects on bird populations in Europe, dark-eyed junco exposure to mine-related copper, sora exposure to lead, and salmonid metapopulation exposure to selenium and total PCBs, passerine bird exposure to mine-related selenium and lead, and waterbird exposure to an oil spill. Through modeling, we found that population viability risk and magnitude of chemical effects differ depending on the (1) direction (increasing, decreasing, or stable) of the population trend; (2) level of suppression below carrying capacity by a chemical vs. natural stressor, (3) amount of natural environmental stochasticity, (4) frequency of catastrophic or bonanza (e.g., predation-release) events, (5) exposure area selected, (6) amount of compensatory mortality, and (7) rate of recovery once stressor is removed, which is strongly affected by density-dependent factors. Calibration of the baseline model to empirical data, often available in the literature, is key to increasing model accuracy. Accounting for habitat quality, the minimum viable population size, metapopulation dynamics, and overlap in mortality and reproductive effects are important to obtaining a realistic understanding of effects when the model is applied to the study site. Traditional risk assessments often ignore key endpoints or treat them in isolation, potentially leading to erroneous conclusions. Population modeling and associated sensitivity analyses allow risk assessors to consider and integrate all life stages and endpoints for a species and identify key factors driving risk. Once the primary risk-driving factors are determined, remediation can be optimally designed by addressing those factors.

370 Lessons Learned after 10 Years of Population Modeling for Ecological Risk Assessments

C.B. Meyer, A.B. Francisco, M. Buonanduci, ARCADIS US, Inc; E. Morrison, ARCADIS

Over the past 10 years, Arcadis has used population models to better understand risk to wildlife populations from exposure to toxic substances and predict effectiveness of remedial actions to reduce such risk. Even when model results are not documented in an ecological risk assessment, they are useful because they can cost-effectively provide guidance on key areas of uncertainty on which to focus during the risk assessment. Additionally, population models often help explain why field observations of abundant wildlife populations seemingly differ from predicted adverse effects from laboratory toxicity studies. Examples of population modeling we conducted include evaluating lead shot ingestion effects on bird populations in Europe, dark-eyed junco exposure to mine-related copper, sora exposure to lead, and salmonid metapopulation exposure to selenium and total PCBs, passerine bird exposure to mine-related selenium and lead, and waterbird exposure to an oil spill. Through modeling, we found that population viability risk and magnitude of chemical effects differ depending on the (1) direction (increasing, decreasing, or stable) of the population trend; (2) level of suppression below carrying capacity by a chemical vs. natural stressor, (3) amount of natural environmental stochasticity, (4) frequency of catastrophic or bonanza (e.g., predation-release) events, (5) exposure area selected, (6) amount of compensatory mortality, and (7) rate of recovery once stressor is removed, which is strongly affected by density-dependent factors. Calibration of the baseline model to empirical data, often available in the literature, is key to increasing model accuracy. Accounting for habitat quality, the minimum viable population size, metapopulation dynamics, and overlap in mortality and reproductive effects are important to obtaining a realistic understanding of effects when the model is applied to the study site. Traditional risk assessments often ignore key endpoints or treat them in isolation, potentially leading to erroneous conclusions. Population modeling and associated sensitivity analyses allow risk assessors to consider and integrate all life stages and endpoints for a species and identify key factors driving risk. Once the primary risk-driving factors are determined, remediation can be optimally designed by addressing those factors.

371 Risk-Informed Prioritization of Resources

F. Cooper, N.C. Garisto, ARCADIS Canada, Inc. / Risk and Radioactivity

A risk-informed approach can be used in deciding when to collect site-specific information rather than rely on literature-based values for an Ecological Risk Assessment (EcoRA). The proposed tool is a Sensitivity Analysis (SA): Step 1: Conduct Tier 1 EcoRA using parameter values from literature. Step 2: Perform a SA on key parameters. The SA can be carried out using a software add-on (i.e., Monte Carlo analysis) or simply by manually running the model multiple times (i.e., based on the upper and lower bounds of each parameter). Benefits of SA software include time saving, reduced error and the ability to assign a probability distribution function to each parameter. The SA will determine which parameters have more influence on the EcoRA results. For example, the SA may indicate that the EcoRA results are very sensitive to variations in toxicity reference values (TVRs) and in soil-plant transfer factors (TFs), and not as sensitive to water-fish TFs. Key parameters and their sensitivities will vary for different sites and receptors. Step 3: Informed by the SA results, design and implement a monitoring program. Field data can be used directly (such as pH) or in calculations to derive parameters such as site-specific TFs. Cost considerations can be applied, e.g., sampling food items, which is generally less expensive than sampling actual biota.
Step 4: Conduct Tier 2 EcoRA using site-specific parameter values where collected, and all other parameters from literature. This approach has been used successfully to refine EcoRA results using site-specific parameters derived from field campaigns. In one assessment, the SA determined that EcoRA results were heavily influenced by soil-water distribution coefficient \( K_d \); therefore, soil data were collected from the site and used to update the EcoRA. In another assessment, field results were used to confirm that the TRVs available from literature were conservative. In terms of prioritizing resources, there is also value in investing in biological field surveys at the outset of a project, specifically for the determination of presence/absence of Species At Risk. Because listed species are required to be assessed at an individual level rather than population level, site-specific information on the likely presence/absence of At-Risk Species will have a substantial impact on the EcoRA outcome.

372 Ecological Risk Assessment of heavy metals in sediment from three oil-producing regions in Ilaje Local Government Area of Ondo State, Nigeria

A.M. Olatunji-Ojo, D.O. Odedeyi, O. Olayinka-Olagunju, Adekunle Ajassin University / Department of Animal and Environmental Biology

Nigeria is one of the developing countries that depend largely on oil exploration as major source of revenue for economic development. More than 400,000 tons of oil has spilled into the creeks and soils of most oil producing communities in Nigeria, thereby, affecting the livelihood of host communities. The study aimed at evaluating the present health status of water bodies proximate to oil wells located in Ilaje communities using six pollution indices which comprises of three single pollution indices \{Contamination Factor (CF), Ecological Risk Factor (ER) and Index of Geo-accumulation (Igeo)\} and three Integrated pollution indices \{Pollution Load Indices (PLI), Potential Ecological Risk Index (RI) and Nemerow Pollution Index (Pnemerow)\} to quantify the extent or degree of heavy metal contamination in the sediment. Eight (8) heavy metals \{Cadmium (Cd), Iron (Fe), Copper (Cu), Lead (Pb), Nickel (Ni), Manganese (Mn), Chromium (Cr), Zinc (Zn)\} from sediment taken for five (5) months from three different regions of Ilaje (Ayetoro, Oreore and Aberoke) were analyzed using Atomic Absorption Spectrophotometer. Heavy metal concentrations range from: Cd (0.0607 - 0.1067ppm), Fe (152.5404 - 246.713ppm), Cu (0.5339 - 1.3073ppm), Pb (0.2612 - 0.5226ppm), Ni (0.1370 - 0.2339ppm), Mn (0.5643 - 0.7345ppm), Cr (0.1785 - 0.2423ppm), Zn (1.0753 - 1.7945ppm). All the pollution indices show the study sites are not polluted with low potential ecological risk. Result of Pnemerow also indicated the areas to be safety domains. Continuous monitoring of these areas using Bioindicators, especially when there is oil spillage, is therefore, recommended.

Relations Between the Bioaccumulation of Organic Chemicals in Aquatic and Air-Breathing Organisms

373 Reliable Methods for Predicting Octanol-Air Partition Coefficients for Use in Bioaccumulation Risk Assessment

S. Baskaran, University of Toronto, Scarborough / Chemistry; Y. Lei, University of Toronto / Physical and Environmental Sciences; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

The potential for air-breathing organisms to efficiently eliminate relatively water-soluble compounds via urination can be assessed with the compound’s octanol-water equilibrium partition coefficient \( K_{OW} \). However, the elimination potential of a relatively volatile compound via respiration is dependent on its octanol-air partition coefficient \( K_{OA} \). Compounds with a log \( K_{OW} \) less than 2 or a log \( K_{OA} \) less than 5 are more readily eliminated. Numerous studies have measured and predicted the \( K_{OW} \) for thousands of structurally diverse organic compounds and values are often reported with a high degree of confidence along with associated uncertainties. This allows for the use of \( K_{OW} \) values in tier 1 chemical risk assessments. On the other hand, measured \( K_{OA} \) values exist for a little over 500 compounds, most of which are non-polar, halo-genated aromatics. In this work we present an overview of all measured \( K_{OA} \) values to date. Using this compilation of measured \( K_{OA} \) values, we assess the performance of multiple property estimation techniques based on poly-parameter linear free energy relationships (pplFERs), quantitative structure property relationships (QSPRs), and quantum-chemistry and statistical thermodynamics. In particular, we assess the prediction performance with respect to (i) temperature, (ii) a model’s applicability domain, (iii) a chemical’s functional groups and (iv) a measured value’s experimental technique. Of special interest is the uncertainty of log \( K_{OA} \) predictions close to the threshold for respiratory elimination of log \( K_{OA} \). \( K_{OA} \) values predicted with pplFERs using experimental solute descriptors agree best with values measured at 25°C; within the threshold region \((3 < \log K_{OA} < 7)\) the prediction uncertainty is ~0.3 log units and thus comparable to the measurement uncertainty.

374 Analysis of attenuating factors for terrestrial food web biomagnification of cyclic volatile methylsiloxanes

K. Plotzke, Dow Chemical Company / Consumer Solutions; D. McNett, The Dow Chemical Company / Toxicology Environmental Research and Consulting; J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting; K.B. Woodburn, The Dow Chemical Company / HES

The critical concern regarding bioaccumulation is the issue of biomagnification, specifically substances that accumulate via the food web to progressively higher concentrations that may toxicologically impact top predators and humans. The key question is how to best predict biomagnification, a complex ecosystem phenomenon that is difficult to model in the laboratory. A laboratory BCF from water uptake is often used as a surrogate for biomagnification. A BCF should only be considered a Tier 1, screening-level surrogate for biomagnification as it addresses only one level in the food chain and can be highly problematic in accurately characterizing dietary accumulation via the food chain. In this work, we examined the biomagnification of two volatile cyclic siloxanes, octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5), in aquatic food webs that terminated with terrestrial organisms and compared data to a recent terrestrial food web study. The toxicokinetics of volatile cyclic siloxanes D4 and D5 have been extensively studied in aquatic and terrestrial organisms up to and including humans. Studies assessing metabolism (in vitro and in vivo) and other important kinetic processes of D4 and D5 will be presented as attenuating factors as to why these materials do not demonstrate biomagnification (TMF>1) through analyzed aquatic/terrestrial food chains.

375 A Chemical-Activity-Based Approach for Assessing Bioaccumulation of Per- and Poly-fluoroalkyl Substances in Aquatic and Air-Breathing Organisms

B.C. Kelly, Simon Fraser University / Civil & Environmental Engineering; F. Gobas, Simon Fraser University / Resource & Environmental Management

Per- and poly-fluoroalkyl substances (PFAS) are an important class of organic contaminants due to increasing evidence of environmental persistence, bioaccumulation potential and toxicity. This presentation will provide an overview of the current state of knowledge regarding PFAS bioaccumulation potential, including governing mechanisms and modeling approaches. We utilize a chemical activity-based modelling approach to further evaluate PFAS bioaccumulation in different food webs, with a particular focus on evaluating bioaccumulation behavior of PFAS in aquatic versus air-breathing organisms. Chemical activity \( (a, \text{unitless}) \) in a given medium is related to concentration \( (C, \text{mol/m}^3) \) by the corresponding solubility \( (S, \text{mol/m}^3), \text{(i.e.,} a = C/S) \). The available data show that bioaccumulation potential of perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkane sulfonic acids (PFASs) is highly related to perfluoroalkyl chain length. For example, bioconcentration factors (BCFs) are relatively
low for C8-C11 PFCAs (4.0-4.900 L/kg), whereas BCFs of longer-chain PFSAs (C12-C14 PFCAs) range between 18,000-40,000 L/kg. Field-based studies have shown trophic magnification factors (TMFs) of PFCAs and PFSAs in aquatic food webs are typically < 1, indicating no biomagnification. Conversely, TMFs in food webs containing birds and mammals generally exceed 1, indicating biomagnification in those air-breathing cations. Conversely, TMFs in food webs containing birds and mammals are elevated above those in environmental media and prey organisms, primarily due to efficient gastrointestinal uptake and negligible elimination via key depuration pathways (i.e., urinary, biliary, respiratory, biotransformation). Lastly, key uncertainties and knowledge gaps related to bioaccumulation behavior and exposure assessment of PFCAs, PFSAs, as well as other PFAS of emerging concern will be highlighted.

376 PCB metabolism by benthic organisms vs. otters in the Green-Duwamish River (Seattle)

L.A. Rodenburg, Rutgers University / Environmental Sciences

Fingerprinting of data from the Green-Duwamish River was used to determine polychlorinated biphenyl (PCB) sources to organisms including benthic (amphipods, clams), fish (six species), shellfish (three species) and otters (in scat). The data sets included 128 samples of tissue from benthic, fish, and shellfish species, and 73 samples of otter scat and were analyzed by Positive Matrix Factorization to identify PCB source fingerprints. One of the five fingerprints isolated from analysis of the tissue data resembled Aroclor 1260 but displayed characteristic evidence of cytochrome P450 metabolism. This fingerprint was present in all of the organisms tested, with the highest proportions in fish and lowest in benthic organisms. Analysis of the otter scat data yielded two fingerprints that were dominated by the unmetabolized coeluting congeners groups 83+99, 129+138+160+163, 153+168, and 180+193. One of these two otter scat fingerprints was higher in molecular weight (MW) with proportionately more 180+193. These two fingerprints explain 67% of PCBs found in otter scat and display variation by location, with samples from the Duwamish River near Seattle displaying the higher MW metabolized congener pattern, and samples from the more rural upstream areas of the Green River displaying more of the lower MW metabolized fingerprint. These results suggest that organisms at all trophic levels metabolize PCBs. Metabolism was most evident in fish tissue and otter scat. Benthic organisms displayed less, but still noticeable, metabolism.

377 A Macro Review on Bioaccumulation and Biotransformation of Many Organic Compounds in Birds

D. Kuo, City University of Hong Kong / Architecture and Civil Engineering

Birds constitute an important animal class with diverse habitats, trophic interactions, and ecological roles in the biosphere. To better grasp the knowledge gaps and research needs on bioaccumulation and biotransformation of organic chemicals in avian species, published experimental studies and reports were reviewed. Review efforts focus on the reporting of bioaccumulation metrics, toxicokinetics, pharmacokinetics, cytoxicological responses, metabolic pathway, taxonomy, and exposure condition. Approximately 15,000 data entries (~1,000,000 filled cells of information) were compiled following a critical review of over 300 primary bioaccumulation, biotransformation, and pharmacokinetic studies. The review so far covered some 400 organic contaminants on close to 300 wild avian species and domestic breeds. The overall bird bioaccumulation and biotransformation data/information space generally differs substantially with those associated with fishes or aquatic invertebrates. In bird studies, bioaccumulation and toxicokinetics are frequently quantified or depicted in terms or metrics different from the established modeling framework in ecotoxicology. Furthermore, field bird surveys often use tissue concentrations alone to indicate the bioaccumulation of target chemicals without reporting concentration or chemical activity of any reference exposure medium. The mobility and foraging behavior of birds also implies uncertainties associated with spatial/medium distribution of target chemicals and dietary makeup of the individual must be properly factored in the characterization of field bioaccumulation potential. Consequently, a number of alternative metrics have been proposed to characterize the bioaccumulation of chemical in birds under diverse experimental protocols. Biotransformation kinetics is generally less well characterized in birds than in fishes or invertebrates. While in vitro characterization based on targeted enzymatic activities are available, a significant portion of these measurements pertain to the baseline activities or responses. Much endeavor and cooperation is needed for advancing bioaccumulation and biotransformation science in birds, and plausible future directions are discussed.

378 Uptake, Deposition and Metabolism of the Flame Retardant and Plasticizer Triphenyl Phosphate in Eggs and Chicks of Japanese Quail

R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; S.C. Marteinson, Government of Canada / Environment and Climate Change Canada; M.F. Guigueno, McGill University / Department of Natural Resource Sciences; K.J. Fernie, Environment and Climate Change Canada; J. Head, McGill University / Natural Resource Sciences

Organophosphate esters (OPEs) are extensively used as flame retardants (FRs) and plasticizers in a variety of products including building materials, textiles, and electronic equipment. An important and current-use OPE is triphenyl phosphate (TPHP), and the production and use of TPHP has increased since the phase-out and regulation of polybrominated diphenyl ether (PBDE) FRs. Concentrations of OPEs in biota are generally considerably lower than for PBDEs, suggesting OPEs (including TPHP) may have comparatively low bioaccumulative potential. Understanding the toxicokinetics and metabolism of TPHP is essential to the exposure, fate and subsequently the risks posed to wildlife by this OPE. The objective of this study was to determine the in vivo uptake, deposition and metabolism of TPHP by Japanese quail (Cortunix japonica) embryos and chicks as well as the formation of a major metabolite diphenyl phosphate (DPHP). Quail were dosed with TPHP at low, medium and high concentrations by air cell egg injection followed by daily oral dosing and compared to vehicle-only exposed controls. Eggs were assessed for TPHP and DPHP at 2 days (prior to any hepatic development) or 10 days after (post-hepatic development) injection, and chicks were assessed at 6 days post-hatch. TPHP was measured in all eggs and chicks from the dosed groups, as well as in control samples albeit at low levels. DPHP was detected in all exposed eggs and chicks at concentrations that increased with the dose. Not all of the depleted TPHP was accounted for by DPHP formation in eggs although DPHP appears to be an important or dominant metabolite in the quail, making up 41-74% of all metabolites formed in eggs. TPHP was rapidly depleted and metabolized in Japanese quail where only 33% of the injected TPHP remained in eggs 2 days post injection, and 2% after 10 days with half-lives ranging from 1.1 - 1.8 days for the three exposed groups. In medium- and high-dose chicks, DPHP concentrations exceeded those of TPHP making up 67% and 76% of the total burden, respectively. The fact that DPHP was formed indicates Phase I CYP-mediated metabolism of TPHP in quail eggs and chicks. TPHP is rapidly metabolized in developing quail embryos, and TPHP concentrations may vary greatly with the age of the embryo and the stage of its development, and thus maternal exposure to TPHP itself may be difficult to elucidate in wild eggs.
379 In Vitro Demethylation of Environmentally Novel and Highly Brominated and Methoxylated Contaminants in Herring Gull Hepatic Microsomes

T.A. Smythe, Carleton University / Chemistry; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division

One trend for newer replacement organic brominated flame retardants (BFRs) appears to be towards higher molecular weight and highly brominated chemicals, such as oligomeric polyhalogenated polynucleic ethers (PHPEs), or polymer flame retardants (e.g. PolyFR). Despite their intrinsically low bioavailability and instability, it is increasingly evident that abiogenic and/or microbial degradation processes can substantially impact their environmental recalcitrance. We have shown that the bio- transformation of emerging BFRs in wildlife species (e.g. birds, fish and marine mammals) is very poorly understood. Since 2015, only one study has investigated the metabolism of BFR degradation by-products, i.e. the in vitro hydroxylation of the photolytic breakdown-products of the PHPE flame retardant tetraedecabromo-1,4-diphenoxynbenzene (TeDB-DiPhOBz) in herring gull (HG, Larus argentatus) liver microsomes. It was hypothesized that HGs were metabolically capable of producing methoxylated polybrominated diphenoxynbenzenes (MeO-PB-DiPhOBz); which are novel contaminants reported in Laurentian Great Lakes HG eggs and tissues; following the dietary accumulation of the TeDB-DiPhOBz photolytic breakdown-products and subsequent hydroxylation and methylation metabolic processes. Our recent measurements of MeO-PB-DiPhOBzs in HG regurgitant, as well as in the soil surrounding selected HG nest sites, suggests instead that MeO-PB-DiPhOBzs are bioavailable and bioaccumulative contaminants, and that HGs are exposed to them directly (e.g. via the diet). To assess the metabolic capacity of HGs for clearance/transformation of these contaminants, the objective of the present study was to utilize existing HG liver microsomal (LM) biotransformation assays for the structure-specific demethylation of 5x unique tetrabromo- and 5x pentabromo-MeO-PB-DiPhOBzs to their corresponding hydroxylated-(OH)-PB-DiPhOBz congeners. Assays were established in both rat (Wistar-Han) LMs and HG LMs using 6-MeO-BDE-47 as an active control across 8 concentrations (0.01 to 10 µM) and 9 time points up to 100 min. The Michaelis-Menten constant (Km) and maximal reaction rate (Vmax) for demethylation was determined for all MeO-PB-DiPhOBzs that exhibited significant depletion. These results suggest that HGs are metabolically competent in the demethylation of MeO-PB-DiPhOBzs, and may suggest a possible route of clearance of these contaminants by the HGs.

380 The case for simple bioaccumulation models for air- and water-breathing organisms

A. Celsie, Queens University; D. Mackay, J. Parnis, Trent University / Chemistry

A key criterion for identifying chemicals of concern is bioaccumulation, usually using bright-line criteria for bioconcentration based on the octanol-water partition ratio (KOW). Using these guidelines has recently led to misidentification of some chemicals drawing criticisms and recognition that it may be time to move beyond simple bright-line criteria. For example, the use of Kow can misidentify chemicals that bioconcentrate in air-breathing species or chemicals that are subject to slow uptake or biotransformation. We suggest that there is a need for simple, freely available and transparent bioaccumulation models for both water and air-breathing species including fish, birds, and mammals using illustrative organism properties. An attractive approach is to base the models on the fugacity concept, explore the dependence of steady-state organism fugacities and concentrations on the input fugacities for water, air and diet and identify conditions under which biouptake results in fugacity magnification (equivalent to biomagnification) from respired water, air or diet. Also interesting is the time required to achieve, or recover from, a steady state fugacity. Since fugacity is the basic driving force for bioconcentration, bioaccumulation, biomagnification, and trophic magnification it makes sense to employ it directly in biotake models as a step towards determining concentrations. Using a simple model available in spreadsheet format has two advantages. First, the model can be used for educational purposes and can readily demonstrate the fundamental causes of bioaccumulation and biomagnification, the relative contributions of diet, respiration and the mitigating roles of biotransformation, growth dilution, and reproductive losses. Second, the model can be used for preliminary evaluation of new chemicals to assess the potential of a particular chemical to cause high fugacity or concentration for a range of selected species. If such potential is identified it may justify the use of more detailed, complex, and rigorous models or tools (such as AQUAWEBC or BAT) that can provide a more in-depth analysis. In this presentation such simple models are described for fish, birds, terrestrial and marine mammals. References: 1. McLachlan, M. S. Environ. Sci. Process Impacts, 2018, 20, 32-37. Arnot, J. Western Research Methods and Indigenous Knowledge: Collaborative Approaches Towards Environmental Quality and Integrity

381 Tribal/EPA Collaboration to advance chemical risk assessments in the US

D.C. Barton, Columbia River Inter-Tribal Fish Commission; F. Corey, Aroostook Band of Micmacs; L. Zender, Zender Environmental Health and Research Group

The National Tribal Toxics Council (NTTC), Tribal Pesticide Program Council (TPPC) and Tribal Science Council (TSC) collaborate with the United States Environmental Protection Agency (EPA) to address issues related to indigenous populations’ exposures to chemicals. The goal of this collaboration is to characterize how tribal exposures to chemicals may differ from that of the general population due to unique tribal customary, cultural, ceremonial and subsistence practices and to identify exposures that result in elevated risks to tribal members. This presentation will highlight key elements of this collaboration and demonstrate how indigenous knowledge can inform the science of exposure and risk assessment. Tribal lifeways are inclusive of, but not limited to, economic, cultural, ceremonial, recreational and subsistence practices. Tribal lifeways include the use of the local ecology for food, medicine, education, religion, occupation, income and all aspects of life. Tribal lifeways stem from tribal culture, which is not an optional lifestyle choice, but rather an essential part of a tribe’s identity. Culturally specific subsistence consumption of locally-harvested foods is particularly important in evaluating tribal exposures. Also, tribal exposures may be influenced by historical patterns of residential construction, unique regional transportation options, and the management of water and waste on tribal lands. While cultural and traditional practices may result in unique exposures for tribes, other factors are important. For example, tribal lands exist in a wide range of geographies and climates that may result in exposures that differ from those of the general population. A current focus of the effort is to ensure that the potential for elevated exposures and risks is considered under the new Toxic Substances Control Act (TSCA). Under TSCA’s risk evaluation process, the EPA is required to “determine whether a chemical substance presents an unreasonable risk of injury to health or the environment, without consideration of costs or other non-risk factors, including an unreasonable risk to a potentially exposed or susceptible subpopulation identified as relevant to the risk evaluation by the Administrator under the conditions of use.” Our collaborative efforts to develop tribal exposure scenarios as an initial case study will inform the evaluation of potentially exposed populations, including tribal populations, in TSCA risk evaluations.
Tuesday Platform Abstracts

382 Empowering Māori indigenous knowledge for better environmental quality and integrity outcomes for New Zealand
J.M. Ataria, Cawthron Institute; R. Tuia-Gordon, Te Kawerau-a-Maki; D. Whaanga, Te Ao Mārama, Inc.; L.A. Tremblay, Cawthron Institute; O. Pantos, ESR; G.L. Northcott, The New Zealand Institute for Plant & Food Research Limited; V. Baker, Institute of Environmental Science Research Limited

Aotearoa New Zealand is not immune to the unaltered anthropogenic environmental pressures affecting all terrestrial, freshwater, marine and atmospheric environments today. In the global rally to tackle increasingly complex wicked problems, there is growing recognition of the importance of indigenous ecocentric worldviews. Here in Aotearoa New Zealand, there is increasing commitment to employing the unique corpus of Māori knowledge alongside western science to address issues like environmental contamination. Further, there is an expectation that Māori, the indigenous people of Aotearoa New Zealand, should be integral involved in natural resource management and strategies to mitigate impact. Robust methodologies to support a meaningful interface and respectful knowledge sharing between indigenous and western science are still evolving, and despite the benefits that can be derived from good collaborations, the quality of engagement is not always satisfactory. Poor interpersonal relationships, inequity and undervaluing of Māori knowledge are just beginning points to consider in the work of supporting indigenous knowledge systems to help re-purpose global and western thinking for environmental sustainability principles and practice. By providing an appropriate historical context, this talk will consider the critical issues now facing Māori and their corpus of knowledge. This gives a lens to consider and identify fundamental requirements that will support international efforts to apply indigenous principles and knowledge within an ecotoxicological, research and natural resource management context.

383 Indigenous science, anti-colonial science, and community-based Western science on marine plastic pollution in Nunatsiavut
M. Libaion, Memorial University / Department of Geography; N. Healey, Memorial University

Settler colonialism is an ongoing structure that, through a diversity of interlocking techniques, maintains settler access to land for settler goals. As many Indigenous people well know, some of these techniques are exercised through research. After introducing the concept of research colonialism, this talk articulates the efforts of CLEAR, an Indigenous-led, marine plastic pollution laboratory that conducts research in Nunatsiavut, to do environmental science by creating and using Indigenous, anti-colonial, and community-based protocols affiliated in Western science. Differentiating between these different approaches is one of the aims of this presentation. Using cases of methodological protocols, we show how rather than integrating (or appropriating) Traditional Ecological Knowledge into Western science projects, CLEAR works to enact Metis and Inuit values of humility, reciprocity, balance, and respect at every stage of research, from how we design research instruments, to how and with whom we collect environmental samples, to how we “dispose” of samples after use. We will discuss some of our anti-colonial protocols and their politics, including community peer review, sampling techniques for food sovereignty, and animal respect protocols as they have been developed and used in plastic pollution research in Nunatsiavut.

384 Commission for Environmental Cooperation (CEC) Project 15: Proper Functioning Condition (PFC) Assessment Report
K. Charles, H. Charles, Chippewas of Georgina Island First Nation; R. Hall, USEPA; D. Mosley, Pyramid Lake Paiute Tribe / Fisheries Department

The Commission for Environmental Cooperation (CEC) facilitates collaboration and public participation to foster conservation, protection and enhancement of the North American environment for the benefit of present and future generations, in the context of increasing economic, trade, and social links among Canada, Mexico, and the United States. CEC supported projects have often focused on preventing degradation of natural resources (essential plant communities, water quality and quantity, etc.) by improving ecological function conditions; enhancing collaboration between North America countries’ natural resource and environmental agencies to address preservation and restoration of ecosystem resilience; and engaging local communities in order for watershed protection to be sustainable. In this context, preserving Traditional Ecological Knowledge (TEK) or Indigenous Knowledge (IK) has been an important objective. Ecosystems are defined as an interconnected community of vegetation, soils and landform, hydrology, and microorganisms linked by physical and chemical interactions. Ecosystems provide a sustainable flow of natural resources and ecological services required to meet the nutritional, cultural, societal and economic needs of indigenous populations. The hydrologic, physical and ecological alterations resulting from terrestrial activity can have a pronounced impact on the natural function of uplands, and stream and wetland riparian areas. This presentation will focus on CEC Project 15, done in collaboration with the Chippewas of Georgina Island, which sought to address the concepts of sustainable ecosystems and communities by using and identifying what role TEK/IK plays in indigenous communities’ approach to natural resource management. TEK/IK provides the foundation for integrated riparian management focused on riparian and upland ecological function relationships. The presentation will highlight the collaborative interactions, based in both TEK/IK and the science of proper functioning condition (PFC) to achieve the this first nation’s goal of restoring a natural stream on Georgina Island.

385 An assessment of the Efficacy of Utilizing Restored Anadromous Fisheries Resulting from Dam Removal in Support of Tribal Sustainability and Sustainability
M. Stover, USEPA Region 1; D.H. Kusnierz, Penobscot Nation / DNR; J. Lin, L. Melnyk, USEPA Cincinnati / National Exposure Research Laboratory; K. Pugh, ATSDR; G. Perelman, ATSDR; J.M. Lazorchak, US Environmental Protection Agency / ORD/NERL/Systems Exposure Division

American Indian tribes have unique traditional cultural practices that are often not adequately protected by classic regulatory approaches. The sustenance fishing practices and rights of the Penobscot Nation (Nation) are currently impacted due to unsafe levels of dioxins, furans, PCBs, and mercury found in the tissues of resident fish species from the Penobscot Reservation. However, recent river restoration efforts, including dam removals, have resulted in the abundant return of several anadromous fish species to waters where Penobscot tribal members fish for sustenance, where these species have been missing for over the past 100 years. Consumption of these species of returning fish will likely restore a major component of the tribal members’ traditional diet. However, information regarding contaminant levels in these fish is needed to guide the Nation with respect to safe consumption. EPA, in collaboration with the Nation and the Agency for Toxic Substances and Disease Registry (ATSDR), assessed the safety of human and wildlife consumption of six species of anadromous fish, Alewife, American Shad, Blueback Herring, Rainbow Smelt, Striped Bass, and Sea Lamprey plus one of roe from American Shad. Fish were collected and filleted in the field by the Nation’s DNR with assistance from EPA. Fillets were then analyzed by EPA in 2017 and 2018 for mercury, PCBs, dioxins and furans. A preliminary assessment of mercury levels in these fish was compared to reference doses as established in the US Integrated Risk Information System (IRIS) and wildlife values. The concentrations of mercury ranged from around 10 µg/kg in roe samples to around 650 µg/kg in sea lamprey. Current health advisories in the area are set at sufficient levels to protect tribal sustenance fishers from harmful consumption of the fish species, except for Sea Lamprey. Using a consumption wildlife value of 70 mg/kg for Mink and 100 mg/kg for Otters, the results indicate that Alewife, Striped Bass and Sea Lamprey pose a risk to Mink, while Rainbow Smelt, Striped Bass and Sea Lamprey pose a risk to Otters. The results of PCBs, dioxin and furans will also be presented in a one health approach included in a public health
assessment the influence of colonization on our approach to scientific inquiry and understanding of ecological health. It will shed light on the benefits of new approaches to environmental decision making that include other bodies of knowledge such as Indigenous Ecological Knowledge. This will be done through the review of two case studies both of which use varying approaches to weaving knowledge systems in order to arrive at a place where environmental decision making can be made. Case study 1 will explore a novel approach to a risk assessment of a contaminated harbour. Case study 2 examines the influence of mercury on traditional food sources and the importance of creating culturally appropriate safe food consumption guides. Through these case studies we will speak to the processes, challenges, and benefits that come with such collaborative approaches to tackling environmental issues.

Wildlife Ecotoxicology: Assessing Effects of Chemical Stressors at Multiple Scales

389 Wildlife Ecotoxicology: High Time for the Top-down Approach as the Essential Forensic Tool

L.V. Tannenbaum, US Army Public Health Center / Army Public Health Center

A fully plausible approach to understanding and assessing contaminant exposure concerns for wildlife, recognizes that contaminated environments have had all the chances they could have possibly needed to severely impact ecological receptors. This admittedly controversial approach argues that the time is well past for ‘bottom-up’ tasks such as engaging with assessing risks, or modeling how contaminants move through ecosystems in support of predictions of toxicological effects that might come to be expressed. The more appropriate approach is to directly assess the health of the actual receptor of concern in the field (in a ‘top-down’ fashion). This presentation will report on several such field-based assessment types. These include a) successes of applications of the ASTM certified Rodent Sperm Analysis method, which has effectively solved the chemical mixtures riddle, b) potential for wild rodent ovarian follicle counting (WROFC) to also demonstrate absent reproductive impacts in terrestrial mammals, and c) illustrate with GPS tracking data, that commonly assessed larger mammals are spatially irrelevant at conventional contaminated sites. Collectively, the information to be presented strongly suggests that a dramatic paradigm shift is in order for addressing wildlife ecotoxicology concerns.

390 Embryotoxicity of diluted bitumen applied to eggshells of wild double-crested cormorants and domestic chickens

M.D. King, Simon Fraser University / Biological Sciences; J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch Ecotoxicology and Wildlife Health Division; T. Williams, Simon Fraser University / Department of Biological Sciences

Breeding birds that become oilied may return to incubate their eggs, but even small quantities (>=1 ul) of conventional crude oils are embryotoxic when applied to the exterior of the eggshell. Therefore, we investigated whether an unconventional oil sands product, diluted bitumen (dibit), was toxic to embryos of two species, domestic chickens (Gallus gallus) and wild double-crested cormorants (Phalacrocorax auritus). We incubated embryos in artificial egg incubators and applied various doses of lightly weathered dibit ranging from 1 to 20 mg to the eggshells during early or late development. In both species, eggshell oiling with dibit caused no significant decrease in embryo survival at sampling (85% development). Furthermore, in chicken embryos exposed during late development, we found no significant difference in growth, haematoctict, haemoglobin, or heart rate. We present additional preliminary growth and heart rate data in double-crested cormorants, as well as more sensitive gene expression analysis data. We discuss briefly how the chemical composition of dibit, including polycyclic aromatic hydrocarbon profile, physical properties of dibit, and the weathering process may contribute to the apparent lack of effect on survival, growth, or aerobic capacity in these species compared to similar studies with conventional crude oils. This study indicates that
391 Arctic seabirds: Do contaminants influence their ability to respond to climate change?

K.J. Fernie, Environment and Climate Change Canada; R.J. Letcher, B.M. Braune, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; J. Head, K. Elliott, McGill University / Department of Natural Resource Sciences

In the Arctic, wildlife encounter multiple environmental stressors, including climate-related changes, ice availability, and chemical pollutants. Because the endocrine system has a critical role in allowing animals to respond to environmental stress (e.g., changing ice patterns), endocrine disruption could influence the ability of wildlife to respond to climate change. We investigated whether contaminants compounded the impact of climate change on Arctic seabirds by limiting their ability to respond to changes in ice availability. During our study, thick-billed murres (Uria lomvia) experienced significant dietary changes, the earliest (2017) and latest (2018) ice conditions and hatch dates in 40 years, as well as average ice and breeding conditions (2016). Nearly 170 thick-billed murres were sampled, including foraging behaviors, circulating hormones and mercury (Hg), and in a subset of birds, per-/polyfluoroalkyl substances (PFASs), and brominated flame retardants (BFRs). The presence of ice determined the birds’ foraging locations that varied annually, as did the composition of their diet, both reflected in dietary proxies (stable isotopes). Dietary proxies explained much of the annual variation in high Hg levels, but not in PFCArs, PFASs, or BFRs that were low and unrelated to hormones or behaviour. During the medium-ice year (2016, positive relationship) and low-ice year (2017, negative relationship), high Hg levels were related to circulating T3, and in turn, T3 was related to time spent diving for prey, directly in contrast to the high-ice year (2018, no relationships). Based on our findings, we tentatively conclude that Hg may be influencing the ability of thick-billed murres to adjust to variation in ice cover, but only in years when ice leaves unusually early.

392 A tail of two birds: Contrasting diet mediated contaminant burdens in herring gulls and double crested cormorants

S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; K. Hughes, Broadening Biological Consulting; G. Barrett, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; C.E. Hebert, Environment and Climate Change Canada

Diet is an important factor for determining exposure of bioaccumulative persistent organic pollutants to high trophic level vertebrates, such as colonial waterbirds. The Great Lakes Herring Gull Monitoring Program has proved valuable in contributing to our understanding of food web dynamics and the importance of understanding diet in interpreting contaminant and related data. We assessed relationships between diet, as assessed using stable isotopes (δN, δC) and essential fatty acids, with contaminants burdens in eggs of herring gulls (HERGs) from 2015 to 2018 and from 15 colonies in the Great Lakes. Eggs of double crested cormorants (DCCO) from some of the same colonies were also collected and analyzed for the same suite of contaminants providing a unique ability to compare similarities and differences in contaminant burdens between a generalist for the same suite of contaminants. DCCOs clearly had a greater aquatic diet than HERGs, intercolony variability in diet had more profound effects on egg burdens in HERGs than DCCOs and both enrichment in δN and ω3:ω6 influenced contaminant burdens in eggs of HERG more than DCCOs. Despite their similarities, cormorants and gulls provide complimentary information about both the food web and contaminant exposure in the Great Lakes.

393 Pesticide exposures in hummingbirds and honey bees in Blueberry agriculture in British Columbia, Canada

C.A. Bishop, Environment and Climate Change Canada / Wildlife Research Division; A.J. Moran, Rocky Point Bird Observatory / The Hummingbird Project; J. Common, Hives for Humanity; M. Woundeh, SGS AXTS Analytical Services, Ltd.; H. Higo, Simon Fraser University / Department of Chemistry; J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch Ecotoxicology and Wildlife Health Division

Globally over 300 species of hummingbirds contribute substantially to both the biodiversity and ecosystem services as pollinators. Recently however studies in Canada determined for the first time that hummingbirds are exposed to pesticides and they are detectable in their urine and feces. Imidacloprid is most commonly detected but also clothianidin and thiamethoxam and, in 2018, we also detected flupyradifurone in hummingbird urine. Furthermore, pesticide synergists used to enhance pyrethroid toxicity are also detected in hummingbird feces and in sediments from irrigation ditches near blueberry crops. In 2017, we sampled hummingbirds throughout Vancouver Island, and the dry interior of BC, and in parks within Saskatchewan. Neonicotinoid detections in hummingbirds were associated with sites near agricultural areas primarily fruit growing areas and highest concentrations were found in the Fraser Valley sites near blueberry fields. In 2018, measurements of pesticides in hummingbird food sources such as flowers, and flower nectar in honey bee hives within our study sites, and water and sediment samples near to berry crops/our study sites in British Columbia, Canada traced hummingbird exposure to sites on and near to the sprayed fields. Concentrations of neonicotinoids found in honey bee nectar are 1-10 µg/kg which literature reports indicate are associated with chronic sublethal effects in honey bees.

394 Intraspecific Variation in Metal Tolerance Across the Landscape Provides Insight into Evolutionary Responses

S.L. Lance, University of Georgia / Savannah River Ecology Laboratory; R.W. Flynn, Purdue University / Forestry and Natural Resources; C. Love, University of Georgia / Savannah River Ecology Lab; C. Rumrill, USGS / Forest and Rangeland Ecosystem Science Center; D. Scott, University of Georgia / Savannah River Ecology Laboratory

Wetland ecosystems experience widespread contamination from human activities. The conditions in these environments are often novel and beyond the range that organisms have adapted to. When faced with novel stressors, populations may go locally extinct if fitness is severely reduced. Alternatively, populations can be rescued by phenotypic plasticity and/or local adaptation. Amphibians are particularly tied to wetland habitats and are highly sensitive to contaminants. However, we know little about the evolutionary responses of amphibian populations to metal contamination. In this study, we leverage nine years of data on patterns of metal tolerance in southern toads, Anaxyrus terrestris, across the Savannah River Site (SRS). The SRS provides a landscape with hundreds of wetlands and heterogeneous patterns of contamination, including constructed wetlands of varying ages and well documented metal mixtures. We used a combination of microcosm, mesocosm, reciprocal transplants, quantitative genetics, and elemental analyses to investigate among population tolerance to metal contamination. Our data demonstrate that populations newly exposed to copper contamination may initially experience reduced fitness, but that local adaptation can occur within 10 generations. In addition, we found evidence that populations can locally adapt within 20 generations to partially ameliorate the fitness reductions associated with metal mixtures from coal combustion wastes. Elemental analyses suggest that the mechanism for adaptation may involve maintaining ionic balance in the presence of osmotic stress induced by metal exposure. Surprisingly,
individuals from populations adapted to coal combustion wastes do not have elevated tolerance to copper, indicating that adaptation does not yield cross-tolerance. Local adaptation appears to come with multiple costs; offspring of parents from a contaminated site can experience reduced larval performance in other environments and juveniles display lower survival and performance. Ultimately the persistence of populations in contaminated environments may depend not only on the potential for local adaptation, but also the costs of tolerance and the spatial and temporal variation in the presence of contaminants.

395 Chronic effects of sewage effluent, EE2 and fluoxetine as well as depuration rates of perfluorooctane sulfonate on male hatching Snapping Turtles

E.M. Leonard, McMaster University; K.D. Oakes, Cape Breton University / Department of Biology; S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; B. Knight, Environment Canada; J.S. Ings, University of Waterloo; G. Barrett, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; G. Dixon, University of Waterloo / Biology; D.A. Holdway, University of Ontario Institute of Technology / Science; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; K.J. Fernie, Environment and Climate Change Canada; M.R. Servos, University of Waterloo / Biology

Pharmaceuticals, personal care products (PPCPs) and Perfluorinated Alkyl Acids (PFAAs) are widespread environmental contaminants frequently detected in the aquatic environment. The persistence and environmental effects of these compounds is not fully understood leading to a heightened research interest evaluating their impact on taxa. Some PPCPs are incompletely removed or degraded to bioactive metabolites during processing at municipal wastewater facilities. Similarly, the use of PFAAs in aqueous film forming foam (AFFF) has been linked to substantial environmental contamination, following its use as a fire retardant for fuel-based fires at airports. Snapping turtles (Chelydra serpentina), being quite tolerant of organic enrichment, are commonly found below Municipal Waste Water Effluent (MWWE) discharges leading to exposure to PPCPs. Previous studies have measured high concentrations (>1 ppm wet weight) of the PFAA, perfluorooctane sulfonate (PFOS), in the plasma of snapping turtles collected near international airports. Male hatching snapping turtles, collected as eggs from a relatively pristine location (Algonquin Park, northern Ontario, Canada) were reared in a laboratory setting and exposed to MWWE (concentrations up to 90%), synthetic estrogens (EE2; 0.1 µg/L) and fluoxetine (0.32, 32 and 320 µg/L) for 82 days. In a separate dietary, depuration, study, turtles were exposed to PFOS (1, 10, 100, 1,000 and 10,000 ng/g wet wt) for 1 month and depuration rates were determined. MWWE displayed reduced liversomatic indices (LSI) and somatic growth commensurate with an observed decrease in appetite. Oxidative stress was induced by EE2 and reduced by fluoxetine. However, no changes were observed in brain citrate synthase, lactate dehydrogenase or acetylcholinesterase activity indicating metabolic rate was not significantly altered in this organ. Overall, these results suggest that chronic exposure to MWWE, EE2 and fluoxetine affected growth and LSI of hatching snapping turtles but had limited effect on metabolism. Depuration rates of PFOS increase our understanding of the effects of spills on aquatic organisms.

396 Hindered phenols and treated effluent: Effects on a native Canadian amphibian

S. Robinson, S.D. Young, D. Carpenter, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate

Municipal wastewater treatment plants (WWTPs) are used to treat sewage in order to reduce suspended solids, total chlorine, and ammonia before releasing as treated effluent. Most WWTPs are required to report carbonaceous biochemical oxygen demand (CBOD) in treated effluent, a measurement used to give an indication of organic contaminants removal through microbial activity. However, WWTPs have been shown to be a vector of many contaminants into aquatic ecosystems via effluent discharge. To understand the implications of the release of this chemical mixture into the aquatic environment, we exposed a native Canadian amphibian, the northern leopard frog (Lithobates pipiens; formerly Rana pipiens) to a dilution series of effluent from Hamilton, Ontario, Canada. In a comparison study, leopard frogs, were exposed to a single compound, 2, 4-di-tert butylphenol (2,4-DTBP; CAS: 96-76-4), an antioxidant (trade name: Prodox 146) for applications including fuels, rubber, and plastics. 2,4-DTBP and other alkylated phenolic antioxidants are of concern due to potential endocrine disruption. Both experiments employed water-borne exposure to tadpoles for up to 30 days and were monitored for survival, growth, and development. Additionally, liver tissue metabolomic profiles were examined as potential biomarkers of toxicity. Lipid metabolites (i.e., acylcarnitines and glycerophospholipids) were elevated with exposure to 2, 4-DTBP compared to controls, putatively through alterations in fat metabolism and excretion. However, survival, growth and development were not affected. Effluent exposures are underway. Continued monitoring of and assessment of the toxicity to effluent released by WWTPs is required to understand the effects on species inhabiting receiving environments. This research is therefore crucial in providing the essential information for the continued improvement of WWTPs. Lastly, this study highlights the need for testing ecotoxicity using complex mixtures that are representative of our ambient environment.
397 Sub-lethal embryonic cardiotoxicity is associated with increased mortality of overwintering juveniles in Pacific herring (C. pallasi)

A.D. Cypher, NOAA Fisheries NWFSRC / Integrated Bioscience; T. Linbo, NOAA Fisheries / Northwest Fisheries Science Center; P. Hershberger, J. Gregg, USGS / Western Fisheries Research Center; N. Scholz, J. Incardona, NOAA / fisheries

In 1989, the Exxon Valdez oil tanker ran aground and emptied 11 million gallons of oil into Prince William Sound. The spill overlapped in time and region with the spawning of Pacific herring, an important forage fish. Several years later when the spawn of 1989 would have returned to breed, the population crashed and has yet to recover. Since then, it has been established that larval herring are extremely sensitive to polycyclic aromatic hydrocarbons (PAHs), a complex mixture of organic compounds in crude oil. The developing heart in particular is the primary target of crude oil toxicity and a strong hypothetical starting point for a cascade of events leading to reduced recruitment at the population level. The goal of this work was to determine latent functional effects and potential sources of delayed mortality during the first year. Herring embryos were exposed to 0 to 3.4 ppt PAHs via a dispersion generator from 24 hours post fertilization to 10 days and subsequently reared in clean sea water. Cardiac morphology, primarily contractility and ventricular ballooning, was assessed during larval and juvenile stages via video microscopy and histology. An overwinter fasting trial was conducted during juvenile stages (100 fish/tank) for oiled/unooled and fed/unfed treatments until 50% mortality. Condition factor and lipid composition were also tracked throughout starvation. We found that oiled herring had reduced ventricular ballooning that persisted well into larval development which can lead to altered morphology and function at juvenile stages. During a simulated overwinter fasting, oiled herring experienced mortality 15-20% sooner than control indicating that early oil exposure may impact the ability of juveniles to survive their first winter if food is scarce. More work is needed to determine the relationship between latent effects on cardiovascular morphology and overwinter survival after embryonic exposure to oil.

398 Acute and latent effects on the teleost kidney following early life-stage exposure to Deepwater Horizon crude oil

F. Bonatesa, University of North Texas / Environmental Science; A. Khursigara, University of Texas; J. Greer, University of California, Riverside / Environmental Sciences; E.G. Xu, University of California, Riverside; D. Schlenk, University of California, Riverside / Environmental Sciences; A. Esbaugh, University of Texas / Department of Marine Science; E. Mager, University of North Texas / Department of Biological Sciences

Much has been learned with respect to the developmental toxicity of crude oil exposure to teleost fish in the years following the Deepwater Horizon oil spill. Among the key findings are several lines of evidence that specific crude oil constituents, namely polycyclic aromatic hydrocarbons (PAHs), impair the function and proper development of the teleost heart. The resulting reduction in cardiac output is believed to elicit a characteristic suite of downstream effects (e.g., pericardial and yolk sac edema) and likely impairs the proper development of other organs, such as the kidney, which is a crucial osmoregulatory organ. While there is some evidence that exposure to individual PAHs impairs development of the early stage kidney (i.e., pronephros), little is known regarding the effects on the pronephros following exposure to complex crude oil mixtures at environmentally relevant concentrations. Furthermore, it is unknown whether early life stage (ELS) effects arising from short-term exposures result in long-term or latent effects on kidney function and, consequently, osmoregulation. To address these knowledge gaps, time-course and dose-response exposures to embryos/larvae of zebrafish (Danio rerio) and red drum (Sciaenops ocellatus) were performed using high energy water-accommodated fractions (HEWAFs) of DHW slick oil. Transcriptional changes in genes with various structural, functional and signaling roles specific to different regions of the developing pronephros (e.g., glomerulus, pronephric tubule and pronephric duct) were assessed by QPCR and whole mount in situ hybridizations. Morphological changes in the pronephros were determined by immunohistochemistry using an antibody raised against Na/K ATPase (NKA). Additionally, latent effects of ELS crude oil exposure on kidney function and overall osmoregulation were assessed by subjecting red drum to an acute salinity transfer challenge. Results demonstrate transcriptional changes in key genes involved in early kidney development and function, and that early stage impairment of normal kidney development might translate into long-term impairment of teleost kidney function. This research was made possible by a grant from The Gulf of Mexico Research Initiative.

399 Developmental Thyroid Disruption Impairs Reproduction: Uncovering Mechanisms Using a Transcriptomic Approach

A. Johnson, Texas Christian University / Biology; P. Burns, Baylor University / Environmental Science; M. Hale, Texas Christian University; M.K. Sellin Jeffries, Texas Christian University / Department of Biology

Thyroid disrupting compounds (TDCs) are known to interfere with normal thyroid hormone (TH) signaling. During embryonic and juvenile development, thyroid hormones modulate a variety of biological processes such as neurogenesis and the growth of the skeletal and muscular systems. Therefore, the majority of research on early life-stage (ELS) thyroid disruption has focused on its effects on growth and development. However, recent research has shown that ELS TDC exposure can also have adverse effects on reproduction later in life. Specifically, fathead minnows exposed to propylthiouracil (PTU), an anti-thyroid drug known to inhibit the synthesis of thyroxine (T4), during early development (from hatch through 42 days post hatch) experienced a 50% reduction in fecundity relative to controls. Data suggested that the observed reductions in fecundity may have resulted from changes in male reproductive behavior and/or female ovarian development. To investigate the potential for and mechanism underlying PTU-induced alterations in ovarian development and male behavior, brains and ovaries of PTU-exposed and control males and females, respectively, were collected immediately after exposure for transcriptomic analysis. Of the genes that were found to be differentially expressed between the brains of PTU-exposed and control males, many were associated with neurogenesis, various aspects of brain development, and steroid hormone signaling. Given the known role of steroid hormone signaling in sexual differentiation of the male brain, these results provide evidence supporting the hypothesis that ELS chemically-induced hypothyroidism leads to altered brain development and subsequent alterations in behavior. Alterations in the expression of genes within ovaries suggest that PTU exposure may affect ovarian development potentially impairing reproductive output in adulthood. Overall, the results of this study may help link transcriptomic alterations in the ovary and male brain to alterations in behavior and reproductive success, which have important population-level consequences.

400 Perchlorate induces non-alcoholic fatty liver disease in developing fish

M.R. Minicozzi, Northern Arizona University / Biological Sciences; F.A. von Hippel, C.L. Buck, Northern Arizona University / Department of Environmental Conservation / Environmental Health; E. Axlid, Northern Arizona University / Biological Sciences

Perchlorate is a pervasive, water-soluble contaminant that competitively inhibits the sodium/iodide symporter, reducing the available iodide for thyroid hormone synthesis. Insufficient iodide uptake can lead to hypothyroidism and metabolic syndromes. Because metabolism, obesity and non-alcoholic fatty liver disease (NAFLD) are tightly linked, we hypothesized that perchlorate would act as an obesogen and cause NAFLD via accumulation of lipids in liver of developing threespine stickleback (Gasterosteus aculeatus). We performed an upshift/
downshift exposure regime (clean water to perchlorate treated water or perchlorate treated water to clean water) on stickleback embryos at two concentrations (30 mg/L and 100 mg/L) plus the control (0 mg/L) over the course of 305 days. Adult stickleback were euthanized, H&E stained and analyzed for liver morphology. We counted the number of lipid droplets, and measured the area of each droplet and the total lipid area of a representative section of liver. We found that perchlorate treated fish had more and larger lipid droplets, and a larger percentage of lipid in their liver than control fish. These data indicate that perchlorate causes NAFLD and hepatic steatosis in stickleback at concentrations commonly found at contaminated sites. These data also indicate the potential of perchlorate to act as an obesogen. We tested this by exposing developing zebrafish (Danio rerio) to perchlorate-contaminated water (0.01, 10, 30 and 100 mg/L) or control water; we euthanized fish at 133 days and stained with oil red O for lipids. Here we report on the obesogenic capacity of perchlorate by examining organ specific lipid accumulation and whether perchlorate induces these effects at concentrations commonly found in drinking water. Future work is needed to determine the mechanisms by which perchlorate induces lipid accumulation, and the relevance for the on-going obesity pandemic in humans.

401 Laboratory and mesocosm investigations of the ecotoxicological effects of metformin on fish

E. Ussery, Environment and Climate Change Canada / Biological Sciences; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate, Aquatic Contaminants Research Division; K.N. Bridges, Geosyntec Consultants, Inc. / Epidemiology; V. Palace, IISD-Experimental Lakes Area; J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute; R. Klaper, University of Wisconsin, Milwaukee / School of Freshwater Sciences; N. Blandford, University of Manitoba; T. Clark, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.G. Wynia, Environment and Climate Change Canada / Aquatic Contaminants Research Division; B.J. Venables, University of North Texas / Biological Sciences; Z.P. Pandelides, University of Mississippi / BioMolecular Sciences; D.A. Holdway, University of Ontario Institute of Technology / Science

Environmental research has recognized the occurrence and fate of pharmaceuticals in the aquatic environment as an emerging issue in aquatic toxicology. Currently, one of the most prevalent contaminants is the type-2 diabetic drug, metformin. Metformin has been measured in the ng-μg/L concentration range in surface waters and wastewater effluent. Our recent laboratory research shows that Japanese medaka (Oryzias latipes) exposed to a range of metformin concentrations (3.2, 10, 32, and 100 μg/L) from embryo through 28-days post hatch have a significant decrease in length and wet weight when compared to control fish. Metabolomic analysis performed on fish exposed to 3.2 μg/L metformin showed changes in the metabolome of the larval medaka, indicating significant dysregulation in fatty acid and lipid metabolism including metabolites associated with cellular energetics. Interestingly, a separate laboratory study performed by our research group, found no effects of metformin on growth in medaka exposed from embryo through adulthood, and despite significant effects on hepatic steroid hormones, metformin did not affect the reproductive output of breeding medaka, differing from results in the literature. The significant effects seen on larval growth and metabolome, and the shift in hepatic sex steroids seen in adult medaka, raised concern regarding metformin’s effects on wild fish. Thus, an 8-week mesocosm study was conducted at the International Institute of Sustainable Development Experimental Lakes Area (IISD-ELA) to investigate the effects of metformin on the overall and reproductive health of wild caught fathead minnows (Pimephales promelas). Specifically, four replicate mesocosms (2 meters in diameter by 1 meter deep, ~3,140 L) were dosed with one of three treatments, 0, 4, and 40 μg/L metformin. Each mesocosm contained 10 fathead minnows (4 males, and 5 females) for the full 8-week study. At study termination the growth (length, weight, condition factor, gonadosomatic and hepatosomatic indices) metrics and reproductive endpoints (egg production, egg fertilization, embryo hatch success, gonad histology, and sex steroid production were assessed).

402 Assessing the Effects of Environmentally Relevant Concentrations of Metformin to Fathead Minnows Exposed over a Full Life Cycle

J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; G. Pacepavicius, K. Shirey, S. Clarence, Environment and Climate Change Canada; H. Khan, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M. Gardner, C. Sullivan, Environment and Climate Change Canada; M. Alae, Environment and Climate Change Canada / Water Science and Technology Directorate

Metformin is a commonly used glucose-lowering drug that has been detected in municipal wastewater effluents at mid μg/L concentrations. We exposed fathead minnow (Pimephales promelas) over a full lifecycle to three concentrations of metformin: 4, 40, and 400 μg/L. The low concentration is similar to metformin concentrations in rivers, and the mid concentration similar to metformin concentrations in MWWEs. Mean measured concentrations of metformin were 3.0, 31, and 322 μg/L. During the life-cycle exposure, no significant changes were observed in survival of fathead minnows. Growth and maturation of the fathead minnows was unaffected by metformin exposure. There were no significant differences in condition factor, gonadosomatic index, or liver-somatic index in the metformin-exposed fish. Mean time to first breeding was significantly delayed by 10 days in 31 μg/L metformin treatment (and was delayed, but not significantly, in the 322 μg/L treatment). Overall, the metformin-exposed fathead minnows produced similar numbers of eggs as control fish. Egg quality was very good and was unaffected by metformin, with % fertilization 92-96 %, and 70-77 % hatching success in F1 fry. Eggs hatched in 5 days, severe deformities in fry were low (2-4 %), and there were no effects on survival or growth of F1 larvae at 9 and 16 days post-hatch from any metformin treatment compared to controls. Exposure to the metformin at environmentally relevant concentrations (i.e. 4 and 40 μg/L metformin) over a full life-cycle caused no adverse effects in fathead minnows.

403 Impact of agricultural pesticides on the endangered copper redhorse: transcriptomic and organismal level responses at an early life stage

H. Marchand, McGill University / Natural Resource Sciences; B. Barst, University of Alaska Fairbanks / Water and Environmental Research Centre (WERC); E. Boulanger, McGill University / Natural Resource Sciences; N. Vachon, Ministère des Forêts, de la Faune et des Parcs; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Head, McGill University / Natural Resource Sciences

The copper redhorse (Moxostoma hubbsi) (CR) is an endangered fish that exists only in the St. Lawrence River and its main tributaries in southern Quebec, Canada. The closely related river redhorse (Moxostoma carinatum) (RR) and the CR share the same habitat and spawning grounds, however, the RR population is faring better (special concern). A myriad of anthropogenic factors may be leading to the poor natural recruitment of the CR, including contamination of their only known spawning grounds and nursery habitats within the Richelieu River with agricultural pesticides (e.g., atrazine, clothianidin, glyphosate, metolachlor). Our efforts focused on measuring the effects of these pesticides on early life stages of fish. CR and RR embryos (1000 per species) were obtained from the provincial government’s artificial breeding program during the summer of 2018. Half the embryos were exposed to Richelieu River water in an in situ flow-through system while the other half were exposed to laboratory water used as control. Embryos exposed to river water hatched
prematurely, with a median hatch time that was 19 hours earlier than the control group. River-water treated embryos also had a lower survival rate (73% vs. 93%). A similar trend was seen with RR in hatching time but the scale of the effects was much smaller, possibly suggesting a difference in species sensitivity. RNA sequencing was performed on 9 pools of 5 larvae per treatment and 137 genes were differentially expressed. Numerous genes involved in anatomical structure development, cell differentiation/proliferation growth were dysregulated following incubation in river water. Differences in the transcription patterns of growth-related genes may be due to differences in hatching time leading to varying developmental stages at termination. However, the opposite may also be true: river water may alter gene expression related to growth and development and may explain earlier hatching. Genes involved in stress, inflammatory and immune responses were also dysregulated. To pinpoint possible causes of the effects we observed, a series of exposures will be performed using chemicals previously identified in the river water. This study will provide valuable data on the effects of agricultural contaminants present in the Richelieu River and increase our knowledge on the individual and mixture effects they have on an endangered fish.

404 Pesticide Detoxification and Handling in Two Life Stages of Lake Sturgeon
O. Bireclegu, H. Bauman, J.M. Wilson, Wilfrid Laurier University / Biology; W. Bugg, K. Jeffries, University of Manitoba / Biological Sciences; M.P. Wilkie, Wilfrid Laurier University / Biology

Two lampricides, TFN and niclosamide, are applied to Great Lakes tributaries infested with larval sea lamprey (Petromyzon marinus) to control populations of this invasive fish in the Great Lakes. While the lampricides specifically target the larval lamprey, which have a low detoxification capacity, non-target fishes are more vulnerable, as they are able to detoxify the pesticides via Phase II detoxification pathways, such as glucuronidation. However, some non-target fishes are vulnerable, including young of the year (YOY) lake sturgeon (Acipenser fulvescens), which are an economically and ecologically significant species, which is currently considered at risk in the Great Lakes basin. We hypothesized the sensitivity of YOY sturgeon to lampricides was due to a lower detoxification capacity, compared to older, more tolerant sturgeon. To test this hypothesis, lake sturgeon (YOY and 1+ year) and larval lampreys were exposed to TFN and niclosamide, alone and in combination. Compared to 1+ sturgeon, YOY and lampreys accumulated greater amounts of both parent lampricides. In sturgeon, however, the levels of glucuronidated and sulfated metabolites, the two main products of lampricide detoxification, were comparable in the two age groups. Therefore, we suggest that the greater sensitivity of the YOY to the lampricides may be due to their higher accumulation of the parent compound compared to the 1+ fish, rather than to differences in detoxification capacity between the age groups. We conclude that delaying lampricide treatments until sturgeon are older could mitigate potential adverse effects on this at risk species. Notably, the sulfated and the glucuronidated metabolites of the lampricides were also detected in larval sea lamprey, suggesting that they may be able to evolve resistance to lampricides by increasing their detoxification capacity.

Freshwater Salinization: Causes, Effects and Working Towards Solutions

405 Chloride water quality guidelines are too high for aquatic life in softwater Boreal Shield Lakes
M. Cels-Salgado, S. Arnott, R. Vallee, Queens University / Biology; A. Paterson, Ontario Ministry of the Environment, Conservation and Parks / Dorset Environmental Science Centre; J.P. Smol, Queen's University / Department of Biology

Chloride concentrations have been increasing in many lakes in Ontario due to the application of road salts to de-ice paved surfaces in winter. Softwater lakes in the Boreal Shield may be more sensitive than hard water lakes to chloride. We conducted 21d static with 48 h renewal bioassays with 10 clonal lines of Daphnia pulicaria, and 6 other species of Daphnia, all widespread species in the Boreal Shield lakes of Ontario, Canada. The Cladocera were collected from softwater lakes in the region, fed 1 mg Carbon/L/day and the bioassays conducted with < 24 h old neonates at 20°C and 16:8h light:darkness in FLAMES medium. The daphnids were examined daily for survival and reproduction. LC50s were calculated for each clonal line and each species under 7 chloride treatments, ranging from 0.39 to 150 mg/L in FLAMES medium, using reagent quality NaCl. The LC50s were lower than the current water quality guidelines for chloride. Our research found that the softwater clonal lines and species tested are at risk when comparing the determined LC50s with the current chloride guideline for the protection of freshwater life. These results are supported by paleoecological data that provide evidence that other Cladocera species have been affected by chloride increases associated with road salt application. Together these results suggest that water quality guidelines for chloride should be reconsidered for softwater lakes on the Boreal Shield.

406 Effects of Seasonal Temporal Variability of Salt Disturbance on Chironomus dilutus survival, emergence, and fecundity
S. Nutile, Pennsylvania State University / Biology; E. Dobry, Penn State Behrend / Biology; G. Schoeniger, Pennsylvania State University, Erie / Biology

Toxicity of road de-icing salts to freshwater aquatic invertebrates is well documented within the scientific literature. Exploration of various aspects of de-icing salt toxicity demonstrate an overall concern for freshwater salinization through runoff of salts during spring snowmelt. This is a confounding issue as salts must be used in northern climates to clear snow and ice from roadways to protect human safety, but such applications risk the integrity of natural systems. Many of the experiments evaluating de-icing salt toxicity, however, utilize static toxicity tests, which fail to encompass the nuances of salt exposure, especially in lotic ecosystems. During winter months, salts entering streams and rivers demonstrate pulsed increases in salinity, as snowmelt brings salt into the system. Conversely, during summer months, pulses of freshwater from rain events cause declines in salinity followed by steady increases as water is lost through evaporation. As such, exposed organisms in these systems must deal with a constant fluctuation in osmoregulatory costs, possibly leading to adverse, chronic effects. Therefore, evaluating toxicity of de-icing salts to freshwater invertebrates inhabiting lotic systems requires a modified approach. The objective of the current study was to evaluate the effects of pulsed exposures of de-icing salt, mimicking exposure during summer months with biweekly pulses of freshwater to exposure chambers, to two generations of Chironomus dilutus. Second instar C. dilutus were exposed to one of three salt treatments based on environmental monitoring data, with biweekly decreases in salt concentration through pulses with freshwater. Endpoints, including survival, emergence success, male to female ratio, and fecundity were evaluated, with offspring of the first test generation serving as test organisms for a repeated experiment using the same experimental design. No significant effects were observed in either the first or second test generation due to the pulsed salt exposure, suggesting environmental exposure patterns observed in local streams may not be harmful to native invertebrates. With novel experimental design and test protocols, more realistic evaluations of the threat caused by freshwater salinization to natural systems can be realized, allowing for development of more effective and credible solutions to the problems of road de-icing salts.
407 Broad-scale assessment of long-term stream chloride trends across Ontario, Canada
B. Mazumder, Ryerson University / Geography & Environmental Studies; G. Kaltenecker, Ontario Ministry of the Environment, Conservation and Parks; R. Sorichetti, Ministry of the Environment, Conservation and Parks / Surface and Groundwater; C. Wellen, C.J. Oswald, Ryerson University / Geography and Environmental Studies

Increasing chloride concentrations in streams due to urbanization is a growing concern today, with numerous detrimental effects on freshwater ecosystems, drinking water resources, and overall watershed health. Several studies have associated chloride with urban road salting practices, while others have reported possible long-term retention of chloride in both urban and rural watersheds. As chloride can follow complex pathways from source to stream, there is a need to assess the roles of different landscape characteristics and anthropogenic activities as drivers of these pathways. The goal of this study is to document long-term changes in stream chloride concentrations in watersheds that span latitudinal, physiographic and land cover gradients, in order to support future research on legacy impacts of chloride as well as inform management decisions that balance winter road safety and reduce salt inputs. Long-term chloride concentration trends assessed using the seasonal Mann-Kendall show both increasing and decreasing trends in provincially monitored sites in multiple regions across Ontario, Canada. These trends and their seasonal variations will be further explored to investigate potential landscape and anthropogenic drivers such as land use/land cover, roads and lane length density, soil type, and population.

408 Transepithelial Potential as a Predictor of Major Ion Toxicity in Fish
B. Po, University of British Columbia / Zoology; K. Brix, EcoTox / Marine Biology and Ecology; M. Grossel, University of Miami / Marine Biology and Ecology; M. McDonald, RSMAS, University of Miami / Marine Biology and Ecology; D.R. Mount, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division; W.J. Adams, Red Cap Consulting; C.M. Wood, University of British Columbia / Zoology

One of the stressors faced by freshwater ecosystems is salinization, for which there are no guidelines that rigorously address the contributions of different ions and their potential interactive effects, including sodium (Na+), potassium (K+), calcium (Ca2+), magnesium (Mg2+) cations paired with chloride (Cl⁻), sulphate (SO42⁻), and bicarbonate (HCO3-) or CO3-2 anions. These major ions elevated concentrations may, to different extents and in interactions, alter the balance of blood ions, acid-base status, and internal fluid volume regulation in freshwater animals in complex ways. To address this complexity, an ongoing modelling approach relates major ion toxicity to the predicted depolarization of transepithelial potential (TEP) across the gills, utilizing the Goldman-Hodgkin Katz (GHK) equation and assumed permeability ratios and internal concentrations to estimate TEP. However, at present there is a critical lack of data relating actual TEP changes to changes in major waterborne ion concentrations, to blood ions, and to mortality. Our research addresses this gap, and so estimate TEP. However, at present there is a critical lack of data relating actual TEP changes to changes in major waterborne ion concentrations, to blood ions, and to mortality. Our research addresses this gap.

409 The acute and subchronic toxicity of major geochemical ions to fathead minnow: Ion interactions and interspecies comparisons
R.J. Erickson, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division; D.R. Mount; B. Forsman, R. Hockett, C.T. Jenson, T.J. Norberg-King, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division

Adverse effects from increased concentrations of major geochemical ions (Na+, K+, Ca2+, Mg2+, Cl-, SO4²-, HCO3-/ CO3-2) to aquatic communities are evident in various locations. Experimental work has shown that the toxicity of ion mixtures to aquatic organisms is dependent on the specific mixture of ions present and on the receptor organism. Based on extensive testing of the acute toxicity of single salts and binary salt mixtures in various dilution waters to fathead minnow fry, the relationships of this toxicity to ion composition will be presented and contrasted with relationships for Ceriodaphnia dubia. For both species, key elements of these relationships include the importance of considering chemical speciation and activity, the existence of multiple mechanisms entailing both additive and independent interactions among ions, and effects of non-toxic levels of Ca on the toxicity of other ions. Differences between the species include a sulfate-dependent toxicity for minnows not evident for C. dubia, a better correlation of the toxicity of Na-dominated mixtures to Na activity for fathead minnow versus to total ions for C. dubia, and different interactions between Na and K. Ion toxicity to fathead minnow in early-life-stage and embryo-larval tests will be discussed and contrasted with the acute toxicity to fry. Consideration also will be given to the applicability of single salt toxicity tests to the more complex mixtures typical of major ion enrichment in surface waters. This abstract does not necessarily reflect U.S.EPA policy.

410 Integrating Laboratory Data on Major Ion Toxicity for Multiple Species into a Broader Assessment Approach
D.R. Mount, R.J. Erickson, B. Forsman, R. Hockett, C.T. Jenson, T.J. Norberg-King, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division

We have completed extensive acute toxicity testing of major ion toxicity to several freshwater organisms, along with more limited chronic toxicity testing. Comparison of analyses across species has shown both similarities and differences. For example, all species evaluated have shown additive toxicity among sodium salts, but for some species exposure response relationships are best represented by solution osmolarity, while for others sodium activity appears to better explain toxicity. For most species, ion mixtures whose cation composition is dominated by magnesium and/or calcium appear to show toxicity via a different mechanism than for those dominated by sodium, though the relative potency of these two mechanisms varies. With minor exceptions, responses are mostly independent of anion composition, except to the extent that anion composition influences the chemical activity of the cations and contributes to overall osmolarity. In all cases, chemical activity better explains toxicity than mass concentration, though less robust mass concentration-based models may be sufficient for most environmental assessments. We review these findings to identify key issues and potential paths forward for developing a broadly applicable assessment approach. This abstract does not necessarily reflect USEPA policy.

411 Conductivity dynamics in green stormwater infrastructure (GSI)
E. McKenzie, A. Behbahani, Temple University / Civil and Environmental Engineering; J. Caplan, S. Eisenman, Temple University / Landscape Architecture and Horticulture

Bioswales are a common infiltration-based stormwater management practices (SMPs), and are touted as one the most highly recommended green stormwater infrastructure (GSI) approaches to manage both water
quantity and quality. Salinization effects are investigated through variety of approaches including total dissolved solids, conductivity, and elemental concentrations (i.e., Na and Cl) in a variety of media including runoff, porewater, underlying groundwater, and plant tissue. Field monitoring results show that runoff, and to a lesser extent porous media porewater, exhibits a flashy saline response which is attributed to deicer salt application. However, soil conductivity values remain elevated farther into the spring indicated that some constituents (e.g., Na) are retained in the soil and may potentially impact plant growth. Sodium uptake and translocation into the plant is also demonstrates.

412 Habitat remediation strategies for mitigating salinity inputs to freshwater systems

K.R. Palmquist, Exponent / Ecological and Biological Sciences Practice; T. Sparacio, Exponent / Environmental & Earth Sciences Practice; W.L. Goodfellow, Exponent / Ecological and Biological Services Practice

Freshwater salinization of large watersheds may greatly affect the system's value for agricultural, water supply, industrial use, and recreational activities. The Colorado River Basin Salinity Control Forum was formed in 1974 to develop and implement salinity reduction projects throughout the basin, to provide agricultural improvements and rangeland projects, and to better manage industrial and wastewater contributions of salinity to the watershed. Habitat remediation strategies to mitigate salinity inputs can help resource managers improve irrigation and land-use protection and evaluate potential projects to understand cumulative benefits. Using case examples, this presentation will explore mitigation options, such as irrigation upgrades, ecosystem restoration, erosion control, and invasive species removal, which can be used for on-site or off-site projects. Remediation strategies incorporate a series of factors such as the determination of benefits and assessing the overall value of the identified mitigation projects, quantification of cumulative benefits, and comparison of normalized cost estimates across a suite of habitat remediation strategies.

Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring New And Novel Approaches - Part 1

413 High Losses and Crossover of Semi-Volatile and Hydrophobic Test Chemicals in In Vitro Assays Conducted in 96 Well Plates

H. Birch, DTU Environment / Department of Environmental Engineering; N. Kramer, Utrecht University / Institute for Risk Assessment Sciences; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

In vitro assays are normally conducted in plastic multi-well plates open to exchange with the ambient air. The concentration of test substances freely available to cells is often not known, can change over time, and is difficult to measure in the small volumes in microplates. However, even a well-characterized toxicological response is of limited value if it cannot be linked to a well-defined exposure level. The aim of this study was to develop and apply an approach for determining time resolved freely dissolved concentrations of semi-volatile and hydrophobic organic chemicals (SVHCs) in in vitro assays: (1) free fractions were measured by a new medium dilution method, and (2) time-resolved loss curves were obtained by measurements of total concentrations in 96-well plates during incubations at 37°C. Headspace solid-phase microextraction was used as an analytical technique for 24 model chemicals spanning 6 chemical groups and 4-5 orders of magnitude in Kow and Kaw. Free fractions were above 30% for chemicals with log Kow < 3.5 and then decreased with increasing log Kow. Medium concentrations declined significantly (>50%) within 24 hours of incubation for all 20 chemicals having log Kow > 4 or log Kaw > -3.5 in serum free medium. Losses of chemicals were lower for medium containing 10% fetal bovine serum, most significantly for chemicals with log Kow > 4. High crossover to neighboring wells was observed also below log Kow of 4 and log Kaw of -3.5. Sealing the well plates had limited effect on the losses, but clearly reduced crossover. The high losses and crossover of most tested chemicals question the suitability of multiwell plates for in vitro testing of SVHCs, and call for (1) test systems that minimize losses, (2) methods to control in vitro exposure, (3) analytical confirmation of exposure and (4) exposure control and confirmation being included in good in vitro reporting standards.

414 Advancing In Vitro Fish Cell Line Culturing Techniques for Routine Regulatory Ecotoxicity Testing

J. Scott, SLR Consulting / Integrative Biology; M. Minghetti, Oklahoma State University / Integrative Biology

In both regulatory whole effluent toxicity (WET) testing and chemical registration, in vivo fish assays compromise a large volume of species tested to measure and identify harmful environmental impacts. In vitro alternatives are an improvement from in vivo methods by allowing identification of a toxicant's mode of action, granting a high throughput approach with reduced test duration and costs, and importantly eliminating the need for live animals. Previous studies have shown that the fish gill cell line RTgill-W1 cultured as a monolayer respond to broad range of chemicals dissolved in water similarly to fish. However, this in vitro system presents some limitations such as the need to manipulate the exposure medium due to low osmotic stress tolerance, which can reduce bioavailability and toxicity of dissolved chemicals. To overcome this limitation RTgill-W1 cells can be cultured on transwells tolerating direct exposure to water samples, thus increasing chemical bioavailability for effluent and chemical toxicity testing. Culturing of RTgill-W1 on transwells facilitates the formation of a polarized epithelium which allows the measurement of key physiological processes such as epithelium permeability, trans-epithelial electrical resistance, and tight junction proteins. This study aims to characterize the responses of selected common and emerging chemicals of concern (metal, metalloid, nanomaterial, persistent organic pollutant, biocide, endocrine disruptor, pharmaceutical and personal care product) to cells cultured on transwells using a multiple viability endpoint analysis. Cells will then be exposed to non-toxic and toxic (EC20) doses of the selected chemicals and mRNA levels of Metallothionein, Vitellogenin, and Cytochrome P-450 1A gene expression will be measured. Additionally, selected real effluent samples will be exposed side by side using cells as a monolayer, and a polarized epithelium to compare sensitivity of the systems. Concluding we will confirm analytical analysis of the effluent sample (e.g. ICP-OES, GC-MS, and LC-MS) and evaluate if the cellular and molecular endpoint measured on RTgill-W1 can identify the toxic chemical in solution. Results from this study will determine if direct sample exposure to RTgill-W1 cells as a polarized epithelium is able to predict and identify toxicity of chemicals and effluents.

415 Liver dethroned!? The caudal fin as a non-lethal alternative to transcriptomics-based evaluation of oil spill effects in Pacific salmon

J. Imbery, E. Koide, University of Victoria / Biochemistry and Microbiology; C. Buday, Environment and Climate Change Canada / Pacific Environmental Science Centre; R.C. Miliano, D. Shang, Environment and Climate Change Canada / Pacific Environmental Science Center; J.M. Round, University of Victoria / Biochemistry and Microbiology; H. Kwok, Environment and Climate Change Canada / Pacific Environmental Science Centre; G. van Aggelen, Environment and Climate Change Canada / Pacific Environmental Science Center; C.C. Helbing, University of Victoria / Biochemistry & Microbiology

Rapid and sensitive tools for assessing environmental toxicity can be crucial to monitoring oil spill impacts and remediation efforts. Transcriptomic biomonitoring of sentinel animals can be a powerful method for tracking and evaluating the impact of environmental toxicants, however, current methods require animal sacrifice. We have previously demonstrated that the salmonid caudal fin, which can be rapidly sampled non-lethally, is a viable alternative to conventional liver tissue sampling. Our previous work using targeted qPCR revealed that cyp1a, a “classic"
hepatic indicator of polyaromatic hydrocarbon exposure, was significantly increased in the caudal fin after exposure to marine diesel demonstrating that this tissue is very sensitive to oil exposure. The purpose of the present work is to create a more comprehensive view of the transcriptome response in comparison to the liver and to identify additional biomarker candidates. Using RNA-Seq analysis, we show that the caudal fin more consistently responds to marine diesel exposure in a sex-dependent manner in comparison to the liver. We performed RNA-Seq on paired caudal fin and liver tissue from 20 genotypically-sexed male or female juvenile coho salmon following a 96 h exposure to either 1000 mg/L marine diesel seawater accommodated fraction (WAF) or seawater control. In the male and female caudal fin, marine diesel WAF exposure induced the differential expression of 620 and 501 transcripts respectively, consistently enriching cellular adhesion and morphogenesis pathways. Cell signaling pathways were uniquely enriched in males and metabolic, apoptotic, and embryonic pathways in females. Of the 176 and 352 transcripts differentially expressed in the male and female livers, some protein folding pathways were commonly enriched, with cellular localization and transport largely enriched in females and cellular metabolism in males. In the caudal fin, 36 marine diesel responsive transcripts were common in males and females, whereas, only 12 transcripts were common in the liver. These results show that the caudal fin exhibited a more consistent response between sexes than the liver tissue. Furthermore, the results indicate that the caudal fin is more sensitive to marine diesel WAF exposure than the conventional liver tissue. Taken together, sampling and transcript analysis of the caudal fin presents an exciting non-lethal alternative for assessing and monitoring oil spill effects.

416 Toward an AOP-based tiered testing strategy for thyroid hormone disruption

D. Knapek, E. Stinckens, University of Antwerp / Zebraslab / Dept Veterinary Sciences; L. Vergauwen, University of Antwerp / Zebraslab / Dept Veterinary Sciences & SPHERE Dept Biology; J.E. Cavallin, G.T. Ankley, US Environmental Protection Agency / Mid-Continent Ecology Division; H. Holbech, University of Southern Denmark / Biology; D.L. Villeneuve, US Environmental Protection Agency / Mid-Continent Ecology Division

Assessment of thyroid hormone disrupting chemicals (THDCs) is considered a major gap in current approaches for the testing of endocrine disrupting chemicals. The need to advance screening and testing strategies for THDCs includes the development of in silico and in vitro methods that anchor chemicals acting through a thyroid mechanism to adverse responses. The Adverse Outcome Pathway (AOP) framework is therefore particularly helpful for the identification of relevant assays and endpoints. Here, we demonstrate the use of in chemico assays targeting specific key events of an established AOP network to predict higher biological endpoints in fish early-life stages. Specifically, an AOP network linking thyroid hormone disruption to impaired swim bladder inflation was used to select assays measuring thyroperoxidase and deiodinase inhibition, key enzymes in the thyroid hormone metabolism. A set of 51 compounds was screened using these assays, and data were used to predict acute and chronic effects on swim bladder inflation. Predictions were validated using FET and FELS in vivo experiments in zebrafish and fathead minnow. A tiered testing strategy for the identification of THDCs was proposed based on these data. Our thyroid hormone disruption AOP network is part of the OECD AOP development programme workplan (project 1.35), and the associated assays align with the thyroid-related assays that are listed in the OECD Conceptual Framework for Testing and Assessment of Endocrine Disrupting Chemicals (revised 2018) as assays for which no formal guidance has been written at present. As part of their endocrine disruptor screening program, the USEPA included this work while assembling a conceptual thyroid hormone disruption AOP network spanning different taxonomic groups (fish, amphibians, mammals) to assist high throughput assay development. The ongoing JRC EURV ECVAM validation effort of in vitro assays for THDC screening is making use of this project’s data to ensure synergies and overlap. The AOP network is currently being used as one of the building blocks of a larger cross-species AOP network within the context of the H2020 ERGO project (“Breaking down the wall between human health and environmental testing of endocrine disrupters”), which aims to improve hazard assessment of endocrine disrupting compounds by demonstrating that it is feasible to extrapolate effects of EDCs across vertebrate classes, from fish and amphibians to humans.

417 Critical evaluation of the “gold standard” fish acute toxicity assay

K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability; B. Steele, Baylor University / Biomedical Studies; B.W. Brooks, Baylor University / Department of Environmental Science; J.M. Rawlings, Procter & Gamble Company / Environmental Stewardship and Sustainability; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship

Regulatory environmental toxicology relies on experimental results from a handful of standardized toxicity tests including the fish acute toxicity assay (e.g., OECD 203, EPA OPPTS 850.1075). Several alternative (AA) assays are currently being developed to replace the acute fish toxicity (AFT) assay including the fish embryo toxicity (FET) test, fish cell line test (FCT), as well as computational approaches. AA assays must be easily-transferred to new labs, statistically robust, reproducible, reliable, and “accurate.” That is, the replacement assay must produce the same result as the AFT (e.g., LC50). Implicit in this comparison is the assumption that the AFT is robust, reliable, and reproducible. Notably, the AFT has never undergone a rigorous validation process. The reliability and reproducibility of the AFT are largely unknown, and widely taken for granted during AA-validation exercises. In this presentation, we will summarize the barriers to regulatory acceptance of AA assays. The rigor of AA approaches will be contrasted to the AFT. We will also explore how the AFT as an assay would be interpreted, if evaluated using todays criteria for a regulatory-appropriate assay.

418 Quantifying Conservatism in ecoTTCs and Chemical Toxicity Distributions: Case Study of Chemicals with Regulatory Water Quality Values

A.C. Bejarano, Shell Health - Americas / Shell Health Risk Science Team; M.G. Barron, US Environmental Protection Agency / Gulf Ecology Division; K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability; M.R. Embry, Health and Environmental Sciences Institute (HESI); K.A. Fay, General Dynamics Information Technology / Office of Chemical Safety and Pollution Prevention

Ecological Thresholds for Toxicological Concern TTC (eco-TTCs) summarize a large array of species-level toxicity data as a probabilistic distribution of Predicted No-Observed Effect Concentrations (PNECs). These probability distributions enable the prediction of untested chemicals based on grouping via a structural attribute, mode of action, or functional use. The approach may be useful for assessing chemicals at early tiers of the risk assessment process, providing hazard perspective on chemicals that lack QSARs, guiding product development discussions, and assisting read across or category justifications. Because PNECs can be regionally based in their development, and apply different Application Factors (AFs), PNEC distributions are expected to vary by region. There may be situations where a researcher or assessor is interested in the toxicity distributions, without the added conservatism introduced by the assessment factors or the regional overtones of their application. A chemical toxicity distribution (CTD) can be used to perform this type of analysis. The purpose of this presentation is to share initial findings of a case study assessing conservatism in eco-TTC and CTD approaches. Aquatic toxicity-based water quality standards (e.g., Water Quality Criteria and Standards; Environmental Quality Standards) provide benchmarks for assessing the conservatism in ecoTTC and CTD approaches. Eco-TTC and CTD estimates were compared to existing criteria and screening benchmark values from regulatory jurisdictions for several groups of chemicals. Groupings were based on: 1) availability of aquatic criteria values from more than
one regulatory jurisdiction; 2) sufficient data to develop eco-TTC and CTD estimates; and 3) identified and articulated grouping criteria (e.g., common mode of action, chemical functional classes, and presence on priority lists). This presentation will provide an overview of the case studies, the approaches utilized, rationale for group selection, and a quantitative comparison of the degree of conservatism in ecolTC and CTD approaches. Guidance will be provided to new users of this tool to explore case studies and applications to chemical evaluation strategies.

419 Revisiting and Updating Chemical Categorizations with High-Throughput Screening Data

The views expressed in this abstract are solely those of the authors and do not represent the policies of the USEPA. Mention of trade names or commercial products should not be interpreted as an endorsement by the EPA. Chemical categorization, or grouping, is routinely employed by academia, industry and government agencies to capture and report salient chemistry and toxicity correlations as well as to identify analogs for chemicals that have limited empirical information. However, there is a continual need to modify chemical categories as new information on chemical hazards becomes available. This study incorporated new approach methodologies (NAMs) to evaluate whether potential refinements could be made to the 56 New Chemical Categories (NCC), as defined under the Toxic Substances Control Act (TSCA) and implemented in the OECD Quantitative Structure-Activity Relationship (QSAR) Toolbox profiler. Specifically, ToxCast and Tox21 high-throughput screening data and chemoinformatic techniques were used to evaluate potential refinements to the chemical categories. Chemical inventories from regulatory agencies of the United States and Canada were grouped into existing NCC and were found to have similar category coverage compared to the ToxCast and Tox21 inventories, suggesting biological information gleaned from these data may inform the current NCC classifications. Examination of the biological activities of the NAM data suggests some refinement of NCC may be needed, including derivation of phenolic ester and phenolic aliphatic amine classes that are currently grouped as multicategories within the NCC definition. This approach also identified data gaps in the NAM inventory and potential analogs for chemicals that may fit the suggested new categories, such as octyl gallate (phenolic ester). Further, hierarchical clustering of ToxPrint chemotypes present in chemicals within the neutral organic NCC category also provided data to support potential subcategorization and class refinement.

420 Toxicity by Descent: A Modern Chemical Hazard Assessment Framework
J. Colbourne, University of Birmingham / University of Birmingham Enterprise; C. Rivetti, Unilever / Safety and Environmental Assurance Centre SEAC; E. Sostare, Michabo Health Science / University of Birmingham Enterprise; B. Campos, Unilever / Safety and Environmental Assurance Centre SEAC; R. Barnett, Michabo Health Science / University of Birmingham Enterprise; D. Hirman, European Chemicals Agency; J. Shaw, Indiana University / O’Neill School of Public and Environmental Affairs; M.R. Viant, University of Birmingham / University of Birmingham Enterprise; T. Sobanski, European Chemical Agency; G. Hodges, Unilever / Safety and Environmental Assurance Centre SEAC

Predicting both human health and ecological hazards for industrial chemicals is extremely challenging, in part because investigations on how chemicals perturb biological processes producing harm historically relies on different animals on which toxicity can be most conveniently studied. This dilemma regrettably has created an unnatural divide in the scientific pursuit at understanding the exposure limits of humans, and the permissible levels of contaminants in the environment, for many thousands of synthetic compounds. This division has been manifested by a reliance on mice and rats as human surrogates (by virtue of our shared mammalian biology) and by a reliance on a fish, a cladoceran zooplankton and an algal species (an aquatic food chain) as sentinels for setting regulatory limits to protect human or environmental health. Yet discoveries made within the past 15 years in studies of animal genomes point to a significant number of conserved genes and their functional associations for growth, maintenance and reproduction. Here, evidence is given on the feasibility of classifying chemicals in the near future for their harmful effects on people, based on gene expression monitoring using distantly related and environmentally relevant model test species. This method aligns human- and eco-toxicology towards a more general understanding of how exposure to pollutants disrupts biological processes that otherwise ensure animal (including human) health. We conclude with a method that determines the likelihood that existing biomarkers that are specific to human pathways are indicative of exposure-related health outcomes using distantly related test species with examples using the waterflea Daphnia.

Fate, Effects, Mitigation and Monitoring of Oil and Oilfield Wastewater Spills in Freshwater Ecosystems - Part 1

421 The impact of photo-oxidation on the chemistry of hydraulic fracturing flowback and produced water
X. Wang, L. Hounjet, R. Gieleciak, C. Lay, Natural Resources Canada

Hydraulic fracturing is a technique where water is pumped into wells under high pressure to increase oil and gas production by fracturing low permeability geologic formations, such as shale, tight sands, coal-beds, and other gas or oil-bearing strata. The fracturing fluids consist primarily of water (90%) mixed with some sand (9.5%) and a small proportion of other chemicals (0.5%). Information provided to the “FracFocus” website (https://fracfocus.org/) by hydraulic fracturing operators has increased public awareness of the chemicals used for hydraulic fracturing. If accidentally spilled, these chemicals could migrate from well pads to groundwater or surface water. In addition, it is possible that chemicals could leak into an aquifer if a wellbore is breached, even given the many layers of protective casing. Furthermore, temporary in-ground storage near the well pads could also increase the risk for chemical leak due to potential lining failure. All the above processes are potential pathways for chemicals used by hydraulic fracturing to enter the environment. In order to predict the environmental fate of hydraulic fracturing chemicals, environmental studies and modeling have to be conducted. In addition, potential treatment strategies have to be screened to target hydraulic fracturing chemicals. In Alberta, the current practice for recycling hydraulic fracturing flowback and produced water is to inject the water after temporary in-ground storage. If or when the water chemistry is such that the water can no longer be used for recycle, it is transported for disposal downhole in deep wells. During the temporary on-site storage process, the water chemistry may change due to photo-degradation or biodegradation, which may affect the water use for extraction and production. In addition, the degradation by-products may be more toxic than the original compounds and become a new source of potential environmental contaminants. In this study, the photo-degradation of chemicals contained within hydraulic fracturing flowback and produced waters is examined. Results of detailed chemical analyses of water samples before and after irradiation are compared. These results shed light on the dynamics of hydraulic fracturing flowback water and produced water chemistry during its temporary on-site storage.
Although A. Weinrauch, E. Folkerts, T. Blewett, G. Goss, University of Alberta / produced water over time following exposure to hydraulic fracturing flowback and of evaluating multiple exposure regimes, but perhaps more importantly driver in chronic toxicity. The findings of this study show the importance acute results. Causality in acute and chronic bioassays differed as acute a significant amount of latent mortality occurring when compared to the chronic toxicity of FPW in this species was more pronounced with acute toxicity was significant at low dilutions of FPW (48h LC50: 4-5%). FPW exposures. Bioassays and pulse toxicity were evaluated to better understand the implications of FPW releases. Bioassays used FPW acquired from a local well in Alberta. Although L. variegatus have a high tolerance to aquatic contamination, acute toxicity was significant at low dilutions of FPW (48h LC50: 4-5%). Chronic toxicity of FPW in this species was more pronounced with LC50s (survival/reproduction) and EC50s (total mass) as low as 0.53% FPW. Investigations evaluating pulse toxicity (6h and 48h) also showed a significant amount of latent mortality occurring when compared to the acute results. Causality in acute and chronic bioassays differed as acute toxicity appeared to be driven mainly by salinity but was not the sole driver in chronic toxicity. The findings of this study show the importance of evaluating multiple exposure regimes, but perhaps more importantly the complexity of FPW.

423 Rainbow trout hepatocyte metabolism is differentially altered over time following exposure to hydraulic fracturing flowback and produced water

A. Weinrauch, E. Folkerts, T. Blewett, G. Goss, University of Alberta / Biological Sciences

Hydraulic fracturing is a widespread practice utilized in North America to extract oil and natural gas from shale reserves. The wastewater produced as a result of this practice is termed flowback and produced water (FPW). The aim of this study was to determine if acute FPW exposure impacts the hepatic metabolism of rainbow trout at either 48 h or 3 weeks following exposure. We hypothesized that FPW exposure would alter nutrient metabolism as the liver would be performing the metabolically demanding role of detoxification. Using isolated hepatocytes, the uptake properties of radiolabeled glucose and alanine were assessed following exposure to 2.5% and 7.5% FPW, with concurrent salt-matched controls also performed. Exposure to FPW led to step-wise increases in hepatic glucose uptake, but had no effect on alanine acquisition. The activity of key enzymes involved in glucose and amino acid metabolism were also assessed following exposure. Amino acid metabolism decreased 48 hours following exposure and was further reduced after 3 weeks. Although FPW exposure did not always elicit immediate effects on glucose metabolism, by 3 weeks there is an overall trend of reducing glycolysis and promoting hepatic glucose mobilization. Overall, these results indicate sustained impacts on hepatic metabolism following acute FPW exposure.

424 Alkylated Polycyclic Aromatic Hydrocarbons Understanding Fate and Persistence in Aquatic Systems following a Condensate Release - a Case Study

L. Mooney, Millennium EMS Solutions, Ltd.

As hydrocarbon mixtures weather, alkylated homologs of parent polycyclic aromatic hydrocarbons (PAH) comprise a greater proportion of the mixture. Little toxicology information for many of these homologs is available. Adverse effects from alkylated forms are documented for aquatic receptors; however, within mixtures the specific contribution of alkylated forms to noted adverse effects is uncertain and the ability of risk assessors to appropriately evaluate risk from these compounds is limited. This case study presents multi-year sediment data following a condensate release into a creek system in northern Alberta. Alkylated homologs persist relative to parent compounds and are mobile, aggregating in depositional areas. Invertebrate tissue analysis reveals a biocumulation of alkylated homologs, when parent PAH are not significantly higher than reference. Despite this, the density and composition of the invertebrate community in exposed erosional areas is not statistically different from reference areas. Fish are documented to transform and eliminate alkylated PAH and one of the documented toxicity endpoints from prolonged exposure is tumor development. Applied endpoints in an ecological risk assessment generally include population-level effects, and tumor development is not generally considered. Risk assessors are then left applying toxicity surrogates and relying on sediment chemistry trending for management decisions related to alkylated-PAH.

425 Chemical and toxicological assessment of water quality downstream of oil and gas produced water discharge

M. McLaughlin, J. Blotvogel, Colorado State University / Civil and Environmental Engineering; B. McDevitt, Pennsylvania State University / Civil and Environmental Engineering; L. Argueso, Colorado State University / Environmental and Radiological Health Sciences; N. Warner, Pennsylvania State University / Civil and Environmental Engineering; T. Borch, Colorado State University / Department of Chemistry

Produced water (PW) is the largest waste stream associated with oil and gas extraction. This fluid contains hydrocarbons, salts, metals, radioactive materials and any remaining chemical additives. In the United States, west of the 98th meridian, the National Pollutant Discharge Elimination System exemption allows for release of PW to surface waters for agricultural beneficial reuse. Due to the complex and variable composition of PW, the downstream impacts of these releases are not fully understood. In this study, a detailed chemical and toxicological analysis was conducted on a PW stream released for agricultural beneficial reuse. Acute toxicity, mutagenicity and developmental toxicity were analyzed using daphnia magna, yeast and zebrafish, respectively. Over 50 geogenic and anthropogenic organic chemicals that were not specified in the effluent limits were detected at the discharge including 1,2-dichloroethane (0.5 µL/L), naphthalene (8-13 µL/L), and nonylphenol ethoxylates (~8-12 µL/L). Most organic chemicals were removed within 15 km of the discharge due to volatilization, biodegradation, and sorption. Inorganics measured at the discharge were all within regulatory effluent limits, though some, such as barium, exceeded chronic water quality criteria. While some inorganics decreased with distance (barium, strontium and radium), the majority increased in concentration downstream (chloride, sulfate, etc.), likely due to evaporation. This resulted in some, including lead, exceeding regulatory limits downstream. The yeast strain used in this study was engineered to measure four types of mutation including copy number variation (CNV) duplication, CNV deletion, forward point mutation and reverse point mutation. In all four assays, higher mutation rates were observed at the discharge and decreased with distance downstream. This was most prominent for CNV duplications. A similar trend was observed for carcinogens detected in the stream (e.g., benzene, naphthalene, radium). Increased rates of CNV deletion, forward point mutation and reverse point mutation were attributed to salts and carcinogenic organic compounds. Acute toxicity was minimal, and no developmental toxicity was observed. Regulatory health thresholds for most chemical species detected at the discharge do not exist. This study showed that chemical analysis alone is insufficient for analysis of PW releases and that an assessment of chronic toxicity is necessary to fully assess PW for beneficial reuse.

426 Environmental influences on phenanthrene accumulation and toxicity from hydraulic flowback and produced water in rainbow trout

T. Blewett, G. Goss, University of Alberta / Biological Sciences

Spills of hydraulic flowback and produced water (HFPW) can be devastating to the freshwater environment. These effluents are extremely complex mixtures, high in salts (Na, Ca, Cl, K, Mg), metals (e.g. nickel, lead) and organics (e.g. polycyclic aromatic hydrocarbons; PAHs). Environmental
influences such as temperature can greatly alter the bioaccumulation and toxicity of organics in HFPW, and subsequently, toxicity. Using a radiotracer-based approach, we examined the effect of temperature (4, 13 and 17°C) and salinity on the uptake kinetics of 14C-phenanthrene as a model HFPW PAH in the freshwater rainbow trout. Total phenanthrene accumulation was temperature-dependent, with 4-fold greater accumulation in 17°C temperatures. However, when co-exposed with HFPW, phenanthrene accumulation dropped from 2.0 (mg/g wet wt. - to 0.2ng/g wet wt). Regardless of temperature, the lowest accumulation always occurred in the HFFPW mixtures. Indicating that the presence of HFPW altered the bioavailability of these complex chemical mixtures. Temperature also altered the tissue-specific distribution of phenanthrenes (highest accumulation in the liver), while changes in uptake patterns with salinity were also noted and attributed to altered gill function (reduced oxidative stress capacity) and morphology (e.g. osmotic stress - histology showed a 6-fold reduction in gill area compared to control fish). Our data suggest that the impacts of HFPW will depend on prevailing environmental conditions at spill sites which will affect the fate of these chemicals, but that these impacts may be able to be predicted through models that account for salinity and temperature.

427 Determination of pathways and potential effects of oil and gas activities on ecological receptors

The U.S. Geological Survey has an integrated team studying historic and current oil and gas (OG) activities on landscapes. Our interdisciplinary team works with organizations inside and outside of government to distinguish perceived vs. actual risks from OG development to organisms. We are focused on three interdisciplinary science objectives: 1) Source mobility and toxicity risks; 2) Exposure pathways and risks to receptors; and 3) Resilience/restoration of environment. To address these objectives, we have conducted numerous laboratory and field studies across the United States, including in North Dakota (ND) where extensive historic and current OG activities provide opportunities to study potential effects from legacy spills and recent releases of wastewater. Studies in ND include determinations of chemical constituent pathways and effects on biota following a 2014 release of OG wastewater to Blacktail Creek, ND. A barium and strontium signal associated with OG wastewater persisted at an experimental site downstream from the spill where an in situ fish bioassay demonstrated increased mortalities 6 months following the reported spill. Toxicity was not observed in later years and the barium and strontium signals, though still existing, were diminished. Additional investigations of ammonia levels in the stream suggested the variable nature of river flow in this watershed contributes to the variability of continued OG wastewater influence on the surface water quality. Laboratory bioassays with reconstituted waters mimicking the ionic composition of a site 1 month after the spill indicated that elevated major ions alone could adversely affect fish and aquatic invertebrates. Investigations of legacy spills included mapping of potentially contaminated sites; toxicity bioassays with aquatic plant, invertebrate, and amphibian; and amphibian surveys. Laboratory studies documented reduced amphibian survival in sediments with elevated salt content, and surveys identified invertebrate diversity and amphibian abundance were sensitive responses to elevated salt content. Changes to wastewater disposal practices instituted after 1982 had a positive influence on water quality and amphibian abundance. OG wastewater plume studies indicate decades to centuries are needed for attenuation of salts affecting wetland systems. These studies highlight how interdisciplinary science provides information about source mobility, pathways, and potential effects of OG wastewater.

428 Can the toxicity of oil sands process-affected water be mitigated by a green photocatalytic method?

B.N. Madison, Queens University / Chemistry and Chemical Engineering; J. Reynolds, Queen’s University / Biology; L. Hallwell, Queen’s University / School of Environmental Studies; T. Leshuk, F. Gu, University of Waterloo / Chemical Engineering, Institute for Nanotechnology; K.M. Peru, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; J.V. Headley, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; D.M. Orihel, Queens University / Department of Biology/School of Environmental Studies

Naphthenic acids (NAs) are common toxic components of oil sands process affected water (OSPW) that reach concentrations in tailings ponds known to be lethal to aquatic animals. The mitigation of NA toxicity is imperative to OSPW management, but storage in interim tailings ponds pose risk of release into the environment and existing detoxification treatment options are limited. Here we examined the ability of a novel advanced oxidative method, UV photocatalysis over titanium dioxide- (TiO2) coated buoyant microparticles, to reduce the toxicity of NA-fraction components (NAFCs) from OSPW to developing fathead minnows (FHM). Experiments were performed using dilutions of NAFCs extracted from OSPW to assess the toxicity of water solutions treated with this method to developing and larval FHM in a controlled laboratory experiment and an outdoor, semi-natural setting. Increased treatment intensity (i.e., duration of photocatalysis) resulted in the greater removal of acid-extractable organic (AEO) compounds in exposure waters. Treatment to 50% AEO degraded (< 20 mg/L) reduced mortality, but the frequency of cardiovascular abnormalities remained elevated in treatments with more than 90% AEO degraded (3 mg/L). Incomplete degradation of AEOs (e.g., 25% AEO degraded, 20-25 mg/L) increased malformation frequency in fish in a manner typically associated with chronic toxicity during development. This study provides the novel assessment of green technology to address a large-scale environmental and ecotoxicological problem in Canada’s oil sands region.

Fate and Effects of Metals: Mechanistic Knowledge of Metal Interactions With Aquatic Biota - Part 1

429 Rare Earth Element Solubility and Speciation: Impacts on Bioavailability

S.D. Smith, S. Brennan, W. Chen, A. Carvajal, Wilfrid Laurier University / Department of Chemistry and Biochemistry; J. McGeer, Wilfrid Laurier University / Biology

In recent years there has been an increased interest in mining of Rare Earth Elements (REEs) in Northern Canada. As the result of this potential development, the release of these metals into the environment poses a potential threat to the health of aquatic ecosystems. However, the speciation information needed for the development of toxicity prediction models for these metals is limited. The main purpose of this project is to understand REE solubility and interactions with dissolved organic matter (DOM). To this end solubility and DOM binding tests were conducted with both a representative light REE (samarium) and a heavy REE.
The solubility of these elements in clean water solutions of variable carbonate concentrations (atmospheric, 1 mM and 10 mM) and pH (6, 7, 8, 9) was monitored for 120 hours. It was found that for the most insoluble systems (i.e., high pH, high carbonate and high total metal) agreed well with equilibrium model predictions (PHREEQC), but for more neutral pH and lower metal concentration, the observed solubility was up to a factor of 4 higher than predicted by the equilibrium model. Fluorescence quenching and REE ion-selective electrodes were used to measurements metal-DOM binding constants and quantify binding sites on DOM. These binding assays demonstrate that existing databases for REE binding actually overpredict complexation at low, environmentally relevant, levels of metal and revisions are required. A conditional solubility/binding model for short exposure times will be presented, and existing toxicity data reinterpreted in context with this model. DOM is known to be a toxicity modifying factor for lanthanides and a detailed understanding of lanthanide speciation in the presence of DOM will eventually facilitate the development of quantitative bioavailability-based models to help manage the impacts of potential lanthanide mining operations in Northern Canada.

430 The issue of REE solubility in determining toxicity thresholds
C. Rickwood, Natural Resources Canada; J. Baker, Nautilus Environmental; J.R. Elphick, Nautilus Environmental Company, Inc.

In recent years, a steady, reliable, and secure supply of critical metals has become increasingly important to major industrialized economies that seek to sustain their industrial base and develop advanced technologies, such as clean energy. In light of this, Canada, with its significant critical metal reserves, has an opportunity to supply some of the global demand for critical metals. However, the present knowledge of potential eco-toxicological effects of REEs is limited, specifically chronic toxicity data are under-represented, which poses a challenge to risk assessors and regulators when trying to understand the potential environmental effects of REEs in freshwater systems. For the past four years, NRCan has developed and funded research to understand the chronic toxicity of four priority lanthanides: Lanthanum (La), Cerium (Ce), Neodymium (Nd) and Yttrium (Y). Species tested include various fish species as well as numerous invertebrate organisms. However, one of the main issues identified during these tests has been the rapid decrease in solubility of the four REEs, ranging in a loss of 30-90% over the course of a 24hr period. To this end, it has posed a challenge to determine an accurate toxicity measure (i.e. EC50, IC10) due to the uncertainty over the rapidly changing exposure concentrations. This presentation will discuss the various factors that could be contributing to this change in solubility and offer a comparison of methods that could be used in determining a relevant toxicity value (i.e. IC10, EC50) with the hopes of providing regulators and risk assessors with approaches to better estimate the toxicity of these REEs.

431 Integrated ecotoxicological assessment of Rare Earth mixtures in freshwater bivalve
N. Lachaux, LIÉC / CNRS UMR 7360; A. Chatel, Catholic University of the West / UBL, Mer Molécules Santé; S. Devin, University of Lorraine / LIÉC, CNRS UMR 7360; J.E. Groenenberg, Wageningen University / Sustainable Soil Management; A. Gutleb, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation ERIN; C. Mounyecr, Catholic University of the West / UBL, Mer Molécules Santé; A. Otero-Farina, University of Lorraine; S. Pain-Devin, University of Lorraine / LIÉC, CNRS UMR 7360; L. Poirier, A. Zalouk-Vergnoux, Université de Nantes / Mer Molécules Santé MMS; E.M. Gross, University of Lorraine / Laboratoire Interdisciplinaire des Ecosystèmes Continentaux; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIÉC, CNRS

Rare Earth Elements (REE) are essential in high-technology products including technology for the transition to sustainable energy and numerous industrial, medical, military applications. Consequently, REE are considered technological critical elements subject to geopolitical issues. For about twenty years, their increasing extraction, processing and use led to their release in the environment including aquatic systems. However, nowadays, little is known about the ecotoxicology of REE particularly in complex natural systems. Moreover, most of the available data concerning REE toxicity is focused on single elements, whereas they are commonly found as a group in nature. REEs are expected to have cumulative toxic effects on organisms, owing to their similar physicochemical properties, but studies on their mixture toxicity, more representative of realistic scenarios, are necessary to uphold this assumption. In this context, the ECOTREE international research program aims to understand better the fate, behaviour and the potential biological effects of REEs on freshwater ecosystems and, particularly in this presentation, on Asian clam, Corbicula fluminea. The bivalves were exposed during one week to 3 REEs representative of the lanthanide series: neodymium, gadolinium and ytterbium alone and in mixture in absence and presence of Dissolved Organic Matter (DOM: 8 mg/L of dissolved organic carbon including 6.8 mg/L of fulvic acid) to assess the influence of DOM on REE toxicity. Main physicochemical properties of the exposure media were characterized in order to study further REE speciation, bioavailability using chemical equilibrium models including ion-binding models for OM. Both, total REE bioaccumulation and subcellular compartmentalization were measured by ICP-MS in gills and digestive glands. Additionally, toxicity responses of bivalves were evaluated using a multi-marker approach at different levels of the biological organization. For the physiological assessment, 12 biomarkers of general stress or metal-specific, involved in antioxidant (i.e. superoxide dismutase, catalase) and antioxidant (acid phosphatase) functions, metal (metallothioneins, hemolymphatic calcium) and energetic metabolisms (i.e. triglycerides) or cell damages (i.e. lipid peroxidation, apoptosis) were measured by automated spectrophotometer and polarography and expressed with multivariate analysis. Exposure experiments were conducted on May 2019 and related analysis are still in progress.

432 Bioavailability of Technology Critical Elements to Aquatic Biota in Freshwater
J. McGeer, Wilfrid Laurier University / Biology; R. Shah, T. Azzano, Wilfrid Laurier University; S.D. Smith, Wilfrid Laurier University / Department of Chemistry and Biochemistry

The growing use of rare earth elements and other technology critical element such as In, Ge and Ga in personal electronic devices, green technologies and medical applications results in a developing concern for impacts in aquatic environments. However, there are no water quality guidelines/criteria for TCEs and few studies available. The objective of this research is to contribute data towards the establishment of assessment tools for the effects of TCEs. We have studied the toxicity of Ce, Sm, Dy, Tm, In, Ge and Ga to sensitive invertebrates (Hyalella azteca and Daphnia). The toxicity modifying influences of cationic competition (Ca, Mg and Na) and dissolved organic matter (DOM) were assessed. With some exceptions, for example Ge, Ca and DOM provide protection against toxicity. The protection that DOM provided for Ge toxicity was minimal. In chronic Dy toxicity studies with Hyalella both Ca addition and DOM addition provided protection and EC50 values for growth over 28 d increased from 1.0 uM (95% CI of 0.83-1.35) in moderately hard culture medium to 2.7 uM (2.4-2.9) with the addition of 1.5 mM Ca uM and to 5.6 uM (5.1-6.0) when 6 mg DOC/L was added to test solutions. These effects were linked to significant accumulation of Dy but there was no correlation between impacts and accumulation. In chronic tests with Tm DOM provided protection against Tm and stimulated growth at low Tm concentrations. A 3 fold increase in Ca levels did not offer protection against Tm but reducing Ca by 50% (to 0.25 mM) resulted in higher toxicity. This may be due to the physiological stress of low Ca on the Hyalella rather than an effect related to competition. Incorporation of effects into toxicity prediction models was inhibited by a lack of understanding of solution geochemistry. Funded by NSERC and Environment Canada via a Strategic Grant.
Lanthanides (LNs) have become an essential commodity in many high-and green-technology applications such as smartphones, computers, wind turbines, electric vehicles. Their increasing economical importance has drawn attention to the limited knowledge about their ecotoxicology. As ecotoxicological studies become available, difficulties in properly appreciating effects of LNs using standardized procedures have emerged, including challenges in maintaining stable exposure concentrations in standardized laboratory conditions and in relating laboratory findings to actual field situations. In the present study, the ecotoxicity of the whole lanthanide series to *Daphnia magna* was tested along with a characterization of the stability of exposure concentrations obtained by measurements of total ($t=0$ and 48h) and total filterable ($<0.45\mu m$) concentrations. For selected elements (Nd, Gd and Yb), exposures were performed in absence and presence of dissolved organic matter (DOM ; 8 mg L-1 including 6.8 mg L-1 of fulvic acid) to assess the effect of this important environmental variable on both the ecotoxicity to daphnids and the stability of exposure concentrations in the test medium. In the absence of organic matter, the decrease in filterable LNs concentrations ranged from 10% to > 95% over 48 hours and showed an inverse relationship with atomic mass suggesting that, as a minimum, EC50 must be corrected to take into account such decrease. The addition of organic matter decreased the ecotoxicity of Nd and Gd, probably by formation of non-bioavailable complexes. On the contrary, addition of organic matter did not significantly affect the effects of Yb.

Due to their distinct physicochemical properties, rare earth elements (REEs) are critical to high-tech and clean energy industries. In nature, they are likely to occur as mixtures and thus most exposures will be for multiple REE simultaneously. Furthermore, since most of the REEs occur as trivalent cations, it is reasonable to hypothesize that they will not be taken up via the same membrane transport proteins as the mono- and divalent metals. Thus, it is not clear to what extent the presence of hardness metals (Ca, Mg) or other REE will affect metal bioavailability or effects. In this paper, we have carefully examined the bioavailability of several REEs for the freshwater alga, *Chlamydomonas reinhardtii*. Biouptake experiments generally showed strictly competitive interactions, i.e., a predictable reduction of the bioaccumulation of a first metal when in the presence of a second metal. Furthermore, these experiments suggested that the REE used a similar uptake pathway, with fairly similar affinity constants. In contrast, following the exposure of *C. reinhardtii* to REEs of interest, we performed on *C. reinhardtii* and *N. palea*. Results show that the role of the silica frustule surrounding the cell membrane will be investigated as a potential explanation for the difference in HA impact on PGEs uptake and toxicity compared to green algae. These results appear to be in conflict with the biotic ligand model, demonstrating the importance to continue such studies in order to better predict bioavailability of metals in presence of complex ligands such as NOM. Also it raises the issue of the impact of platinum on microalgae in realistic environmental conditions (with ubiquitous NOM), primary producers being of great ecological importance.
Concentrations and Thresholds for Effects of Current Use Pesticides in Aquatic and Terrestrial Ecosystems - Part 1

437 An ecological assessment of the effects of fipronil and degradates on US streams

The U.S. Geological Survey performed chemical and ecological surveys at 442 wadable streams in regions of the U.S. during 2013-17. Field sampling included as many as 14 weekly water samples for analysis of 225 pesticide compounds, followed by a survey of ecological communities. The insecticide fipronil and its degradates were detected in 19% of water samples nationally but in 53% of samples in the Southeast region. To refine ecologically relevant benchmarks for fipronil compounds used in risk assessments, we conducted a 30-day mesocosm experiment. Natural stream invertebrate communities were transplanted into 36 experimental streams under laboratory control. Treatments included 6 controls and 6 un-replicated concentrations of each fipronil compound: fipronil, fipronil amide, desulfinylfipronil, fipronil sulfone, and fipronil sulfide. Nominal exposure concentrations were 3-1563 ng/L (fipronil and amide) and 1-31,256 ng/L (desulfinyl, sulfone, and sulfide). Effect concentrations eliciting a 50% response (decline in abundance, EC50) were developed for as many as 15 taxa response signatures for each compound. The EC50s were combined with aquatic toxicity values from the EPA ECOTOX database to develop Species Sensitivity Distributions. Hazard concentrations for the 5th percentile of adverse effects on stream organisms (HC5) were derived for each compound using maximum likelihood methods and a parametric bootstrap technique. Resulting HC5s were: 1.7 ng/L for sulfone, 4.5 for sulfide, 5.1 for fipronil. No HC5 was calculated for the fipronil amide, which caused little toxicity to insect larvae in the mesocosm experiment. Values of HC5 were used to normalize fipronil compound concentrations in field samples to toxic units (TU), and the median TU was calculated for each site. The median TU was >0.1 in 30% of streams and >1.0 in 17% of streams. Based on a regionally specific measure of invertebrate ecological condition (invertebrate multi-metric index [MMI]), 168 streams were rated to have “Poor” ecological condition (38% of all streams sampled); 40% of these Poor streams also had a TU >= 1.0 for fipronil compounds. The highest number of streams with Poor ecological condition were in the Southeast region. These results suggest that fipronil compounds could be degrading the ecological integrity of streams throughout the U.S., and effects are heightened in the Southeast region where fipronil compound use is higher than in other regions.

438 The facts about fungicides: exposure, effects and risk using monitoring data from around the globe

K.L. Smalling, US Geological Survey / NJ Water Science Center; J.P. Zubrod, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, University of Koblenz-Landau / Institute for Environmental Sciences; G. Arts, Wageningen Environmental Research - WUR / Environmental Risk Assessment; C. Bruehl, University of Koblenz-Landau / Institute for Environmental Sciences; G. IMFELD, University of Strasbourg - LHyGeS; A. Knäbel, University of Koblenz-Landau / Institute for Environmental Sciences; S. Payraud, Laboratoire d’Hydrologie et de Géochimie de Strasbourg (LHyGeS), Université de Strasbourg/ENGEES; J. Rasmussen, Aarhus University / Bioscience; J.R. Rohr, University of Notre Dame / Department of Biological Sciences; A. Scharmüller, S. Stehle, R. Schulz, R. Schaefer, University Koblenz-Landau / Institute for Environmental Sciences

Fungicides are increasingly used in conventional agriculture to ensure global food security and their use is forecasted to intensify under changing climatic conditions and the proliferation of invasive fungi. The intensity of fungicide use varies both regionally and with the target crop. Fungicides can reach aquatic ecosystems and can occur in surface waters in agricultural catchments throughout the entire growing season due to their frequent, prophylactic application. Despite the intensive use of fungicides and the potential ecotoxicological risks to aquatic organisms, the exposure, fate and effects of fungicides have received less attention compared to herbicides and insecticides. To document the extent of exposure, the direct and indirect effects of a variety of fungicides and the potential risks to aquatic organisms, we conducted a detailed literature review of monitoring data from 5 continents. Our analysis showed that fungicides occur widely in aquatic systems, that the accuracy of predicted environmental concentrations is debatable, and that fungicide exposure can be effectively mitigated. We additionally demonstrated that fungicides can be highly toxic to a broad range of organisms not typically prioritized in current risk assessments of herbicides and insecticides. Finally, we outlined central research gaps that challenge our ability to predict fungicide exposure and effects, promising research avenues, and shortcomings of the current environmental risk assessment for fungicides.

439 Large-scale evaluations of pesticide concentrations in surface waters

R. Schulz, S. Bub, L.L. Petschick, S. Stehle, J. Wolfram, University of Koblenz-Landau / iES, Institute for Environmental Sciences

Pesticides are regularly detected in surface waters worldwide. Despite numerous local monitoring studies, our cumulative knowledge on both exposure in large parts of global agriculture and factors driving aquatic pesticide concentrations is still sparse. Transient exposure profiles at low, yet environmentally-relevant concentrations, for instance for some insecticides, provide additional challenges in obtaining data suitable for thorough assessments. Studies evaluating pesticide data at larger spatial or temporal scales only appeared over the last few years. Comparisons of field concentrations with regulatory threshold levels provide ample opportunity to evaluate pesticide monitoring data. Meta-analytical approaches can help to contextualise findings e.g. with type of pesticide, use-data, sampling procedures, site characteristics, and environmental regulations. Those few studies focusing on global or continental data e.g. from Europe or the U.S. will be synthesized. Results show that detected pesticide concentrations often exceed regulatory threshold levels suggesting that pesticide regulations often fail to protect agricultural surface waters. Amongst others, shortcomings in predictive modeling applied during regulatory exposure assessment contribute to these failures. Provided that surface waters are facing the strongest biodiversity declines, and water security threats are a global phenomenon, we need to rethink the use and management of pesticides in agriculture.
440 Meta-Analysis of insecticide risks and their drivers for surface waters in the United States

J. Wolfram, R. Schulz, S. Stehle, L.L. Petchick, S. Bub, University of Koblenz-Landau / Institute for Environmental Sciences

Pesticide contamination of nontarget aquatic ecosystems via agricultural nonpoint sources is an issue globally, as well as in the United States. Especially insecticides, due to their high toxicity, can adversely affect surface water integrity, thus, comprehensive assessments of their potential ecological implications are necessary on large spatial scales. To address this challenge and to provide an additional line of evidence for risk managers, a literature synthesis and meta-analysis (1962 - 2017) of 259 peer-reviewed publications was conducted, detailing the occurrence and associated risks of insecticides and their degradates (n = 38) in United States surface waters. Measured insecticide concentrations (MIC) obtained via this procedure (n = 5830) were compared to regulatory threshold levels (RTL) to investigate, (i), overall and substance-specific risks in combination with potential future use trends, and (ii), spatio-temporal factors driving these risks, which were subsequently used for a national risk model. MICs were found to regularly exceed their RTL in both the water and sediment phase (48%, n = 5830) and more frequently thresholds, above which adverse effects for regional biodiversity can occur, questioning if current pesticide risk assessment and application schemes can be considered environmentally benign. Pyrethroids showed highest exceedance rates of all insecticide classes, which may be most concerning given that some of these products have seen rapid adoption by agricultural producers in recent years. Several significant risk determining factors were identified, e.g., toxicity-normalized use was found to be the most important predictor describing local risks, moreover sampling intervals affected risk characterizations by up to one order of magnitude. Also, in smaller watersheds (< 100 km²), MICs were found to pose significantly higher risks. Lower order streams, which rarely are the focus of monitoring programs, are hence most vulnerable to adverse insecticide contamination, threatening biodiversity and their function. Finally, spatio-temporal factors, such as rainfall erosivity and irrigation practices, affected insecticide risks significantly. Relevant predictors were used to model potential insecticide risks in U.S. surface waters for 2017.

441 Assessing agrochemical pollution in shallow well waters and chronic kidney disease in endemic Sri Lankan villages

E. Shipley, University of Connecticut / Marine Sciences; P. Vlahos, University of Connecticut / Departments of Marine Sciences and Chemistry; R. Chandrajith, P. Wijeratna, P. Hewavitharana, N. Nanayakkara, University of Peradeniya; S. Anand, Stanford University; S. Schensul, University of Connecticut Health

Agriculture has become a major industry in Sri Lanka since the Green Revolution. Subsequent increase in use of agrochemicals and the resulting burden of drinking waters by these chemicals has become suspect as a cause of the increase in chronic kidney disease of unknown etiology (CKDu) in lowland agricultural communities over the last two decades. This work provides the first data on select agrochemical compounds observed in Sri Lankan well and groundwaters and relates this data to the occurrence and progression of the disease in a cohort of 300 participants identified as having CKDu through a national screening. Results show strong indications that consumption of well water correlates with initial estimated glomerular filtration rates (eGFR) and that agrochemical concentrations in these wells often exceed US Environmental Protection Agency and World Health Organization guidelines for drinking water.

442 Mitigating Pesticide and Nutrient Contamination of Agricultural Wetlands in Canada’s Prairie Pothole Region

A. Wade, University of Saskatchewan / Toxicology; K. Liber, University of Saskatchewan / Toxicology Center; C. Sheedy, Agriculture and Agri-Food Canada (AAFC) / Trace Residue Analysis and Immunochemistry; E. Malaj, University of Saskatchewan / Toxicology Center; C.A. Morrissey, University of Saskatchewan / Department of Biology

Wetlands in the Prairie Pothole Region of North America are a valuable resource to humans and the environment alike. However, intensive agriculture has led to the loss and degradation of wetlands in this region which are frequently contaminated by pesticides and excess nutrients. Therefore, this project investigates the potential effects of pesticides and eutrophication on Prairie Pothole wetland invertebrate communities and the efficacy of vegetated buffers in mitigating contamination. Over the summers of 2018 and 2019, 71 Saskatchewan wetlands in cereal and canola fields were sampled for aquatic invertebrates using the Canadian Aquatic Biomonitoring Network (CABIN) protocol for wetlands and pesticide and nutrient concentrations. Over 160 common use pesticides were measured in water samples as well as major nutrients such as ammonia and orthophosphate. Pesticide concentrations were converted to Toxic Units based on species sensitivity distributions and are being modeled with wetland vegetated buffer zone (VBZ) characteristics and nutrient measures for their potential effects on aquatic invertebrate species abundances. All 32 wetlands sampled in 2018 were contaminated with one or more pesticides, some wetlands containing as many as nine. The most commonly detected pesticides were the neonicotinoid clothianidin and the herbicide 2,4-Dichlorophenoxyacetic acid. We are currently examining the efficacy of different configurations and amounts of producer implemented VBZ plantings to assess their ability to improve wetland condition. Identifying what VBZ implementation strategies are most effective will allow land owners and conservation organizations to design and prioritize incentive programs that best protect our wetland resources in working agricultural landscapes.

443 Neonicotinoid insecticides in wetlands of Western Canada: Putting monitoring data into the context of risk for aquatic invertebrates

C. Harrington, Syngenta Canada, Inc. / Regulatory and Biological Assessment; J. Overmyer, Syngenta Crop Protection, LLC / Environmental Safety; W. Chen, Syngenta Crop Protection, Inc.; S. Chen, R. Underwood, Syngenta Crop Protection, LLC

Water monitoring was conducted in 2018 to determine weekly concentrations and dissipation of thiamethoxam, clothianidin and imidacloprid in 56 wetlands located within thiamethoxam seed-treated fields across the agricultural areas of Saskatchewan, Canada. Detection limits for thiamethoxam (0.0006 µg/L), clothianidin (0.002 µg/L) and imidacloprid (0.0006 µg/L) allowed for high resolution of these analytes in the wetland water; thiamethoxam and clothianidin were detected in 64% and 31%, respectively, of samples collected. Overall mean concentrations of thiamethoxam ranged from 0.0007 µg/L to 0.1406 µg/L per wetland; clothianidin mean concentrations ranged from 0.001 µg/L to 0.018 µg/L. Imidacloprid was detected in five samples from a single wetland over the study duration. The greatest thiamethoxam concentration recorded in the current study was 1.9 µg/L, which is below the acute HC5 value (9 µg/L) for freshwater aquatic invertebrates. The majority of wetlands (44 of 56) exhibited 21-day rolling average thiamethoxam exposure levels < 0.025 µg/L. Wetlands with chronic exposures exceeding 0.025 µg/L had maximum 21-day average concentrations ranging from 0.029 µg/L to 0.54 µg/L. Thiamethoxam aquatic mesocosm NOEC values of 0.3 µg/L was exceeded 4 times (< 1% of 21-day averages), in a single wetland, from Week 6 to 12, but this result was driven by a single peak on Week 9. For clothianidin, the greatest concentration recorded in the current study was 0.12 µg/L, which was below the aquatic invertebrate HC5 value of 1.5 µg/L for acute exposure. The maximum 21-day average concentrations of clothianidin in sampled wetlands ranged from 0.001 µg/L to 0.038 µg/L. With regard to chronic toxicity, all calculated 21-day
average concentrations were below the clothianidin aquatic mesocosm NOEC value of 0.281 µg/L. The current study expands upon the suite of neonicotinoids typically analyzed for and provides a robust chronic dataset, contributing to our understanding of the presence of neonicotinoids in prairie wetlands. Detection and concentration patterns were consistent with usage patterns and precipitation events, as has been observed in previous studies. The likelihood of exceeding acute and chronic effects thresholds was low under the current conditions in these wetlands.

444 Neonicotinoid Concentrations in Canadian Prairie Surface Waters - Evaluation of Potential Chronic Concentrations

S. Hanson, Bayer CropScience / Environmental Affairs; S. P. McGee, Bayer CropScience / Environmental Health Sciences; D. Netzband, Bayer Crop Science / Residue Chemistry; J. Tang, Bayer CropScience; D. G. Dyer, Bayer CropScience / Environmental Safety

The presence of neonicotinoids in surface waters of aquatic ecosystems of North America has been documented in several publications, but these data tend to lack sufficient sampling frequency to evaluate the potential dissipation of residues in these waters. Neonicotinoids are known to dissipate in water through photolytic processes, but this is often not considered when evaluating concentrations from such studies. Therefore, maximum (acute) concentrations are often compared to chronic toxicity endpoints. The temporal aspects of aquatic concentrations are critical to understanding potential effects on aquatic organisms, specifically aquatic invertebrates in the case of neonicotinoids. Results from previous and ongoing, neonicotinoid-targeted, field-scale monitoring studies in Canadian prairie wetlands will be described, along with an evaluation of the temporal and spatial aspects of the observed water concentrations.

Advances in Passive Sampling Across Environmental Compartments - Part 1

445 Assessment of the potential biological relevance of chemicals sampled in tributaries of the Great Lakes using passive sampling and ToxCast

The Great Lakes Basin and associated tributaries include a highly diverse set of land uses ranging from watersheds that consist of relatively pristine forests and wetlands to agricultural areas, industrial centers, and urban environments. Sources within each of these land uses can contribute a suite of chemical contaminants to streams, posing a potential threat to aquatic biota and other wildlife. Determination of exactly which contaminants are of concern, requires integration of both biological and chemical data. The ToxCast program provides a method to screen sample results for potential biological effects using information from hundreds of high-throughput assays that characterize a range of cell responses and approximately 300 signalling pathways for more than 9000 chemicals. Passive samplers can provide data on the time-weighted average (TWA) concentration of select chemicals in the water which can be a reasonable estimate of an organism's exposure to dissolved chemicals. This study describes the combination of these two techniques to determine the potential biological impact of chemicals in surface waters. In 2010 and 2014, a combined total of 67 sites along tributaries of the Great Lakes were sampled using semipermeable membrane devices (SPMDs) and polar organic chemical integrative samplers (POCIS). Extracts from these samples were analyzed for 189 chemicals including organochlorine pesticides, polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), polycyclic aromatic hydrocarbons (PAHs), pharmaceuticals, current-use pesticides, plasticizers, flame retardants, fragrances, and other chemicals related to wastewater effluents. Resulting TWA water concentrations were evaluated for pathway-based bioactivity using exposure-activity ratios (EAR = measured concentration/ToxCast activity concentration) Of the 145 chemicals with at least one detection, 90 were listed in the ToxCast database, allowing for determination of EARs. A comparison of EAR values from each site indicated that several tributaries of Lake Michigan and Lake Erie had a considerably higher level of contamination and potential bioactivity compared to other sites. The largest EARs were a result of the presence of several pesticides, PAHs, fire retardants, and detergent metabolites.

446 Legacy contaminant concentrations in porewaters and well waters measured using novel passive sampling methods on a remote Northwestern Hawaiian Island

R. Adams, Loyola Marymount University / Civil Engineering & Environmental Science; B. Chadwick, W. Robberson, Coastal Monitoring Associates / Environmental Science; P. J. Earley, Naval Information Warfare Center Pacific / Environmental Science Branch; J. Leather, Naval Information Warfare Center Pacific / Energy and Environmental Sustainability Branch; G. Rosen, NIWC Pacific / Energy and Environmental Sustainability; I. Rivera-Duarte, SPAWAR Systems Center Pacific; N. Hayman, NIWC Pacific (Naval Information Warfare Center Pacific) / Energy and Environmental Sustainability; H. Allen, USEPA Region 9 / Superfund Emergency Response; A. Cook, USEPA Region 9 / Office of Research & Development

Historic federal operations on some islands in the Northwestern Hawaiian Island chain have led to environmental contamination including elevated concentrations of polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs) in specific areas. Some of these islands are now marine protected areas and home to several threatened/endangered species and exposure to these contaminants has the potential to negatively impact the wildlife and the marine ecosystem. The objective of this study is to assess the level of contamination and the potential for the bioavailable contaminants to move to the nearshore environment and the potential ecological risk to threatened/endangered species on this remote island location accessible only by boat. To this end, low-density polyethylene passive samplers (PEPS) in addition to sediment samples were used to measure both freely-dissolved and sediment contaminant concentrations, respectively. A series of 20 upland stainless-steel (SS) wells associated with previously measured contamination and associated with expected reference levels were installed. PEPS were deployed in nearshore sediments adjacent to the wells using SS frames. The concentration gradients between the inland wells and nearshore areas will be evaluated to assess the potential for contaminants to migrate from the island. Performance reference compounds for PCBs and PAHs were used with a first-order model to correct for disequilibrium. Preliminary measurements show freely-dissolved PCBs in well- and pore-water (NOAA 18 congener sum) ranged from non-detect to a high of 24 ng/L. Freely dissolved PAHs in well- and pore-water (USEPA priority pollutant 16 PAH sum) ranged from 0.2 ng/L to a high of 190 ng/L. The highest levels (PCBs and PAHs) were measured in well-water samples in and near to a historic dump site. Near-shore sites located closest to the dump site also exhibited the highest PCB and PAH porewater concentrations. Sediment bioaccumulation tests conducted with marine polychaetes showed similar trends. Overall, both PEPS deployment systems (coils and frames) were demonstrated to be effective in this remote location despite significant weather and sediment movement events. PEPS-measured dissolved concentrations were directly correlated with sediment measurements and suggest that contaminants in the historic dump are migrating to the near-shore porewaters. This work will be important to assess potential ecological risks to the island ecosystem.

447 Mechanistic modeling for aquatic integrative passive samplers: How can we realize linear uptake?

S. Endo, National Institute for Environmental Studies (NIES) / Center for Health and Environmental Risk Research; Y. Matsaura, Osaka City University; E. Vermeirssen, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology

Aquatic integrative passive samplers such as Chemcatcher and the Polar Organic Chemical Integrative Sampler (POCIS) have received increasing...
attention in environmental analytical chemists, primarily because this type of passive samplers has the potential to measure time-weighted average (TWA) concentrations in relatively simple, inexpensive, and sensitive manner. Many field applications have been reported, and the performance of passive samplers depends on the devices, the chemicals, and the environments. Particularly, it is not always the case that the uptake behavior shows linearity against time, which is necessary for an accurate calculation of TWA concentrations. In this work, we introduced a mechanistically based, diffusion-sorption model into characterization of the uptake of chemicals by Chemcatcher. The model was verified with data from laboratory channel and tank experiments for ca 20 various polar pesticides and pharmaceuticals. The model reproduced varying uptake profiles such as occurrences of lag-times, curvilinearity, and equilibrating behavior. From model simulations we came up with three general suggestions that help achieve linear uptake for diverse chemicals. (1) The diffusion-limiting membrane filter should not significantly sorb the chemicals; (2) the receiving phase (sorbent) should be “very” strong; (3) a thick aqueous boundary layer and/or a thick (non-sorbing) membrane filter helps extend the linear uptake period.

448 Differential Influences of Decentralized and Centralized WWTP across Four Bayous following Hurricane Harvey in the Houston Area using Passive Sampling

B. Grabac, A. Borík, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters / South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocones; R. Mole, Baylor University / Department of Environmental Science; B. Vrana, J. Sobota, Masaryk University / Faculty of Science / RECETOX / Research Centre for Toxic Compounds in the Environment; B.W. Brooks, Baylor University / Department of Environmental Science

The greater Houston metropolitan area is the most populated and fastest growing places in US with a high concentration of industry. The Texas Gulf coast was highly impacted by Hurricane Harvey in August 2017. Subsequently, we applied a battery of passive samplers to investigate possible organic compound pollution after the hurricane in four different small bayous in this area. The bayous were selected to test hypothesis that more extreme flooding impacted more recipients with prevailing decentralized sources of communal pollution (e.g., septic tanks) than those with centralized wastewater treatment. We used polar organic compound integrative samplers (POCIS pest configuration) and silicon rubber sheets for nonpolar pollutants. Three sampling sites were selected in each catchment and passive samplers were deployed for 10 days in March 2018. We performed targeted and nontargeted analysis of wide range of organic compounds in all passive sampler extracts using state of art techniques including LC and GC MS/MS and HRMS. The list of polar compounds includes 69 pharmaceuticals and metabolites, 105 pesticides and metabolites, 28 PFCs, 14 bisphenols, 4 linear alkylbenzenesulphonates, 6 sunscreens and UV stabilizers, 9 organophosphorous flame retardants. Principal component analysis of this data set showed significant differences in contamination patterns among bayous. While sites that were not severely flooded were grouped, more extremely flooded sites with onsite septic tanks were had a distinct contamination pattern from those with central wastewater treatment. However, explanation of principal component with corresponding variables (determined compounds) is not straightforward and needs more detailed data on population and agricultural activities in sampled bayous. Almost the same grouping we obtained when PCA was applied on HRMS nontarget data. Within HRMS data processing we obtained very promising results identifying a number of xenobiotics compounds in different basins. We can conclude that passive sampling combined with robust analytical exploitation of the samples can be used as prospective tool for unraveling complex contamination in aquatic ecosystems. In addition, HRMS data can be used for long term monitoring of changes in basins with possibility of retrospective analysis.

449 Comparison of Chemical Contaminant Measures Using CLAM, POCIS, and PED Samplers in Estuarine Mesocosms

Sampling chemical contaminants in the water column using discrete grab samples can present multiple problems. For example, the ephemeral nature of constituent concentrations in marine environment (i.e. changing with tides, currents, precipitation, etc.) means that a discrete water sample only represents a “snapshot” that may not be temporally representative of the system. Additionally for some analytes, large volumes of water may be required in order to detect the chemicals; this may not be logistically feasible, especially at remote field locations. To address this issue, both passive and active sampling devices have been engineered. Passive and active samplers have been in field studies, where the contaminant loading is unknown. The objective of this study is to assess the performance of three samplers compared to grab samples in estuarine mesocosm systems with known quantities of chemical contaminants. To this end, three different types of systems were compared: two passive samplers [POCIS (Polar Organic Chemical Integrative Sampler) and PED (polyethylene devices)] and one active sampler [CLAM (Continuous Low-Level Aquatic Monitoring)]. The CLAM and the CLAM utilize semi-permeable membranes, whereas the PED is a polyethylene sheet that directly adsorbs contaminants on its surface. This experiment utilized 9 estuarine mesocosms containing saltwater, sediment, and marsh vegetation to test the response of passive and active sampling technologies in comparison with traditional grab sampling methodologies. The systems received doses of representative contaminants from three different contaminant classes (a hydrocarbon, a pesticide, and an antimicrobial). The test was a stacked design whereby the systems received a low dose of contaminants for 30 days. After that, the systems received doses of the same contaminants at higher levels for an additional 30 days. The passive (POCIS & PED) samplers remained in the systems continuously for each 30-day period. Active (CLAM) sampler deployments occurred once each week for no more than a 24-hour period. Grab samples for traditional lab-based extraction methods were collected weekly to coincide with the deployment of the CLAM samplers. All samples (POCIS, PED, CLAMs, and grab samples) were extracted, eluted, and analyzed via established quantitative analysis methods. Results from these comparative trials will be reported.

450 Evaluation of Equilibrium Passive Sampling Polymers for Monitoring Munition Constituents in Aquatic Systems

M. Rakowska, Texas Tech University / Envirostatus / Civil and Environmental Engineering; L. A. Fernandez, Northeastern University / Civil and Environmental Engineering; R. M. Burgess, US Environmental Protection Agency / Atlantic Ecology Division

Military munition constituents (MMCs) are persistent environmental pollutants identified in water bodies surrounding historically deposited unexploded ordnance. In general, concentrations of MMCs in waters and sediments are very low and widely distributed. Therefore, fast detection and identification of trace levels of explosives is of great importance for monitoring and assessing of remedial implementation and effectiveness. In turn, passive and sensitive monitoring techniques provide a better understanding of the bioavailability and potential long-term bioaccumulation and toxicity of MMCs in different aquatic environments. This study explores the use of commercially available nonpolar polymers including polydimethylsiloxane (PDMS), low density polyethylene (LDPE) and polyoxyethylene (POM) as equilibrium passive samplers for measuring freel (free) concentrations of munition constituents. The potential of fabricated polymer sheets and polymer blends including ethylene vinyl acetate (EVA), a PDMS and Ambersorb mix, and more polar resins such as Isolute Env+, Oasis HLB and Porapak incorporated into Agarose gel is
also explored. Commercial and fabricated polymers were exposed in batch water systems spiked with the munition constituents 4-amino-2,6-dinitrotoluene (4-A), 2-amino-4,6-dinitrotoluene (2A), pentachlorothiol tetranitrate (PETN), 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (HMX), hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), picric acid (PA), and 1-nitroguanidin (Ngua). The uptake and change of explosive compounds was monitored in polymer and water phases over time with LC-MS/MS operated in electro-spray ionization mode (Sciex Qtrap 4500). Mass transfer coefficients ($K_L$) and partitioning constants ($K_{PW}$) were obtained from the kinetic and equilibrium portions of the datasets using a two compartment model. Results suggest that POM, EPA, PDMs, and Agarose-HLB are the most promising passive samplers for MCMs. It appears that $K_{PW}$ is also a master variable for describing the partitioning behavior of compounds with low hydrophobicity (< log 4). The two-compartment model provides excellent agreement between measured and predicted $K_{PW}$ values for different polymers and $K_c$ values, which can then be used with polymers exposed in the laboratory or field. The presentation provides information both on the uptake and release of explosive compounds to a variety of polymeric materials and discusses their potential for application in equilibrium passive sampling.

451 Advantages of Passive Sampling as a Decision Making Tool
M. Healey, J. Roberts, SiREM; J.M. Conder, Geosyntec Consultants, Inc.; M. Vanderkooy, Geosyntec Consultants

Passive sampling devices (PSDs) present numerous advantages over conventional sample collection methods for quantifying hydrophobic organic compound (HOC) availability in sediment, soil, surface water and storm water. PSDs can provide superior convenience, cost and data quality compared to conventional grab or mechanically extracted samples. A major advantage of PSDs is their property of quantifying only the freely dissolved, bioavailable fraction while not measuring the sorbed or non-bioavailable fraction. Measuring only bioavailable contaminants with PSDs provides a better measure of actual toxicity and mobility for environmental receptors and a lower tendency towards toxicity overestimation than conventional sampling methods. This presentation will highlight examples where PSDs have been used in the laboratory and in the field for decision making in site investigation and remediation, including techniques and advancements that simplify and improve ease of sampling, increase data quality and lower costs. We will demonstrate how a combination of an in situ application of peelers as PSD to analyze sediment porewater mobility of heavy metals and ex situ testing with polyethylene PSDs for polychlorinated biphenyl (PCB) and organochlorine pesticide (OCP) porewater concentrations was applied to site investigation. A second -in situ application will highlight the use of polyethylene-based PSDs to evaluate depth profiles of PCB porewater concentrations in sediment up to two feet below the sediment surface. A third laboratory case study will highlight the use of PSDs to evaluate the effectiveness of different levels of activated carbon to immobilize PCBs. The study reduced the remedial budget significantly by avoiding the addition of excess activated carbon amendment. The application of PSDs for in situ field monitoring pre- and post-remedy at the site were then used to evaluate remedy performance in the field.

Chemistry and Exposure in the Indoor Environment - Part 1

452 Indoor exposure to per- and polyfluoroalkyl substances (PFAS): Presence of PFAS in U.S. childcares
E. Schreder, Toxic-free Future; G. Zheng, Indiana University; A. Salamova, Indiana University / SPEA

PFAS, with their varied uses including as surface treatments for carpets, rugs, and upholstery as well as in waxes and cleaners, are potential contaminants of the U.S. childcare environment. To obtain a preliminary assessment of children's exposure in this environment, floor and surface dust samples as well as samples of nap mats were collected from eight childcares in Washington State and Indiana and analyzed for 42 ionic and neutral PFAS. Samples of mats and dust were analyzed for 42 PFAS as follow, including 31 ionic and 11 neutral PFAS. Ionic PFAS were analyzed on a UPLC-QQQ MS (Agilent 1290 Infinity II UPLC - 6470 QQQ-MS) with negative electrospray ionization (ESI-). Neutral PFAS were analyzed on an Agilent 7890 gas chromatograph (GC) coupled to an Agilent 5975C mass spectrometer (MS) in the electron capture positive ionization (PCI) mode. In the 20 samples analyzed, neutral PFAS including 6.2 FTOH (median level 125 ng/g), 10.2 FTOH (40.3 ng/g), and 8.2 FTOH (19.5 ng/g) were present in the highest concentrations. Precursor compounds EtFOSE and MeFOSE were also detected at relatively high concentrations (median 15.1 and 10.8 ng/g, respectively). Among the ionic PFAS, the fluorotelomer sulfonate compounds 6.2 FTS and 8.2 FTS were detected at the highest levels (median 11.9 and 5.8 ng/g, respectively). None of the childcares had carpeting, but sources of these compounds may include treated upholstery, rugs, and cleaners/waxes used on flooring. The surprisingly high concentrations of the fluorotelomer sulfonates may result from their use as fluorosurfactants in indoor cleaners, waxes, and polishes. In foam and polyester batting from nap mats in use at the childcares, ionic PFAS levels were consistent, ranging from < LOD to 11.2 ng/g, with PFHxDA present in the highest concentrations in most samples. Analysis of the mat samples found ?Neutral PFAS ranged from < LOD to 192.6, with a profile similar to that of dust, with the foam in the mats possibly serving as a passive sampler. These results indicate PFAS-containing products are likely used in childcares, with the result of exposing young children for a large portion of their day.

453 Human Exposure to Semi-Volatile Organic Compounds (SVOCs) in Social Housing Apartments
Y. Wang, University of Toronto / Physical and Environmental Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences; J.A. Siegel, University of Toronto / Civil and Mineral Engineering

When compared to outdoors, the indoor environment often has higher concentrations of some SVOCs, such as brominated flame retardants (BFRs) and phthalates that are used as additive flame retardants and plasticizers from consumer products and building materials. Some outdoor SVOCs such as polycyclic aromatic hydrocarbons (PAHs) can be transported into indoor environments which increase indoor exposure to these compounds. Most indoor sampling studies have focused on homes from mid-to-high-socio-economic status (SES) occupants. Residents of low-income social housing are vulnerable to health effects from exposure to indoor air pollution and yet have received much less attention. This study documented concentrations of FRs, phthalates and PAHs in indoor air with the goal of assessing indoor exposure in lower income social housing. Silicone rubber (polydimethylsiloxane or PDMS) passive air samplers were deployed for one week in 71 units in 7 multi-unit social housing buildings located in Toronto, Canada, during the summer and winter of 2017. Seventy-one PDMS samplers deployed were recovered for analysis on a GC-MS in EI and CI modes. Chemical mass collected by the samplers was converted to air concentrations. Tris(1,3-dichloro-2-propyl) phosphate (TDCPP) and Diethyl phthalate (DEP) were the dominate flame retardant and phthalate in indoor air in both summer and winter with median concentrations of 2160 pg/m³, 748 pg/m³ and 2070 ng/m³, respectively. The most abundant PAH was phenanthrene in summer with a median concentration of 82.8 ng/m³, whereas naphthalene was the most abundant PAH in winter with a median concentration of 81.7 ng/m³. No seasonal difference was observed among most of the SVOCs except for Di-n-octyl phthalate (DnOP), Dibutylphthalate (DBP), Acenaphthylene and BDE-49 which had relatively higher concentrations in winter than summer, and TDCPP which had a higher concentration in summer. In general, residents in social housing units experienced 2 to 19 times higher air concentrations of FRs and phthalates than those of predominantly detached and semi-detached houses in Toronto measured using the same passive samplers, presumably occupied by occupants with higher SES and with lower occupant densities, suggesting the potential for exposure disparity.
454 Associations of exposures to flame retardants and thyroid hormones in adults living in central Appalachia
S. Wang, Indiana University, Bloomington / School of Public and Environmental Affairs; K. Romanak, Indiana University; M. Hendryx, Indiana University / School of Public Health; A. Salamova, M. Venier, Indiana University / SPEA

Health disparities still exist in rural Appalachian coal mining communities and environmental pollution from activities of the mining industry can contribute to population health inequities. Indoors environment is recognized to be intensively contaminated with flame retardants (FRs). The quality of indoor air has an important impact on health as people normally spend 80 - 90% of their time indoors. Our objectives were to evaluate exposure to FRs and to explore the relationships between chemicals exposures and health effects. We used passive air samplers with polyurethane foam (PAS-PUFs) to investigate the levels of polybrominated diphenyl ethers (PBDEs), novel brominated flame retardants (nBFRs), and organophosphate flame retardants (OPFRs) in indoor air and silicone wristbands to examine personal exposures to these chemicals in 8 communities in central Appalachia. PAS-PUFs were deployed indoors for 30 days in 101 residential homes during March 2017 - July 2018. One resident in each home wore a silicone wristband for 7 days. Whole blood was also collected from each participant by finger prick (blood spots) for thyroid hormone analysis. Relationships between PBDE, OPFR, and nBFR levels in wristbands and thyroid hormones including free thyroxine (FT4), triiodothyronine (FT3), and thyroid stimulating hormone (TSH), were assessed using multiple linear regression. The median total concentration for OPFRs, PBDEs, and nBFRs were 25,018, 206, and 69 pg/m³ in indoor PUFs, and 671, 49, and 114 ng/g wristband in wristbands. The most abundant chemicals in both air and wristbands were tris(2R)-1-chloro-2-propyl phosphate (TICIPP) among OPFRs, BDE-47 and -99 among PBDEs, and 2-ethylhexyl 2,3,4,5-tetrabromobenzocate (EHTBB) and bis(2-ethylhexyl) tetrabromophthalate (BEHTBP) among nBFRs. When controlling for age and smoke, positive and significant associations were observed between 2-Ethylhexyl diphenyl phosphate (EHPD), BDE-197, -100 and FT4, between tri-ethyl phosphate (TEP), pentabromobenzene (PBBZ) and FT3, and between tris(3,5-dimethylphenyl) phosphate (TMDPP), BDE-28, pentabromoethyl benzene (PBBE), anti-DP and TSH. These results indicate that wristbands are a good matrix for evaluating human exposures to FRs and possibly to other compounds as well.

455 Human Exposure to Phthalates via Indoor Dust Ingestion at Urban and Rural Homes in Eastern Slovakia
H. Demirtepe, L. Melymuk, G.P. Codling, J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; I. Paškošíková Murinová, D. Richterová, V. Rašplová, Faculty of Public Health, Slovak Medical University / Department of Environmental Medicine; T. Trnovec, Slovenska Zdravotnicka Univerzita v Bratislave

Phthalates are used as plasticizing agents in polyvinyl chloride (PVC), food packages, toys, and many other products. They are easily released from the products to the indoor environment and partition to dust particles due to their hydrophobicity. Dust can be an important exposure route, especially for children. Health effects of phthalates have been identified as reproductive system dysfunction, endocrine disruption, allergy and asthma in children and obesity. Despite being restricted and regulated in many countries, the release from polymer products and human exposure may continue for decades since the products containing phthalates remain in use and even on the market. Therefore, it is crucial to identify concentrations and human exposure to phthalates in indoor environments. The current study investigated the phthalate concentrations in homes in Eastern Slovakia. In 60 homes one dust sample was collected from a child’s bedroom. Samples were solvent extracted with sonication. The extracts were fractionated and analyzed by GC–Orbitrap in full-scan (70-1000 amu) in EI with 30 m column. Blank subtraction was employed for final quantification. The median phthalate concentrations ranged between 0.01 μg/g for dipentyl phthalate to 327.8 μg/g for bis(2-ethylhexyl) phthalate (DEHP). DEHP constituted 83.3% of the total ten phthalates, followed by di-n-butyl phthalate (7.45%). DEHP concentrations in Slovakian homes were comparable to those in France, Denmark, USA, a few regions of China, and Qatar, but were lower than that in Germany, Sweden, Kuwait, China and Japan. Mann-Whitney U-tests revealed a statistically significant difference for butylbenzyl phthalate and dimethyl phthalate concentrations in urban and rural homes (p < 0.05). However, no significant difference was found between the homes with and without PVC flooring, suggesting that other indoor phthalate sources are influencing the concentrations in these homes. The estimated DEHP exposure via dust ingestion was 216 ng/kg/day for children and 98 ng/kg/day for an adult female. Our previous study identified phenanthrene as the compound having the highest estimated total intake among the semivolatile organic compounds identified in the same homes. In the current study, DEHP exposure was nearly 50-60 times higher than that of phenanthrene.

456 Occurrence and Human Exposure Assessment of Phthalates in Indoor Environment of Residential Buildings in Guangzhou, South China
Y. Guo, C. Huang, Jinan University / School of Environment

Phthalates are environmental endocrine disruptors that might have adverse effects on human health. In the present study, one hundred families were randomly selected, and indoor air, dust and urine of family member were collected to analyze phthalates or their metabolites in 2018, Guangzhou, South China. We aimed to evaluate the contribution of phthalates in indoor environment to total human exposure by comparing their external and internal exposure. Our results indicated that concentration of total phthalates in the indoor air was in the range of 279-5080 ng/m³, with a median value of 1920 ng/m³. Among all targets, Di-n-butyl phthalate (DBP), Di-isobutyl phthalate (DIIBP) and Di-(2-ethylhexyl) phthalate (DEHP) were the main pollutants, accounting for 52.3%, 28.1% and 10.0% of total amount, respectively. For the indoor dust, the concentration of total phthalates was 48.7-2850 μg/g, and DEHP, DBP and DIIBP were also the three main pollutants, accounting for 80%, 17% and 2%, respectively. For urine samples, concentration of metabolites was 10.7-2840 ng/mL. The concentration of Σ4 DEHP (sum of 4 metabolites of DEHP) ranged from 2.68 to 180 ng/mL. The total daily exposure of phthalates based on urinary phthalate metabolites was 10.8-62.4 μg/kg/day for all families. The exposure dose was significantly different among various age groups, with the sequences as infants (< 1 year old, 62.4 μg/kg/day) > toddlers (1-3 years old, 16.4 μg/kg/day) > teenagers (11-18 years old, 15.2 μg/kg/day) > adults (> 19 years old, 12.8 μg/kg/day) > Children (4-10 years old, 10.8 μg/kg/day). The daily exposure of DEHP for infants had exceeded the reference dose (RFD) given by the U.S. Environmental Protection Agency. In addition, the external exposure assessment showed that the daily intake of phthalates via dust ingestion and air inhalation was 0.166-2.54 and 0.297-1.54 μg/kg/day, respectively. The main exposure way of phthalates changed from dust ingestion to air inhalation with age increased. By compared with the total exposure, the contribution of phthalates exposure via indoor dust ingestion and air inhalation was less than 13.3%. The present study demonstrated that phthalate pollution in the indoor environment of residential buildings in Guangzhou was relatively serious. The total exposure levels for the family members were lower than the reference dose, but relative higher for infants. Indoor dust and air were non-negligible sources for human exposure to phthalates.

457 Sources of Isocyanic Acid (HNCO) Indoors: A Focus on Cigarette Smoke
R. Hems, C. Wang, University of Toronto / Department of Chemistry; D.B. Collins, Bucknell University / Department of Chemistry; S. Zhou, University of Toronto / Department of Chemistry; N. Borduas-Dedekind, ETH Zurich / Department of Environmental Systems Science; J.A. Siegel, University of Toronto / Civil and Mineral Engineering; J. Abbatt, University of Toronto / Department of Chemistry

The sources and sinks of isocyanic acid (HNCO), a toxic gas, are largely uncharacterized in indoor environments. In particular, cigarette smoke has...
been identified to be a significant source of HNCO and possible precursor compounds. Identification of indoor sources and conditions that lead to elevated HNCO are necessary to understand the health risk for occupants. In this study, controlled smoking of tobacco cigarettes was investigated both in a residence in Toronto, Canada and in an environmental chamber using online chemical ionization mass spectrometry. Fast measurements, inside and outside of the Toronto residence, allowed for the determination of the emission rates of HNCO from cigarette smoke, the background conditions in the house, and comparison to outdoor concentrations. Chamber measurements explored possible indoor-relevant reactions - oxidation by ozone, hydroxyl radical (OH), and photo-reaction under indoor fluorescent light - that could lead to secondary production of HNCO from cigarette smoke precursors. The HNCO emission ratio from side-stream cigarette smoke was determined, from both the residence and chamber studies, to be in a similar range to emission ratios from previously reported biomass burning smoke sources. Side-stream smoke from a single cigarette introduced a large pulse of HNCO to the indoor environment, increasing the HNCO mixing ratio by up to a factor of ten above background conditions of 0.15 ppb. Even in the absence of smoking, the indoor HNCO mixing ratio in the Toronto residence was elevated compared to concurrent outdoor measurements by approximately a factor of two. Oxidation of the cigarette smoke by OH was the only investigated process to produce secondary HNCO. After 30 minutes of oxidation by OH (1.1 x 10^7 molecules per cm^3), the HNCO mixing ratio was observed to double and continued to increase with further oxidation. Loss of HNCO by partitioning or reaction at indoor surfaces was identified to be significant, in addition to mixing within the house and ventilation to outdoors.

458 The influence of bleach cleaning emissions on indoor chemistry: Formation of secondary gases and particles
C. Wang, C. Wang, J. Abbatt, University of Toronto / Department of Chemistry
Application of chlorine bleach solution (major component sodium hypochlorite, NaOCl) in indoor environments emits gaseous hypochlorous acid (HOCl) and chlorine (Cl2), both of which are strong oxidants. HOCl and Cl2 may react with unsaturated organic compounds on indoor surfaces and in indoor air but their impact on indoor air quality has not been well characterized. In this study, we studied the reaction of limonene, one of the most common indoor volatile organic compounds (VOCs) arising from use of cleaning products, fragrance, air fresheners, with HOCl and Cl2 in an environmental chamber. A dark reaction was observed between limonene and HOCl/Cl2 leading to gas-phase reaction products investigated using on-line mass spectrometry. With subsequent exposure to indoor fluorescent lights or diffuse sunlight through a nearby window, a significant mass loading of secondary particles formed. Mass spectrometry measurements of the aerosols indicate a large contribution of particulate chlorine species and formation of high molecular weight products. This is the first study of the oxidation of limonene with HOCl and Cl2, and it illustrates the potential for particle formation to occur with indoor lighting during the use of common cleaning products. Formation of secondary products and particles may lead to health effects for indoor occupants.

459 Hydrogen Peroxide Emission and Fate After Cleaning Events
T. Kahan, University of Saskatchewan / Chemistry; S. Zhou, Syracuse University / Department of Chemistry; Z. Liu, Syracuse University / Mechanical and Aerospace Engineering; C. Young, T. Vandenboer, York University / Department of Chemistry; A. Cregan, Syracuse University / Department of Chemistry; Z. Wang, N. Carslaw, University of York / Environment and Geography; J. Zhang, Syracuse University / Department of Mechanical and Aerospace Engineering
Low oxidant levels and rapid exchange of air between indoor and outdoor environments often makes chemical transformations of gas-phase species unimportant indoors. However, perturbations to these environments such as cooking and cleaning can dramatically increase indoor oxidant levels, leading to rapid chemical transformations that can affect human health. While a number of studies have reported the effects of cooking on various markers of indoor air quality (such as oxidant levels and particulate matter formation), few studies have reported the effects of cleaning on indoor chemistry. High levels of gas-phase reactive chlorine species and hydrochloric acid (HCl) have been reported after washing surfaces with bleach, and hydroxyl radical (OH) levels were reported to increase greatly after cleaning surfaces with a limonene-based cleaner. In this work, we report time-resolved measurements of gas-phase hydrogen peroxide (H2O2) during and after cleaning floors with a peroxide-based cleaner. Peak H2O2 levels after cleaning were more than 1000 times higher than background levels. We used the INdoor air Detailed Chemical box Model (INDCM) to investigate the effects of H2O2 photolysis (initiated by room lights or sunlight attenuated through a window in the chamber wall) on air composition and radical formation in the chamber.

Micro- and Nano-Plastic Methods Research: Harmonizing Methods and Addressing Challenges - Part 1

460 A Methodology for Making Standardized Microplastics: Effect of Particle Size on Surface Area of “Weathered” Particles
A. Sanchez, University of Maryland, College Park / Civil and Environmental Engineering/Marine-Estuarine Environmental Sciences; K. Bailey, Micromeritics; D. Rubaye, University of Maryland, College Park / Chemistry and Biochemistry; L.T. Yonkos, University of Maryland / Environmental Science and Technology; A. Torrents, University of Maryland / Civil and Environmental Engineering
It is known that organisms ingest microplastics and that they may cause deleterious effects, but it is unclear how large a role microplastics play as a particle versus as an exposure route to organic pollutants. Many studies have tried to address this issue; however there has been much criticism for environmentally irrelevant conditions. Additionally, ecologically relevant experiments have not used standardized microplastic particles and have shown mixed results. The heterogeneity of methods makes comparing studies challenging, if not impossible. There is a clear need for the development of standardized methodology for testing the toxicity of microplastics and sorbed pollutants. An integral part of this process will be the creation of “weathered” microplastics of consistent surface area, as this attribute is important for sorption. In order to address this problem, the objective of this study was to develop a methodology to fabricate pitted and irregularly shaped (“weathered”) microplastics with standardized surface area on a mass basis. Rods of high-density polyethylene and polypropylene were cooled in liquid nitrogen and shaved with a stainless-steel wood file. The particles were sieved through nine different pore sizes and cleaned with solvent. Surface area was measured using Brunauer-Emmett-Teller theory with krypton gas. Results presented will show how surface area and surface morphology changes with particle diameter, including a study with the antimicrobial triclocarban to demonstrate the effects of surface area on sorption. Having standardized microplastics will enable the design of more realistic and comparable experiments, and will be a step closer to creating ecotoxicity tests for microplastics and organic pollutants.

461 Introducing New Application-Based and Spectral Libraries of Microplastics (SLoPP & SLoPP-E) for Raman Spectroscopy
K. Munn, H. De Frond, University of Toronto / Ecology & Evolutionary Biology; B. O’Donnell, Horiba Scientific; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology
As smaller microplastic particles are increasingly included in research, it is critical to chemically characterize microparticles to identify whether they are indeed microplastics. To increase the accessibility of methods for characterizing microparticles via Raman spectroscopy, we created an application-based library of Raman spectroscopy parameters specific to microplastic particles based on color, morphology and size. We also created two spectral libraries that are representative of microplastics found in environmental samples. Here, we present SLoPP, a Spectral Library of Plastic Particles consisting of 148 reference spectra, including a diversity
of polymer types, colors and morphologies. To account for the effects of aging on microplastics and associated changes to Raman spectra, we present a Spectral Library of Plastic Particles aged in the Environment (SLoPP-E). SLoPP-E includes 125 spectra, including a diversity of polymer types, colors and morphologies. The microplastics used to make SLoPP-E spectra were sourced from environmental samples across a range of matrices, geographies and time points. Like many environmental samples, many of the particles included in SLoPP-E have undergone some form of chemical treatment or digestion (e.g., KOH digestion or density separation via CaCl2). Both libraries increase the likelihood of spectral matching for a broad range of microplastics, likely because our library includes plastics with a range of additives and pigments, and that have been exposed to the environment, characteristics that are not generally included in commercial libraries. When SLoPP and SLoPP-E are tested in combination with commercial libraries of over 24,000 spectra, they account for 69% of the top 5 matches across all particles tested (product and environmental). Furthermore, 80% of the top matches (first match) are from SLoPP and SLoPP-E. These tools were developed to improve the accessibility of microplastics research in response to a growing and multidisciplinary field, as well as enhance data quality and consistency. The development of accessible microplastics libraries are also intended to facilitate higher throughput and faster automation of polymer identification for Raman spectroscopy.

462 Method development for the isolation and analysis of micro- and nano-plastics using a potassium hydroxide digestion and particle pattern observations

C. Thaysen, L. Hermabessiere, K. Munno, University of Toronto / Ecology & Evolutionary Biology; C. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology

The global presence of micro- and nanoparticles (M/NPs) prompts concerns about the negative effects they may have on the environment and wildlife. To understand the potential effects of M/NPs, one must first understand exposure -- which involves isolating particles in a sample and determining how much is present. There are currently no standard methods for isolating and analyzing M/NPs. A common isolation procedure for environmental samples uses a potassium hydroxide (KOH) solution to digest organic matter. While this method has demonstrated that plastics ≥ 10 μm are not significantly degraded by the KOH, it is unknown whether plastics smaller than this size are affected. Once isolated, Raman spectroscopy is a common analysis method, but can be time-consuming. Automation has been proposed to make Raman analysis more efficient, but an appropriate subsampling strategy should first be determined. We present two related projects on the method development of M/NPs isolation and analysis. First, we aim to determine whether plastic particles contamination. Blank correction of samples was carried out as per common chemical analyses, including reporting concentrations based on limit of detection (LOD) and limit of quantification (LOQ), in order to reduce the possibility of reporting false positives. Further, given the possibility that not all particles would be recovered with the techniques used, spiked recoveries were essential to account for any losses during the processing. While we used two dense polymers (nylon and PVC), spiked recovery using a range of polymers and particle sizes, extracted using the same techniques as the environmental samples, is essential to gain an understanding of how recovery may vary based on particle type, shape and size. We employed state-of-the-art analytical techniques (linear array FTIR combined with MP Hunter software for data analysis). Such techniques require substantial sample processing, including digestion of organic material, to produce a ‘clean’ sample for analysis. As such we optimised wet peroxide oxidation (Fenton’s reagent) and enzymatic digestion (cellulase and trypsin). For complex inorganic matrices such as sediments and sludge, a flotation step is also essential. This presentation will detail the challenges faced in implementing such controls, and highlight the critical need for such standards, especially when communicating levels of microplastic contamination and risk to governments, industry and the public. Our results highlight the critical need to account for blank contamination: many studies to date would have reported far lower concentrations if carrying out such rigorous quality controls as implemented here.

464 Method optimization of microplastic extraction from marine sediments

M. Cashman, University of Rhode Island / Geosciences; K.T. Ho, US Environmental Protection Agency / Atlantic Ecology Division; T.B. Boving, University of Rhode Island / Department of Geosciences; T. Langknecht, ORISE / EPA AED; R.M. Burgess, US Environmental Protection Agency / Atlantic Ecology Division

The distribution and fate of microplastics (MPs) (plastic particles < 1 mm in size) in marine environments are largely unknown. There are over 100 peer reviewed extraction methods for the isolation of microplastics from marine sediments; however, major procedural differences prevent meaningful comparisons among methods. Prior to this study, we conducted a method comparison analysis to assess the applicability of five popular methods to recover microplastics of different polymers, sizes, and shapes from two sediment types. Results from the method comparison analysis suggested that isolation of different MPs is strongly dependent upon MP properties, isolation method, and sediment characteristics. These prior results were used to develop a new method to extract microplastics (45-1000 μm) from amended environmental sediments which varied in sediment composition and percent organic carbon. Plastics tested included polypropylene (PP), low density polyethylene (LDPE), high density polyethylene (HDPE), polyethylene terephthalate (PET), and polystyrene (PVC). Results indicated that this new method generally extracts over 70% of tested MPs from both sandy and silty sediments. The results presented include quantification of the performance of this hybridized method, as well as initial recommendations for routine microplastic monitoring in marine sediments.

465 Chemical compatibility of microplastic polymers with commonly used and novel biological preservation and digestion methods

J. Karr, Hawaii Pacific University; R. Sandquist, University of Miami; J. Whitney, J. Gove, National Oceanic and Atmospheric Administration; D.K. Hyrenbach, Hawaii Pacific University / Natural Science; K. Korsmeyer, Hawaii Pacific University; J. Lynch, National Institute of Standards and Technology

Plastic pollution is abundantly present in diverse marine habitats of Hawaii, including the nearshore habitat of planktonic larval fish that are economically and ecologically important. We have documented, using labor-intensive micro-dissection and Raman microscopy methods, that larval fish in this habitat are ingesting microfibers. Like other labs we are on a quest for higher throughput and automated methods to monitor the quantities and identities of microplastic debris in environmental samples.
Instead of micro-dissection, we considered five categories of previously published methods for digesting biological tissues away from ingested microplastics: acid, base, hydrogen peroxide, enzyme and ultrasonication. The first three methods use chemicals that are poorly compatible with some plastic polymers. Certain polymers anticipated in our samples are expected to dissolve in the chemical treatments (e.g., nylon in acid, base or hydrogen peroxide), leading to significantly underestimated quantities. Chemical compatibility with typical sample preservation methods is also a concern. The goal of this study is to test the compatibility of 14 polymers from several commonly used and novel preservation and digestion techniques, in triplicate and in the absence of biological tissue. Polyethylene terephthalate (PET), high density polyethylene (HDPE), polyvinyl chloride (PVC), low density polyethylene (LDPE), polypropylene (PP), polystyrene (PS), cellulose acetate, nylon, polymer containing a high proportion of phthalates, polyurethane, as well as cotton and polyester fibers (1-2 mm particle sizes) will be used as representatives of the most common polymers found in Hawaiian marine debris and understudied fibers used in textiles. We will also test the stability of each polymer in two common preservatives, 95% ethanol and formalin, for 1, 7, 30, 60, 120 days and beyond. Recovery of each polymer will also be measured from treatments replicated from five published digestion methods and a novel method using bleach. Changes in particle count, mass, shape, surface texture, and spectra from attenuated total reflectance Fourier transform infrared spectroscopy will be measured. The data will be used to demonstrate the extent of possible underestimation of polymer quantities in previous studies that analyzed biological samples and to select optimal methods for future analysis of a large repository of preserved larval fish sampled from nearshore Hawaii.

466 “One Pot” Method for Collection and Preparation of Water and Sediment Samples for Detection and Characterization of Microplastics

A. Scirele, J.V. Cizdziel, University of Mississippi / Chemistry

In microplastic analyses, one of the most commonly encountered challenges is avoiding sample contamination and minimizing losses during sample preparation steps. This contamination can be addressed through a combination of vigilant laboratory cleanliness and conscious decisions on materials used and worn during analysis, and losses can be minimized by decreasing transfer steps. However, there still exists a very real chance of contamination, carry-over, or loss events which can limit conclusions drawn. Here, we describe a “One-Pot” method (this includes sample preservation, storage, digestion, density separation, and dye-staining steps) which minimizes sample contamination and avoids transfer losses and carry-over events by keeping a sample in the same jar it was collected in until the sample is placed on a filter for analysis. Furthermore, this method uses relatively inexpensive and easily purchased or assembled materials such as canning jars and wire screens. Insight from the use of this method on samples collected from the Mississippi River is also detailed. In summary, the “One-Pot” improves the reliability of microplastic analyses, particularly for the smaller size fraction (less than about 0.5 mm) which are more prone to contamination and transfer losses.

467 Development of Evidence-Based Standards: Optimization of Raman Microscopy Methods for 1 um Particles of Five Different Plastics

J. Gielenga, University of California, Davis / School of Veterinary Medicine; G. Liu, M. Van Zijll, University of California, Davis / Department of Chemistry; J. Lang, S. Teh, University of California, Davis / School of Veterinary Medicine

Raman microscopy is a non-destructive method for definitive identification of microplastic particles from environmental samples and is useful for evaluating microplastics in the 1-20 um size range. Integration of imaging software and automation with Raman analysis provides the opportunity for more efficient and comprehensive evaluations of microplastics. However, analytical settings and target particle characteristics such as laser power, integration time, particle size, and the type of plastic being analyzed can all affect the quality of spectra produced. This can significantly impact results especially for samples containing particles of different sizes or composition. Evaluation and optimization of these parameters is necessary to ensure results are accurate and reliable. This study evaluated the effect of laser power and integration time settings on target particle integrity and spectral quality for 1 um particles of five different plastics commonly found in environmental samples. Particles were filtered onto aluminum-coated polycarbonate filters and analyzed using Raman confocal microspectroscopy with a 532 nm wavelength laser using different combinations of laser power and acquisition times. Following analysis, particle integrity was visually evaluated and the quality of each resulting spectrum was determined by measurement of signal to noise ratios and comparison to an in-house reference. This data was used to determine optimized Raman analysis parameters for the five plastic types evaluated. The results of this study are a step forward towards the goal of validation and optimization of Raman microspectroscopy for application to environmental microplastics samples, which is necessary for establishing evidence-based methodology standards for this important analytical technique.

Incorporating New Approach Methodologies to Improve Ecological Risk Assessment - Part 1

468 Transcriptomic Dose-Response Modeling Provides Points of Departure that are Highly Correlated to Apical Measures of Aquatic Toxicity

J. O'Brien, F. Page-Lariviere, D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre

Transcriptomic dose-response modeling (TDRM) is a promising quantitative approach to derive protective estimates of points of departure (POD) for chemical risk assessment. To date, this method has primarily been applied in rodent and human models. Few studies have evaluated its application to environmental species. Here, we used publicly available toxicogenomics datasets to demonstrate that TDRM can produce protective POD estimates for various aquatic species (fish, daphnia, frog) exposed for short (<7 days) or long (>14 days) periods to different classes of chemicals (endocrine disruptors, flame retardants, herbicides and a metal). Toxicogenomics datasets (n=12) from aquatic organism exposure experiments with a minimum of four dose groups were downloaded from the gene expression omnibus (GEO). For each experimental dataset, transcriptomic points of departure (tPODs) were determined using the benchmark dose (BMD) method. Briefly, the tPOD was identified as the first mode or tenth percentile (whichever was lowest) of the distribution of the BMDs of all significantly differentially expressed transcripts. Most of the chemicals tested demonstrated a multimodal distribution of transcript BMDs, indicating a dose-specific co-ordination in the expression of large groups of genes. In most instances, the tenth percentile BMD was lower than the first mode BMD, and was used as the tPOD. tPODs were then compared to lowest observable effect concentrations (LOECs) for traditional apical measures of chronic toxicity (e.g. reproductive toxicity, lethality) determined in the same species as the transcriptomic datasets. LOECs for each chemical/species combination tested were identified from risk assessment documents from various regulatory jurisdictions. Overall, we found a very strong correlation between tPOD and the apical LOEC (R2=0.88). All of the tPODs were within one order of magnitude of the LOEC. Greater than 90% of tPODs were protective (i.e. equal or lower than the LOEC). These results provide compelling evidence that TDRM can be used to generate a POD that is protective of chronic toxicity for various aquatic species, chemicals and exposure durations.
469 Development of a zebrafish minimal set of sufficient key events (minSSKE) PCR array to screen chemicals for the potential to cause cancer

E.J. Perkins, L. Burgon, M.S. Wilbanks, US Army Engineer Research and Development Center / Environmental Laboratory; J. Mylroie, N. Reyero, USACE Engineer Research and Development Center / Environmental Laboratory

Determining the potential of a chemical or mixture of chemicals to cause cancer can be a costly and lengthy process. Many of the mechanisms underlying tumor formation and cancer are conserved among vertebrates suggesting that Key Events underlying Adverse Outcome Pathways (AOPs) for tumor formation could be used to screen chemicals in animal alternative models such as zebrafish embryos. To explore this, we first developed a liver cancer (AOP) network based on mammalian literature. We then identified a set of 6 genes where individual AOPs converge and whose activation or inactivation is sufficient to predict activation of a Key Event within the AOP network. The minimal Set of Sufficient Key Event (minSSKE) genes included vegfa (angiogenesis), rbl (regenerative proliferation), foxm1 (regenerative proliferation), cdkn1a (regenerative stasis), and pcna (translesion synthesis). The genes were validated using analysis of microarray data for rats exposed to several known carcinogens in the Open TG-GATES data set. A PCR array for zebrafish embryos was designed from the minSSKE and was used to assess the carcinogenic potential of extracts from passive sampling devices exposed for one month to rivers near the Great Lakes and in complex mixtures of known chemicals. Exposure to PAHs from passive sampler extracts resulted in upregulation of rbl, cdkn1a and pcna while acs1a was downregulated indicating the potential for the chemical mixtures in the river water to cause tumor formation. We also examined the carcinogenic potential of mixtures of 20 known chemicals on zebrafish embryos using the PCR array. While the full mix of 20 chemicals caused upregulation of vegfa and foxm1, withholding Individual chemicals or classes of chemicals from the mixture resulted in no change of gene expression or upregulation of rbl and/or vegfa. This analysis indicates that a PCR panel based on the Liver Cancer minSSKE can be used to assess tumorigenic effects of chemicals. This approach has the advantage that each gene examined can be mechanistically linked to an adverse outcome of regulatory concern. Being able to directly connect chemical exposure to adverse effects by examining gene expression of sufficient Key Event components should facilitate prioritization activities in addition to hazard and risk assessment activities.

470 Linking molecular to bioenergetic responses: Metabolomic and lipidomic data inform changes in energy budgets of freshwater alga exposed to copper

L.M. Stevenson, Bowling Green State University / Biological Sciences; R.M. Nisbet, University of California, Santa Barbara; N. Garcia-Reyero, US Army Engineer Research and Development Center; P. Antczak, University of Liverpool

Comprehensive and efficient Ecological Risk Assessment depend on our ability to quantitatively extrapolate the effects of stressors, including toxic chemicals, under various environmental conditions, across levels of biological organization, and among species. The utility of bioenergetics models, such as Dynamic Energy Budget (DEB), has been demonstrated with many species to extrapolate from individual- to ecological-level effects of multiple stressors. However, DEB’s use of abstract variables obscures mechanistic connections to suborganismal biology, which complicates the use of “omics” data (OMICs: transcriptomic, metabolomic, lipidomic, etc) to predict impacts of contaminants on individuals. It would significantly strengthen DEB’s predictive power to be able to utilize the vast amounts of suborganismal data made available by advances in molecular and computational approaches. The ability to connect suborganismal (e.g. OMIC) data to bioenergetic impacts could allow the extrapolation of contaminants effects across levels of biological organization. We collected data on the molecular and individual-level response of the model freshwater green alga, Chlamydomonas reinhardtii, to copper (Cu, as CuCl₂). We generated metabolomics and lipidomics data from algae exposed to 4 concentrations of Cu over 7 time points (0-145h). The design of the experiment was guided by requirements of both DEB modeling and OMICs data analysis. We identified metabolites and lipids that varied significantly across time, concentration, and their interaction. Analysis of the metabolomic and lipidomic data sets have identified potentially impacted pathways that may further inform a DEB model of the algal response, similar to the identification of cascading impacts that lead to adverse outcomes in the Adverse Outcome Pathway (AOP) framework. In parallel, we developed a DEB model to describe Cu’s impact on the algae. We developed a toxicokinetic model of Cu uptake by the alga, and the internal concentration of Cu impacts algal bioenergetics. Cu’s mode of action within the model is both informed by the OMICs data analysis and also by identifying the mode of action yields the best fit of the DEB model to the algal and extracellular phosphorus data (similar to traditional “DEBtox” methods). In this way, we can test our framework of connecting OMICs data to a DEB model by comparing its result to the more traditional “DEBtox” method of identifying the mode of action of a toxicant.

471 New approach methodologies to elucidate smoke dyes adverse effects

N. Virus, US Army Corps of Engineers / Engineer Research and Development Center; L. Truong, Oregon State University / EMT; L. St. Mary, Oregon State University; L.D. Burgon, US Army Engineer Research and Development Center / Environmental Laboratory; R.L. Tanguay, Oregon State University / Sinnhuber Aquatic Research Laboratory and the Environmental Molecular Toxicology; E.J. Perkins, US Army Engineer Research and Development Center / Environmental Laboratory

The field of (eco)toxicology keeps evolving towards the development of New Approach Methodologies (NAMs) not only as alternatives to animal models but also as faster and more accurate approaches to predict adverse effects on different species. Here, we explore the use of a set of biological and computational approaches to elucidate the potential adverse effects of six smoke dyes. Smoke dyes are specialty colorants designed specifically for pyrotechnic colored smokes, which have several uses including distress signals, smoke locators, or pyrotechnical devices among other. Some of those dyes can be used as food colorant as well. We used the zebrafish embryo to understand the potential adverse effects of six smoke dyes by analyzing morphological and behavioral effects as well as changes at the transcriptional level. The tested dyes were anasol red, anasol violet, anasol yellow, anasol green, anasol blue, and anasorpe red. All dyes except for anasol green had some morphological effects. Three of the dyes also presented behavioral effects. In order to understand if the behavioral effects were due to the ability of the dyes to cross the blood brain barrier (BBB), we used the in vitro PAMPA permeability assay. Four of the dyes showed some permeability to cross the BBB. In order to develop a transcriptional point of departure leading to predict hazard, we performed RNAsq on five different concentrations of each dye. The transcriptional data together with the apical effects is being used to develop a better understanding of smoke dyes hazard following an Adverse Outcome Pathway framework approach.

472 Swimming in circles: Improving detection of altered fish larval behavior after exposure to environmental chemicals

J. Albers, J. Steibel, Michigan State University; R. Klingler, University of Wisconsin, Milwaukee; L. Ivan, Michigan State University / Fisheries and Wildlife; D.E. Nacci, B.W. Clark, US Environmental Protection Agency / Atlantic Ecology Division; M. Jones, Michigan State University / Quantitative Fisheries Center; N. Reyero, US Army Engineer Research and Development Center; M.J. Carvan, University of Wisconsin, Milwaukee / School of Freshwater Sciences; C.A. Murphy, Michigan State University / Department of Fisheries and Wildlife

Fish swimming behavior is often measured in aquatic ecotoxicology because it is a sensitive endpoint that can indicate neurological impairments after chemical exposure. Recent advancements in animal
movement models that contain components of discrete-time random walks suggest an improved approach to detecting altered behavior. Our application of this approach uses swimming behavior assessed at every recorded time point instead of summarized over time or over groups of fish, as is done often. We propose that the construction of hierarchical movement models that use individual fish frame rate movements will incorporate the multiple levels of variability and sensitivity recorded in these assays so that subtle behavioral responses, essential to fish survival and growth, can be detected. We applied this approach to analyze swimming behavior assays on fish larvae after exposure to sublethal levels of polychlorinated biphenyl congener 126 and methylmercury, two known neurotoxins that are common in the Great Lakes ecosystem. Over a set amount of time, the x-y coordinates of each individual fish were recorded at every video frame and the mean step length and turning angle were calculated. Using these parameters and animal movement models, we determined the characteristics of slow and fast swimming states, the probability of changing between states, and how they were altered under different chemical doses. The results from the movement models will be used to simulate individual non-random larval movement rates in population models and predict how altered swimming patterns might impact simulated growth or survival due to chemical exposures.

473 Towards risk assessment of data-poor species - from life history to physiological models through phylogenetic inference

Practical ecological risk assessment is a world apart from standardized ecotoxicological studies: it deals with time-varying exposure, non-lethal endpoints, and a multitude of species. This calls for physiological models that translate exposure to chemicals to relevant organismal endpoints, and for methods that extrapolate physiological and life history information across species, especially to those with limited data. The value of physiological models in risk assessment is widely recognized, as evidenced by mention of Dynamic Energy Budget (DEB) models in ISO and OECD guidance and EFSA scientific opinion. These models offer process-based descriptions of growth, reproduction and survival, readily adapted for effects of toxicants. However, DEB models can be difficult to parametrize, which is an obstacle to their wider adoption. This is especially challenging for species listed under the Endangered Species Act (ESA): as these are subject to regulatory limitations on data collection, we usually know little about them beyond taxonomic classification and a few life history statistics (e.g., maximum size, lifespan, fecundity). Here, we show how new physiological models can be built by combining a database of existing DEB models (over 1700 species in the Add-my-Pet database) with information on the taxonomy and life history of the species of interest. Our method produces an ensemble of DEB parameter sets, characterizing the most likely model and associated uncertainties (https://deb.bolding-bruggeman.com). Using a new compilation of traits of freshwater bivalves listed under the ESA, we demonstrate how a carefully picked set of life history statistics suffices to produce well-constrained DEB models, ready for further integration into population models for use in risk assessment.

474 Assessing risk to imperiled species: Modeling freshwater mussel populations

A. Moore, University of Minnesota, Twin Cities / Department of Ecology, Evolution, and Behavior; N. Galic, R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety; D. Hornbach, Macalester College; V. Forbes, University of Minnesota / Ecology, Evolution & Behavior

Freshwater mussels are a highly diverse and imperiled faunal group; of 296 species currently identified in the US more than 70% are considered threatened or endangered (“listed”), or of special concern. Due to restrictions on testing endangered species and the difficulty of working with freshwater mussels in the laboratory, it is essential that predictive methods be developed to better assess the risks posed to listed freshwater mussels by a multitude of aquatic contaminants and other stressors. Dynamic Energy Budget (DEB) theory describes allocation rules of energy to metabolic processes and can be applied to quantify physiological responses (described as changes in growth, survival, and reproduction) of an individual to stressors in its environment. A major advantage of DEB models is the generic nature of the underlying theory which allows for broad applicability across species due to similarities in model structure. In this project we develop a trait-based modeling approach for freshwater mussels with the aim of assessing potential risks to listed species from exposure to various stressors. First we performed a life-history analysis in order to group mussel species into life-history categories for modeling and to identify appropriate and well-described representative species. Using these life-history categories, we then developed a generic DEB model framework for the representative species, allowing for comparison of parameters between species with different life-history traits. The DEB modeling framework we develop for the life-history types will be an integral component of individual-based models which simulate population properties from local individual behaviors. Ultimately the aim of this project is to provide improved population modeling approaches for assessing risks posed by various stressors for data-sparse listed species.
Advocating Science: Practical Approaches to Presenting Information and Results Without Advocating Policy or Preference

476 Practical Examples to Effectively Presenting Science Information and Results Without Advocating Policy or Preference

W.L. Goodfellow, Exponent / Ecological and Biological Services Practice; T. Canfield, US Environmental Protection Agency / National Risk Management Research Laboratory; P.D. Guiney, University of Wisconsin / Molecular and Environmental Toxicology Center

Currently presenting technical information and one’s position is seemingly under increasing pressure to make sweeping claims, maximize impacts or simply enhance being noticed. Environmental management and policy is only as good as the science that informs the discussions and ultimate decisions. Without a sound understanding of how environmental systems work and how stressors on these systems can affect ecosystems, programs intended to manage these systems will continually be off target and policies developed to protect and enhance these systems may be inadequate due to this overall lack of scientific understanding by decision makers and the general public. An important aspect of the science that forms the foundational information needed to make correct decisions for managing these systems and developing policy is that the science and how it was obtained have to be transparent, well documented and impartial to the potential regulatory decisions that are under consideration. This talk will set the stage for the session “Advocating Science: Practical Approaches to Presenting Science Information and Results without Advocating Policy or Preference” by providing examples and experiences of the authors. Using case examples, the authors will explore issues related to proper science integrity and how the general misuse of science is most particularly in ecotoxicology and chemistry applications can be related to proper science integrity and how the general misuse of science at the core business is directed by policy and regulatory requirements, research provides an opportunity to perform and present scientific information in a pure form with clear research questions, methods, results, and conclusions. The key to disseminating unbiased scientific information within our organization is tied directly to our research and development program philosophy and the research design applied within the program. Each year, our small CRO sets aside research funds based on a percentage of the prior year’s profit which provides an opportunity to conduct research and offers financial incentives through tax dollar savings. Within this program, applied research which has no agendas, only solid research questions are performed. The research design that follows the initial work, including eventual connection with outside funding sources, is key to conducting and eventually presenting unbiased scientific information. Ultimately, this philosophy bleeds into all aspects of study work yielding higher quality science and less bias in the dissemination of the information. A case study from within this research program examining the neurological and behavioral mechanisms of BMAA (beta methylamino-L-alanine) toxicity in zebrafish will be presented. BMAA a ubiquitous algal toxin thought to cause CNS effects higher animals, including in humans. The discussion will demonstrate how this work has emerged from our program to be of interest in the private sector and how we maintain a non-agenda driven focus for this program while furthering the work including securing outside funding.

479 As science advances, so should its implementation in environmental policy and management

V. Forbes, University of Minnesota / Ecology, Evolution & Behavior

My premise is that environmental management decisions and policies informed by robust science are likely to be more effective than those that are not. As academic scientists, we view our role as advancing scientific understanding of natural systems and the impacts of human activities on them in ways that can be helpful to decision makers. Challenges in doing this include that natural systems are often extremely complex and characterized by non-linearities and emergent properties that make predictions difficult to achieve with confidence. This can result in one of two tendencies: to ignore the complexity and default to simplistic, presumably worst-case assumptions; or to over-complicate matters by focusing on the complexities without offering pragmatic solutions. Neither strategy appropriately balances the costs and benefits of management decisions to ensure that the things people care about are being protected. Despite substantial advances in the science, there are strong tendencies to retain traditional, simplistic approaches for using science in management and policy due to the time and effort needed to learn and implement new methodologies, various legal constraints, and basic resistance to change. Improving the scientific underpinnings of management and policy means replacing outdated approaches with better ones; not continuing to add new methods on top of existing ones. Such changes in how and which science is used will be most effective if debated with some distance from ongoing decisions and if doing so involves a partnership among all affected stakeholders to minimize bias and conflicts of interest and to ensure transparency and buy-in.

480 SETAC International Programs Committee (IPC) as a Vehicle for Promoting Objective Scientific Dialogue

K. Thomas, Global Silicone Council

Encouraging non-biased scientific dialogue that addresses advancements, and weaknesses, in the science associated with environmental toxicology and chemistry benefits practitioners from industry, government, and the academic community. For government experts, this dialogue informs the development of risk evaluations that ultimately impact regulatory decision-making. For industry, it provides useful insights that provide direction for product research, development, and stewardship, and for the academic community it helps to identify critical data and information gaps that drive priorities for basic research. The SETAC International Programs Committee (IPC) has been actively engaged in fostering scientific dialogue in way that is mutually beneficial to SETAC’s
core constituency in government, academia, and industry. The IPC has hosted symposia and workshops on a variety of topics including national and regional chemicals management approaches and methodologies for conducting ecological risk evaluations. The IPC has also engaged the global scientific community by hosting side events with international organizations such as the Stockholm Convention Persistent Organic Review Committee (POPRC) and the Conference of the Parties (COP). This dialogue has taken place across a variety of geographic regions including North America, South America, Europe, and Asia. These sessions have brought scientists together in a collaborative manner with a primary goal of leveraging SETAC’s strengths to advance the science. This presentation will summarize the work that the IPC has done to advance the scientific dialogue and highlight work that is planned for the future.

481 A Logical and Applied Ethics Analysis of Scientific Integrity and Perceived Conflicts of Interest in Environmental Toxicology

L. Burgoyne, US Army Engineer Research and Development Center / Environmental Laboratory

The primary objective of science is to obtain knowledge and identify the truth. Some advocacy groups, and some national and international agencies that identify chemical hazards and risks, refuse to use guidelines and studies funded by industry interests. Instead, these groups prefer to rely upon only those studies that have been published in peer-reviewed journals, or in some rare cases, guideline studies that they have paid to be peer-reviewed by an independent panel. In addition, some organizations and prominent scientists have argued that the public must be suspect of scientific studies in the peer-reviewed literature paid for by industry interests. In this presentation, I will discuss the logical fallacy that underpins these arguments, and perform a logical analysis that demonstrates how these arguments centered on sources of funding and conflicts of interest actually lead to the logical conclusion that all of the scientific literature, regardless of funding source and potential conflicts of interest, are false and untrustworthy. I will also examine this situation under an applied ethics lens, and illustrate the unethical behavior associated with discounting of science not based on how the study was performed, but rather on labels of who paid for the study. I will then discuss ways out of this conundrum, ways to defeat/avoid the logical fallacy, highlight the importance of critical thinking, and methods to ensure the soundness of science through Bayesian statistical approaches. The US Army Chief of Engineers has approved this paper for release. The views presented in this article do not necessarily reflect current or future opinion or policy of the U.S. Army Corps of Engineers.

482 The roles for and constraints derived from method standardization in international chemical environmental risk assessment

S.E. Belanger, Procter & Gamble Company / Global Product Stewardship

A recent Pellston workshop, “Improving the Usability of Ecotoxicology in Regulatory Decision-Making,” held in 2015, addressed the role of ecotoxicity testing in risk assessment. Many facets of data development and utilization were discussed resulting in a series of published manuscripts on reliability assessment, relevance assessment, weight of evidence formulation, and the philosophies to improve testing. A good balance of private sector, academia, and government scientists from across the globe worked through many aspects that also intersect with science advocacy. In this talk, I discuss how methods standardization at the international level is essential to the remove some features of bias, but at the same time is limiting as science advances. Non-standard and novel approaches fill the scientific gap between old “tried and true” methods and scientific progress on their way to become accepted and standard approaches themselves. Use of non-standard approaches therefore become integral to weight of evidence formulation and can become key cogs in the evaluation of new and existing chemical technologies in global management of chemicals. Openness to adapting and adopting the new science becomes a difficult challenge for prescriptive regulatory environments and requires a dispassionate evaluation of reliability, relevance, and repeatability of the generated information.

483 Agenda-Driven Normative Science, White-Hat Bias and Censorship: Why Peer-Review Needs an Overhaul

C. Borgert, Applied Pharmacology & Toxicology, Inc.

In applied sciences, “normative” is defined as “a type of information developed, presented, or interpreted according to an assumed but usually unstated preference for a particular policy or class of policies. By example, public health, and ecosystem health, are often presumed to be desired outcomes and are promoted as explicit policies, while health risks are to be avoided. The enaction of these policy preferences constitutes advocacy. “White Hat Bias” is a phrase coined by public health researchers David Allison and Mark Cope to describe a “bias leading to the distortion of information in the service of what is perceived to be righteous ends,” often involving cherry-picking of evidence and publication bias. Righteous zeal and indignation toward certain aspects of western industry are used to construct a white-hat veneer. “Righteous ends” as described by Allison and Cope, serve well the objectives of normative science. Normative science and white-hat bias work together to distort public perceptions of science and its place within society and politics and ultimately, to justify a type of censorship defined as “-suppressing scientific reports by delaying their release or failing to make them available to the public” and/or “-removing otherwise qualified scientists from important positions by virtue of their disagreement with the current politics ... or because their research yielded results that did not favor the administration’s policy.” This presentation details a case study, the scientific underpinnings of which were published as companion articles in Environmental Toxicology and Chemistry in 2007. These publications debunked a body of literature promoted as evidence of endocrine disruptive effects on gender determination in endangered reptilian species. Despite scientific discreditation, that body of literature continues to be promoted as normative science to promote policy objectives regarding chemical regulation in the European Union. Fueled by the perception of righteous ends, these policy objectives have led to white-hat bias and scientific censorship within at least one prominent scientific society. This situation is not unique; collectively it erodes the epistemological basis of scientific inquiry, evidence, and progress. Only a drastic revision of the peer-review process and a tidal change within science can rectify this revolutionary trend and effectively correct societal and political misperceptions of science.

Ecosystem Services for Improved Decision-Making

484 Linking ecosystem services to health, economics and wellbeing through classification systems and achieving 18 benefits

J. Finisdore, Sustainable Flows

Recent studies show that ecosystem services analysis can have greater impact, be more accurate, and be more interoperable with the use of formal classification systems. These systems embody approaches such as: focusing on direct benefits to people, or “final” ecosystem services; clearly defining ecological endpoints and published in ERA or LCA; and using consistent, inclusive, and mutually exclusive hierarchies for defining ecosystem services. The Common International Classification of ecosystem services (CICES v 5.1) and the National Ecosystem Services Classification System Plus (NESCS Plus) are exemplary ecosystem services classification systems. These ES-CS were proposed by the European Environment Agency and USEPA, respectively, to improve communication among ecologists, economists, policy makers, and stakeholders. Effectively, they link ecological conditions, processes, and functions to economies and communities. This presentation will review the development of ES-CS and the 18 benefits that their use can provide. Case examples will be provided from real and desk applications of these ES-CS possibly including in ESA and LCA fields.
486 Integrating Aquatic Designated Use Protection and Restoration Strategies Using an Ecosystem Goods and Services Framework

J.M. Diamond, B. Tonning, K. Parry, Tetra Tech, Inc.

Water quality standards programs in the United States and other countries are based on designated uses (DUs), which are linked to criteria specifying maximum pollutant levels and other characteristics that are thresholds for waterbody compliance with regulatory goals. Most DUs are similar to certain provisioning ecosystem goods and services (EGS), such as drinking water supply and recreation (e.g., boating, fishing). Absent in the DU concept is supporting or regulating services, which results in disjointed and often ineffective aquatic ecosystem protection and restoration strategies. The focus on discrete sets of water quality parameters in the DU concept can often result in the appearance of conflicting DUs, resulting in poor provisioning of certain DUs. We present a framework that uses EGS to provide a more holistic assessment of DUs and help inform best management practices that could result in fuller attainment of DUs while providing greater provisioning of desired goods and services. Two case studies are discussed demonstrating some of the issues with the DU concept, how it is implemented in the U.S., and how the EGS framework can provide a crosswalk between the DU paradigm and stakeholder goals for a watershed. A process is presented that could help regulatory agencies and stakeholders make better use of the EGS framework in DU decisions, including watershed protection and restoration. The EGS framework presented here, coupled with a watershed stakeholder process focused on developing an integrative management strategy based on the framework, could help achieve multiple beneficial uses in an aquatic system.

487 EPA's EcoService Models Library (ESML): Applied Use Cases for a New Tool for Quantifying and Valuing Ecosystem Services

Ecosystems provide a variety of goods and services. For example, they regulate the quality of our air and water, provide protection from storms and floods, produce foods and other essential materials, and provide opportunities for recreation. Recognizing ecosystem services (ES) and understanding how society’s decisions affect them, is critical to sustaining human well-being. Computational models describing the processes underlying ES are useful for protecting, enhancing, and creating ES and thereby increasing human well-being. However, discovering and selecting those models is difficult because information about them is scattered throughout journals, websites and government reports. Information describing these models also is not uniform and can be difficult to assess via typical bibliographic searches. The EcoService Models Library (ESML) has been developed as a repository for ecological models. ESML is a publicly available website and database for finding, examining and comparing over 160 EMs for estimating ES. This presentation will demonstrate how ESML was used to find ecological models for identifying and characterizing ES socioeconomic benefits for three environmental scenarios: 1) adding constructed wetlands to agricultural landscapes to manage nutrient pollution; 2) during the ecological risk assessment process at hazardous waste sites; and 3) applying best technology available (BTA) to minimize adverse environmental impacts from impingement and entainment of fish and invertebrates at facilities operating cooling water intake structures.

488 Joining ecosystem services with ecological risk assessment to better articulate ecosystem protection importance for hazardous waste site cleanups

C.G. Maurice, US Environmental Protection Agency / Research & Development / Science Policy; G. Ferreira, US Environmental Protection Agency / Region 2 / Land, Chemical, & Redevelopment Division; T. Newcomer-Johnson, US Environmental Protection Agency / NERL / Systems Exposure Division

In the United States, federal hazardous waste site cleanups are conducted under the Environmental Protection Agency (EPA) Superfund and Resource Conservation and Recovery Programs. The statutory mission of these two cleanup programs is remediation rather than rehabilitation; however, untapped opportunities exist to conduct remediation in more ecologically beneficial ways. We propose a logic train of: better understanding to increased appreciation to greater attention/action during cleanup planning and implementation; however, greater action needs to be fed with ways ecosystems can be supported within the cleanup statutory framework. We provide some suggestions of ways ecosystem classification systems and ecosystem goods and services (EGS) models and other tools could be employed to bolster the use of ecological risk assessment (ERA) findings in the hazardous waste site cleanup decision-making process. We propose that better articulation of the benefits to human well-being and health in local communities from healthy, functioning ecosystems ultimately will help lead to greater consideration of ecosystems during cleanups. To this end, we consulted the EPA EcoService Models Library (ESML) as well as EPA guides and publications on ERA and EGS to identify opportunities for better articulating the significant benefits provided to human communities by ecosystems. In addition to increasing general recognition ecosystem benefits, the other part of the challenge is to incorporate EGS and EGS tools into hazardous waste site cleanup process, especially ERA through roadmaps more clearly linking ecosystems, ecorisk, remediation, and ecological protection and rehabilitation. We have organized EGS models according to their topic and parameter foci to facilitate their application in ERA. Similarly, we have organized EGS concepts, tools, and approaches. In doing so, we have initiated the development of roadmaps to clarify the importance of ecosystem protection and provide insight regarding ways that considerations and modifications during hazardous waste site cleanups can lead to increased benefits for local communities. We suggest EGS models and other tools to facilitate their use in helping to clarify and strengthen ERA findings at hazardous waste sites. We are working toward applying these approaches and roadmaps to specific hazardous waste site cleanups.

489 The Integration of Ecosystem Services Into Human Health and Ecological Risk Assessment to Foster Better Risk Communication

M.W. Kierski, C. Menzie, Exponent / Ecological and Biological Services Practice

The U.S. Environmental Protection Agency (EPA) defines ecosystem services as the outputs of ecological processes that contribute to social welfare or have the potential to do so in the future. An example of an ecosystem service would be the food that a healthy fish population in a river provides to recreational anglers, the key being that ecosystem services provide tangible human benefits to ecological protection that occurs within a properly functioning ecosystem. In this presentation, we will explore the concept of ecosystem services and show how integrating ecosystem services into ecological risks assessments can provide a clearer way to communicate results to decision makers and other stakeholders including the public. While integrating ecosystem services into ecological risk assessment has begun to gain favor with EPA, it has not gained traction within the general practice of ecological risk assessment. We will explore possible reasons why and provide examples of how ecosystem services can be easily integrated into ecological risk assessments. In addition, we believe that the concept of ecosystem services allows a risk assessor to integrate both the human health and ecological risk assessment components of baseline risk assessments together in ways that are not possible without it. We will also explore examples of how this integration...
can be accomplished and improve risk communication. We will use an example of a baseline risk assessment performed under the Superfund program to compare and contrast the look and feel of the risk assessment results using the standard risk assessment approach and the integrated ecosystem-service-based approach. We believe that with this integration it is possible to more clearly communicate the ways that fostering a healthy ecosystem can lead to a healthy life, which will provide stronger and clearer arguments for when and why remedial action is required to solve an environmental problem.

490 An Exploration of Economic Valuation of Phosphorus in the Environment and its Implications in Decision Making
M. Sena, M. Rodriguez, University of Wisconsin, Madison / Civil and Environmental Engineering; M. Seth, Madison Metropolitan Sewerage District; A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering

In decision making processes today it is typically economic considerations that are the focus and that dictate what choices are made. However, this approach neglects or minimizes significant potential impacts these decisions can have, namely impacts to the environment and on our ecosystems. One way in which environmental considerations can be incorporated better into current decision making processes is through monetary valuation of ecosystem services or environmental damages. This work surveys environmental economics literature on monetary valuation of nutrients and nutrient pollution focusing specifically on phosphorus (P), and applies monetary valuation of P to a case study of nutrient recovery in wastewater treatment. The literature assessment highlights how widespread nutrient pollution issues are, and demonstrates the range in potential economic consequences from nutrient pollution related issues. Additionally, the literature survey shows a discrepancy between what the public has said they are willing to pay for P removal or reduction versus actual costs to remove P once it has entered the environment, and alludes to a lack in understanding by the public of the potential economic impacts nutrient pollution can have. Furthermore, the wastewater treatment nutrient recovery case study demonstrates how monetary valuation of environmental damages or ecosystem services can be applied in a realistic decision making scenario, and highlights how variability in monetary valuation methods and results can affect decision making.

491 Applying the National Ecosystem Services Classification System Plus (NESCS Plus) to ecosystem services analysis, revealing benefits
C. Rhodes, TDB Economics

The National Ecosystem Services Classification System Plus (NESCS Plus) is a robust, scalable, and flexible system for linking ecological changes to specific uses of ecosystem services by people. These include uses by communities, governments, and businesses that impact human health and wellbeing, as well as the economy. NESCS Plus, compared to all ecosystem services classification system (ES-CS), most embodies best practices in classification systems design. As a result, it is arguably the most effective ES-CS for delineating elements of ecosystem services that help to select appropriate metrics for analysis or accounting of ecosystem services. This presentation will provide an overview for applying NESCS Plus, building any introductions made during previous presentations in this session. Then, the definitions of ecosystem services--and their metrics--used in studies described in previous presentations will be reviewed with NESCS Plus. Case examples from other studies may also be used. Effectively, opportunities to improve the robustness, utility, and interoperability of the previous presentation will be highlighted. A discussion of the implications of the NESCS Plus follows. This discussion is relevant to all ecosystem services practitioners. The USEPA is very likely to release NESCS Plus before the SETAC North America 40th Annual Meeting. Moreover, even if not fully applying NESCS Plus, ecosystem services practitioners can easily benefit from using some of the definitions and methods associated with NESCS Plus.

Plants in Environmental Risk Assessment: Assessing and Predicting the Effects of Chemicals on Plant Communities

492 Glyphosate Effects and Accumulation in Invasive and Native Wetland Macrophytes
V. Sesin, Trent University / School of the Environment; C.M. Davy, Ontario Ministry of Natural Resources and Forestry / Wildlife Research and Monitoring Section; M.E. Dorken, Trent University / Department of Biology; J.M. Gilbert, Ontario Phragmites Working Group; J.R. Freeland, Trent University / Department of Biology

Invasive aquatic plants can disrupt native wetland communities, with considerable ecological and economic impacts. Glyphosate-based herbicides can control invasive plants, thereby potentially restoring native plant biodiversity, but glyphosate is toxic to all plants. Land managers therefore must weigh the benefits of using glyphosate to manage invasive plants against the potential harm to nearby non-target plants. A balanced decision requires an understanding of the individual sensitivities of target and non-target plants, and the persistence of glyphosate in plant tissues post-exposure. We performed an experimental outdoor microcosm concentration-response study, in which we sprayed a range of glyphosate concentrations (0.1 - 8% solutions of the formulated product, corresponding to 0.5 - 43.2 g/L glyphosate) representing ‘real-world’ applications on two emergent plants that have invaded North American wetlands, Phragmites australis (Common Reed) and Typha x glauca (Hybrid Cattail), and a native co-occurring plant, Typha latifolia (Broadleaf Cattail). At 27 days post-exposure we compared sensitivity and accumulation of glyphosate, AMPA (one degradation product) and alcohol ethoxylate surfactant (from formulation) among the three taxa. Phragmites australis exhibited higher glyphosate sensitivity than both Typha taxa and accumulated more glyphosate and AMPA in above-ground tissues. We observed a qualitative trend of lower sensitivity and lower glyphosate and AMPA accumulation in T. x glauca compared to T. latifolia. Accumulation of surfactant residues was similar among taxa. This is the first evidence of inter- and intra-generic differences in glyphosate sensitivity and accumulation in emergent macrophytes. Our data show that responses of emergent macrophytes to glyphosate cannot be generalized among taxa. Understanding this variation can improve accuracy of predicted responses of invasive and native emergent wetland plants to glyphosate. These predictions can inform environmental risk assessments of glyphosate spray applications in wetlands, and can contribute to implementing effective and sustainable wetland management plans. Our detected glyphosate retention in treated plant tissues calls for further research on its fate in macrophytes.

493 Modeling phytoextraction of Ni-elevated soils using Alyssum species, Port Colborne, Ontario
S. Dehghani, K. Zupfer, L. Vasiluk, University of Guelph / School of Environmental Sciences; M.D. Dutton, hpa, Ltd.; M. Bellantino-Perco, Vale Canada, Ltd.; B.A. Hale, University of Guelph / SES

Abstract- Alyssum spp. as well-known hyperaccumulators of nickel (Ni) are of interest for phytoextraction of Ni-elevated soils such as those resulting from past Ni refining in Port Colborne, Ontario. A greenhouse study using Alyssum spp. planted in three main types of Ni-polluted soil in Port Colborne (heavy clay, organic muck, and sand) investigated the feasibility of using Alyssum spp. for soil-Ni mass transfer. These soils have different physicochemical parameters; irrigation and fertilization treatments were imposed on the three soils. The observed Ni mass distribution between soil and above ground vegetation was used in Stella modeling software to predict hypothetical timelines for the target reduction in soil Ni concentration. In addition, hypothetical Alyssum Ni extraction in several improved phytoremediation systems resulting from manipulation of effective soil physico-chemical properties, were modeled. Nickel concentration in organic, sand and clay soils was 914 mg/kg, 6180 mg/kg, and 4431 mg/kg, respectively. Clay and organic soils demonstrated
494 Evaluating mercury concentrations in edible plant and fungi species of Iqaluit, Nunavut and the surrounding area

R. Bergin, A. Rutter, Queens University / School of Environmental Studies; I. Koch, B. Zeeb, Royal Military College / Chemistry Chemical Engineering

Environmental mercury (Hg) concentrations in the Canadian Arctic is a current area of concern. While efforts are being made to reduce mercury releases into the environment, Hg levels continue to increase within flora and fauna. To date, while there are numerous published articles on the impacts of mercury in Arctic wildlife species, literature on the accumulation in edible plant and mushroom species of the Canadian Arctic is very limited. Therefore, the main objectives of this study were to evaluate the mercury content in edible plant and fungal species of the Canadian Arctic and estimate the potential risk of mercury by consumers. This study was conducted during the summer of 2018 to determine the total mercury concentrations in 47 samples from 18 plant and four lichen species, and 74 samples from five fungal (mushroom) species growing in Iqaluit, Nunavut and the surrounding area. Samples were assessed using cold vapor atomic absorption spectrophotometry and mean mercury concentrations ranged from a high of 3.52 ± 2.0 ppm dw and 2.22 ± 1.59 ppm dw in Lycopodium perlatum and Calvatia cretacea (both puffballs), respectively to a low of 0.008 ppm Hg dw in Eriophorum scheuchzeri (Arctic cotton grass). There were significant differences in mercury concentrations across plant species as well as mushroom species. Work is currently underway to: i) determine if the mercury is from sources in the soil or atmosphere, ii) investigate the potential for mercury to bioaccumulate within consumers, and iii) assess the possible health effects associated with this consumption.

495 Role of duckweed - microbe interactions in the elimination of benzotriazole from salt-contaminated water

Z. Yu, University of Toronto / Chemical Engineering and Applied Chemistry; A.M. O'Brien, D. Luo, J. Laurich, M. Frederickson, University of Toronto / Department of Ecology and Evolutionary Biology; E. Passeport, University of Toronto / Department of Civil and Mineral Engineering and Department of Chemical Engineering

Benzotriazole is a corrosion inhibitor that is environmentally persistent and potentially carcinogenic. Due to its limited removal in conventional wastewater treatment plants, complementary treatment strategies are being explored, such as constructed wetlands. In this study, we investigated the role of duckweed that grows naturally on the water surface of constructed wetlands. Specifically, we evaluated several factors that might influence the transfer and transformation of benzotriazole, including the concentrations of benzotriazole and salt in water, duckweed genotypes, and genotype-associated microbes using three duckweed genotypes collected from ponds located in Ontario, Canada. The reduction in benzotriazole concentration was investigated with and without the presence of microbes, as well as salt at typical stormwater runoff concentrations. Without salt and microbes, the reduction in concentration ranged from 26 to 69% for the duckweed genotypes and initial benzotriazole concentrations tested. In the absence of salt, the decline in concentration was comparable whether microbes were inoculated or not: with microbes, the reduction ranged from 28 to 68%. Without microbial inoculation, the presence of salt at 10 g/L decreased the reduction in benzotriazole concentration to a range of 1.0 to 32%. When both salt and microbes were present, the effect of salt was reduced, and the reduction in benzotriazole concentration ranged from 7.1 to 50%, which is greater than the case where microbes were absent. With the experimental setup, adsorption and phototransformation of benzotriazole were likely negligible. It is therefore expected that the biotransformation of benzotriazole carried out by duckweed and microbes was the primary pathway. Selected samples were further analyzed for benzotriazole transformation products using high-resolution mass spectrometry, and the results suggest the formation of both phototransformation and microbial transformation products. Taken together, these results suggest that duckweed has the potential to remove benzotriazole via biotransformation. Microbes associated with duckweed might further improve water quality, either by directly transforming benzotriazole or by altering plant transformation capacity. Further experiments will be conducted to study the performance of additional duckweed genotypes and the associated microbes, and to determine the depth of the water column that is impacted by duckweed for water treatment.

496 Toxicity of novel fire suppression gels to plant germination and emergence

S. Grotez, P.K. Sibley, R.S. Prosser, University of Guelph / School of Environmental Sciences

Previous research has shown that fire suppression additives containing perfluorinated compounds negatively affect the environment through persistent contamination and bioaccumulation. Manufacturers have introduced ‘environmentally-friendly’ alternatives, but limited studies on their fate and effect in the environment have been completed. A study was completed to investigate the toxicity of six fire suppression gels: Eco-Gel(TM), Thermo Gel 200L(TM), Fire Aid 2000(TM), Solberg Fire Foam(TM), Novacoal Foam(TM), and F-500(TM). Through direct aerial application of fire suppression gels, soil contamination can occur. Toxicity to three plant species was investigated through a root elongation assay and a seedling emergence test. The crop species Fagopyrum esculentum (buckwheat) and Raphanus sativus (radish), were tested in addition to the flowering plant species, Rudbeckia hirta, as it is commonly found within the boreal forest where fire suppression gels may be used to control wildfires. Emergence, growth and/or germination were documented after each test, and the concentration-response relationship determined, allowing the EC50 to be estimated. It was found that there was a large variation in toxicity between the fire suppression gels tested, and that some would pose a hazard to plants when released into the environment. With the knowledge gained from this study, a better understanding of the potential effects of fire suppression gels on terrestrial ecosystems can be developed.

497 Analysis of Non-Target Terrestrial Plant Studies

J.W. Green, JohnWGGreen-ecostats.com / Data Science and Informatics

Two types of Non-target terrestrial plant (NTTP) studies are required for registration of crop protection chemicals. Unlike many aquatic studies, it is not uncommon to test 8 to 10 treatment groups (application rates) or even as many as 12 to 14, in addition to one or two negative controls, with 4 to 10 replicates per application rate. There are three primary response: shoot height, dry weight and survival. Requirements include NOEC determination and ECx estimation, x=50 in Europe and x=25 in the US. There has been recent interest in the US of requiring estimation of ECx for much smaller values of x, such as x=10 or even x=5, at least for the growth responses. Issues of both statistical and regulatory importance for the survival response include how to account for (1) background (or control) mortality and (2) replicate variability, including treatment of the overdispersion that is sometimes observed. Issues of importance for the growth responses include how to (1) model hormesis or low-dose stimulation, which is not uncommon, (2) how to assess the quality of ECx estimates.
for all responses, and (3) to determine what size effects can be estimated reliably from the data resulting from these studies. Another issue is whether the experimental design should be changed, either to improve the quality of the statistical analysis or to reduce the cost of these studies without sacrificing the quality of statistical conclusions. These issues are explored through real data examples and extensive computer modeling. Some common errors are demonstrated that can seriously bias results. Simple, practical recommendations are made to eliminate these errors and improve the quality of results.

498 A Field Spray Drift Study to Determine Downwind Effects to Non-target Plants

D. Moore, Intrinsik Environmental, Inc.; L. S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; R. J. Isemer, Bayer Ag / Environmental Safety - Environmental Effects; T. Xu, Bayer AG Crop Science Division / Environmental Fate; J. Tang, Bayer Crop Science Division / Environmental Exposure Assessment; T. Hall, Bayer CropScience / Environmental Toxicology and Risk Assessment; A. Chapple, Bayer Crop Science AG; Y. Yang, Bayer CropScience / Environmental Fate; J. Hanzas, Stone Environmental, Inc. / Agrochemical Fate and Exposure; B. Brayden, K. Watson, Stone Environmental, Inc.; S. I. Rodney, Intrinsik Environmental Sciences, Inc. / Biology; C. Banman, SynTech Research, Inc. / Ecotoxicology

A spray drift and associated vegetative vigor study was performed to determine the off-field drift deposition and potential toxicity of a herbicide to sensitive non-target plants at various distances downwind from the treated area. Each treatment consisted of four 100 foot wide spray swaths that ran perpendicular to the target wind direction. There were three trials and each was performed on a 515 foot x 334 foot area that included the upwind control plants, treated area, and downwind plants. One trial had vegetation (approximately 12” tall mowed grass; typical scenario) in the downwind deposition area and two trials had bare ground deposition areas (worst-case scenario). Drift collectors placed 5, 30, 50, 75, and 100 feet downwind of the application area were analyzed for herbicide residues. Pots of lettuce and navy bean plants (2-4 leaf stage), two species known to be sensitive to the herbicide, were placed 5, 30, 50, and 100 feet downwind of the application areas. There were 25 replicate pots/species at each downwind distance and 5 replicate pots/species for the corresponding upwind controls. Each pot had 2 plants and plant height was determined prior to application for use as a covariate in the statistical analyses. The lettuce and navy bean plants were subsequently grown out in a greenhouse for 28 and 21 days, respectively. Plant survival, growth stage, phytotoxicity, and height were assessed at 7, 14 and 21 days after treatment (DAT) for all plants and at 28 DAT for lettuce. Dry weight was determined at test termination. No effects occurred to either test species placed in downwind vegetation at any distance. No statistical differences from controls were observed in navy bean or lettuce shoot height or dry weight at downwind distances of 30 feet or further from the edge of the application area for plants placed on bare ground. The field study results contrasted sharply with the high/larger predicted effects and effect zones that can result from using modeled spray drift curves and greenhouse bioassays with direct overspray exposure. This study confirms that comparing spray drift modeled exposure estimates to the greenhouse bioassay results can seriously over predict effects to downwind non-target plants.

499 Experimental studies to provide long-term data sets for testing population models for Lemna sp. and Myriophyllum spicatum

G. Arts, Wageningen Environmental Research WUR / Environmental Risk Assessment; U. Hommen, Fraunhofer IEM; E. Bruns, Bayer AG, Division Bayer CropScience / Ecotoxicology; S. Heine, Bayer Ag / Effect Modelling; A. Solga, Bayer AG Crop Science Division; S. Taylor, ADMA Agricultural Solutions UK

TK-TD (toxicokinetic-toxicodynamic) models are considered a promising tool in higher tier risk assessments for the analysis and prediction of the effects of diverse, dynamic and complex exposure profiles on aquatic organisms. TK-TD models can be linked to population models to assess effects of these realistic exposure profiles on seasonal population dynamics. With respect to aquatic macrophytes, the EFSA PPR panel (2018) considered the Lemma model by Schmitt et al. (2013) ready to use, however a Myriophyllum spicatum model was reviewed with the conclusion that it needs further elaboration and testing. The TK-TD part of the models can be calibrated and validated by means of lower-tier laboratory test data. However, there is a lack of data on long-term seasonal dynamics of these species to test the model predictions of typical population dynamics in the field. In order to generate such data, a long-term study was set up in outdoor experimental systems from 2017 to 2019. The growth of Myriophyllum spicatum was monitored in baskets installed in an experimental ditch, while the growth of Lemna sp. populations was studied in outdoor microcosms. The monitoring of biomass (fresh, dry weight) and shoot length or frond numbers was carried out weekly to monthly, depending on the season. Apart from the standing crop, seasonal dynamics of short-term growth rates for shoots or fronds in baskets respectively microcosms were assessed for Myriophyllum and Lemna. In addition, relevant environmental parameters and weather data were collected. The results showed an increasing variability over time but a clear seasonal pattern. Both species displayed only slight declines of frond number respectively shoot length and biomass during the last two, relatively warm winters. Despite starting conditions as similar as possible, developments of replicates were partly highly variable. For Lemna, filamentous algae could have inhibited growth and caused variability between microcosms. For Myriophyllum, intraspecific competition might have played a role. For Lemna, dry weight per frond number increased in the winter season as plants increased weight during autumn as a result of storage of starch and the reduction of air spaces. Periodical growth rates highly correlated with temperature, while correlations with light conditions were less pronounced. The data will be published open access to allow testing of different models.

Contaminant Mixtures in Food: How Did They Get There and Should We Be Concerned?

K. Crawford, Boston University / Epidemiology; D. Almberg, M. Badri, Boston University; W. Heiger-Bernays, Boston University / Environmental Health

The field of environmental health science has undergone a marked transformation from the era of research and policies pertaining to single-chemical exposures, to broad recognition that chemicals co-occur in mixtures that must be studied in aggregate to accurately reflect human and wildlife exposures and associated health impacts. The complexity of these mixtures has necessitated the development of new analytical and statistical methods, strengthened our understanding of adverse health effects caused by contaminants across a wider range of environmentally-relevant concentrations, and identified novel and understudied exposure scenarios. The food we eat represents the ultimate complex mixture. We chose to leverage data from the US Food and Drug Administration’s TOTAL Diet Study, USDA’s Pesticide Data Program data, US Environmental Protection fish contaminant data and data from the primary literature to begin to answer the question: if “everything” is contaminated, what can we eat? For example, seafood contains omega-3 fatty acids, which are beneficial to neurodevelopment and cardiovascular health. Fish are also an important source of protein globally. However, they can contain harmful concentrations of mercury, polychlorinated biphenyls (PCBs), dioxins and perfluoroalkyl substances (PFASs). Similarly, dark-green, leafy vegetables contain many nutritionally-important characteristics, including high levels of vitamins, antioxidants and essential nutrients, which collectively support healthy function of a wide range of organ systems and protect against the development of cancer. However, these vegetables may also contain pesticide residues, heavy metals and PFASs. The complexity of weighing nutritional benefits with health risks of the food we eat poses difficult questions to scientist.
regulators and the public. In this study, we sought to answer the question of “Which foods should I eat?” by synthesizing data for major pathways of food contamination, health benefits and risks associated with staple foods in the United States and throughout the world. We then used a semi-quantitative approach to compare health risks and benefits in support of a tool that can be used by consumers to guide selection of the healthiest foods for themselves and their family, while also providing a research framework for addressing the scientific uncertainties.

501 Environmental contaminants in backyard chicken eggs from wildfire affected communities of California

C. O’Brien, University of California, Davis; I. Gennity, University of California, Davis / School of Veterinary Medicine; A. Huang, T. Kelman, M. Pitesky, University of California, Davis; B. Puschner, Michigan State University / College of Veterinary Medicine; A. Tah, University of California, Davis / Food Science and Technology

Wildfires are becoming increasingly common in California, more destructive, and more costly. In the fall and winter of 2017, several large wildfires broke out in northern and southern California causing 320,000 people to be evacuated, 185 hospitalized, 46 deaths and over 8,000 structures burned. The major concerns surrounding these semi-urban fires is the combustion, release, and volatilization of compounds such as polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs) and polycyclic aromatic hydrocarbons (PAHs) from the burning of household hazardous waste, building materials, furniture, electronic equipment, and capacitor and transformer fluids. The emissions of these chemicals can result in contamination of land, soil, water, and urban agricultural products including chicken eggs. Urban agricultural products can concentrate pollutants up to five orders of magnitude more than those produced in rural areas and this risk may be exacerbated post-fire. The aims of this study are to determine the extent of PCB, PBDE, and PAH contamination in backyard chicken eggs collected from fire affected communities in northern and southern California, and to determine if proximity to wildfires affects contaminant load. Preliminary results suggest that backyard eggs from fire affected communities contain higher concentrations of these chemicals compared with eggs purchased from a local supermarket. Ongoing analysis will determine the effect of proximity to fire on contaminant concentrations. Characterizing toxic chemicals in urban agricultural products after fire events will help guide the development of food safety guidelines and intervention strategies to be used after future catastrophic fire activities.

502 How safe is the rice in our homes? Human health risk assessment of some potentially toxic elements in commonly consumed rice brands in Lagos, Nigeria

A.O. Fumuyiga, Y.A. Lanre-Iyanda, S.O. Babajide, Moshood Abiola Polytechnic / Science Laboratory Technology

Rice is a major staple food and a good source of nutrition for the world population particularly in Africa. In recent times, the Federal government of Nigeria has embarked upon a strategy to overcome food shortage and improve self-sufficiency drive for both local consumption and export of rice. However, rice may accumulate potentially toxic elements from groundwater and soil and this may cause serious health issues to consumers. Apart from the rice grown in Nigeria, there are several brands of rice imported from different countries to cater for the 200 million Nigerian populace. Despite the large consumption of rice, there are no comprehensive investigations of potentially toxic elements levels in Nigerian grown rice varieties and imported brands sold in Nigerian markets. No published report is available for the bioaccessibility of PTE in rice varieties sold in Nigeria. To this end, a total of 21 rice samples were collected from mills, markets in Lagos and International Institute for Tropical Agriculture in Ibadan, Nigeria. These samples were acid digested and analysed for As, Cd, Cr, Ni, Pb and Zn by Microwave Plasma Atomic Emission Spectrometry (MP-AES). The mean concentrations for the elements analysed were 0.03, 0.75, 0.22, 0.55, 0.35, and 2.46 for As, Cd, Cr, Cu, Pb and Zn respectively. The average concentrations of the elements investigated were below the permissible threshold limit set by WHO/FAO with the exception of Cd and Pb. Human health risk assessment performed on the concentration results revealed individual hazard quotient calculations for the rice samples did not exceed the safe limit of 1 but the summation of the hazard quotients in all elements analysed which yielded the value for hazard index (HI) exceeded the safe limit of 1 in about 40% of the rice samples studied, suggesting risks to consumers. Results also revealed As and Cd as the largest contributors to non-carcinogenic risks to humans. Also, the results revealed no carcinogenic risks from As and Pb concentrations in the rice samples but the 10-4 threshold was exceeded for Cd and Cr.

503 Carrageenan as a source of arsenic, lead and cadmium to infant foods

T. Puschner, Dartmouth College / Biology; K. Nachman, Johns Hopkins; B.P. Jackson, Dartmouth College / Department of Earth Sciences

Carrageenan is an FDA-approved seaweed-derived ingredient in nearly 6% of foods in the USDA Food Composition Database, including organic, vegan and vegetarian foods. It is used to thicken, set, or stabilize processed foods. Because the seaweed from which carrageenan is derived is grown in seawater, it can accumulate significant concentrations of arsenic (As), cadmium (Cd), and lead (Pb); raising concerns that consumption of foods containing carrageenan will increase population exposures to toxic metals. Exposure to As, Cd, and Pb from consumption of carrageenan-containing foods has not been studied. Carrageenan is used extensively in the US as an emulsifier in ready-to-eat infant formula (not powder-based formula). The European Union (EU) prohibits carrageenan in infant formulas, citing the increased permeability of the infant gut and the potential for immunological effects, although direct evidence of harm has never been shown. Carrageenan has been associated with various gastrointestinal disorders in adults, particularly ulcerations and general inflammation, which has called its use into question. Links between these effects and the toxic metals in carrageenan have never been explored. Despite this, carrageenan remains approved for use in the EU in follow-on formulas aimed at infants > 4 months of age. Arsenic, Cd, and Pb are developmental toxicants. Early-life chronic, low-level exposures to these metals can have tangible impacts on cognitive development. For As and Pb at least, the existence of a safe exposure level, even for adults, is still actively debated. Given the critical windows of vulnerability in the first year of life, exposure to these toxic metals from consumption of ready-to-eat infant formulas and follow-on formulas made with carrageenan may have serious consequences for infant neurodevelopment. We hypothesize that the use of carrageenan in infant and follow-on formula results in significant elevations of concentrations of As, Cd, and Pb compared to formula without carrageenan or breastmilk. We are conducting an international market-basket study of infant formula foods (powder-based, and ready-to-eat) for analysis of As species, Cd, and Pb and will use these measurements alongside complementary measurements of these metals in breast milk to 2) conduct a comparative dietary toxic metals exposure analysis across the various types of infant foods. Preliminary findings are presented.

504 Dispersant-crude oil mixtures and seafood safety testing and consumption after the Deepwater Horizon oil spill

J. Gohlke, Virginia Tech / Department of Population Health Sciences

Communities dependent on fisheries in the Gulf of Mexico faced a number of challenges during and following the British Petroleum Deepwater Horizon explosion, oil spill and cleanup (DWH). Re-opening of federal waters to fisheries by the National Oceanic and Atmospheric Administration and Food and Drug Administration followed a protocol developed after the Exxon Valdez oil spill based on analysis of 13 polycyclic aromatic hydrocarbons (PAHs) in seafood tissue; however numerous groups, including members of Congress, non-governmental organizations, scientists, local fisherman, processors, and chefs, raised concerns over the adequacy of the protocol for ensuring the safety of seafood, particularly due to the large amount of dispersants (Corexit 9500A and Corexit 9527) applied on the water surface and subsurface to alter the fate...
and transport of the oil. Fisherman-led sampling and testing was combined with government-led results to geospatially evaluate PAH levels and potential pyrogenic versus petrogenic sources from a variety of seafood. Additional government-led protocol development and seafood testing for the Corexit 9500A component dioctyl sodium sulfosuccinate (DOSS) suggested direct exposure via seafood consumption and hence toxicity was expected to be minimal; however there is uncertainty regarding the potential for alterations of exposure and toxicity of chemically dispersed oil when compared to non-dispersed oil. Other research suggests oil spills may alter bioavailability of heavy metals. This talk will provide an overview of the current methodology for ensuring seafood safety after oil spills, seafood tissue analysis results after DWH, quantification of seafood consumption patterns before and after DWH, and how properties of dispersant-oil mixtures can be used to improve future human health risk estimates.

505 Implications of Polycyclic Aromatic Hydrocarbon (PAH) Mixtures Found in Food Using In Vitro Metabolism, Computational Modeling, and Human Microdosing

J. Smith, P. Pande, E. Stoddard, S. Nag, Pacific Northwest National Laboratory; J. Hummel, E.P. Madeen, L. Siddens, Oregon State University; T. Ognibene, K. Turlettchaub, Lawrence Livermore National Laboratory; K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology; R. Corley, A. Wright, Pacific Northwest National Laboratory; D. Williams, Oregon State University

Cereals, vegetables, and smoked foods, especially traditionally smoked fish, contain complex mixtures of polycyclic aromatic hydrocarbons (PAHs). Once absorbed, various cytochrome P450 enzymes (e.g. CYP1A1, CYP1B1, etc.), glutathione transferases, and other enzymes metabolize PAHs resulting in competing rates of bioactivation to procarcinogens and detoxification via clearance. Since multiple PAHs can be substrates for various enzymes, we hypothesize that exposure to PAH mixtures may cause metabolic competition, inhibiting PAH metabolism, and affecting PAH clearance, detoxification, bioactivation, and toxicity. We used in vitro metabolism assays, computational modeling, and human microdosing studies to test the implications of human exposure to PAH mixtures using benz[a]pyrene (BaP), dibenzo[def,fp]chrysene (DBC), and a mixture of the top 10 most abundant PAHs found at the Portland Harbor Superfund Site (Supermix10) as model compounds. We observed competitive in vitro metabolism when co-incubating various combinations of PAH substrates in hepatic microsomes of mice, rats, and humans. In general, DBC was the most potent inhibitor tested. We calculated and incorporated inhibition coefficients into a physiologically based pharmacokinetic (PBPK) model to simulate internal dosimetry and metabolic interactions between BaP and DBC. To assess impact of co-administration of food with high levels of a complex PAH mixture, humans were orally dosed with 46 ng of [14C]-BaP neat, with smoked salmon (Confederated Tribes of the Umatilla Indian Reservation) or with commercial canned salmon. Levels of BaP were measured in plasma and urine using ultra performance liquid chromatography and accelerator mass spectrometry. Co-administration of smoked salmon and canned salmon reduced and delayed BaP absorption, suggesting a food matrix effect rather than a PAH mixture effect. The PBPK model was able to accurately simulate these observations in humans, and extrapolate these findings to other doses, exposure scenarios, and internal organ concentrations. These simulations suggest that competitive PAH metabolism is not expected to significantly alter BaP pharmacokinetics at environmental exposure levels. 506 Prenatal Co-Exposure to Methylmercury and Inorganic Arsenic

S. Rothenberg, Oregon State University / Environmental & Occupational Health

Background: Prenatal co-exposure to inorganic arsenic and methylmercury may adversely impact offspring development, and these impacts may be synergistic. Mercury may also impact the metabolism and excretion of arsenic. In the human body, arsenite is accumulated in cells through aquaporins, while mercury may act as an aquaporin inhibitor. In Oregon, there are statewide fish consumption advisories for methylmercury, due to historic mercury mining from the 1890s-1960s. Groundwater arsenic levels are also elevated. In Oregon, it is important to investigate prenatal co-exposure to both methylmercury and arsenic, because of their health impacts to the developing fetus, and their unique association with aquaporins. Methods: We are currently enrolling pregnant mothers (< 21 weeks gestation) in a pilot study at two hospitals in Oregon. After providing written informed consent, biomarkers are collected (blood, urine and hair samples). Total mercury and/or methylmercury are analyzed in all three biomarkers, while arsenic species are analyzed in urine [inorganic arsenic, dimethylarsinic acid (DMA), and monomethylarsonic acid (MMA)]. Mothers complete a questionnaire concerning demographics and fish/rice consumption, and a tap water sample is brought from home for analysis of arsenic. Preliminary Results: To date, 32 mothers were enrolled. All tap water arsenic concentrations were below the detection level (< 2 ppb, n=13); however urine sum of arsenic species (= inorganic As + DMA + MMA) averaged 2.8 ppm (median: 3.2 ppb, inter-quartile range: 0.31-4.4 ppm, unadjusted for specific gravity, n=13). These values were comparable to other cohorts of pregnant mothers in the U.S. and Europe, where drinking water arsenic levels were low. Maternal hair total mercury averaged 0.27 ppm (median: 0.17 ppm, range: 0.02-1.0 ppm, n=27). Hair total mercury not strongly correlated with urine sum of arsenic species, urine DMA, urine MMA, or urine DMA/MMA (Spearman’s rho range: -0.03, 0.19, p=0.54-0.92, n=13); however the number of paired samples was small. Enrollment and lab analyses are ongoing, including analyses of arsenic species, total mercury, methylmercury, and aquaporins.

507 Modeling chemical mixture effects on health using Bayesian kernel machine regression

J. Bauer, Boston University School / Environmental Health; K. Devick, B.A. Cooll, Harvey T.H. Chan School of Public Health / Biostatistics; R.F. White, Boston University School of Public Health / Environmental Health; R.G. Lucchini, Icahn School of Medicine at Mount Sinai / Environmental Medicine and Public Health; R.O. Wright, Mount Sinai School of Medicine / Environmental Medicine and Public Health; D.R. Smith, University of California, Santa Cruz / Microbiology and Environmental Toxicology; B. Claus Henn, Boston University School of Public Health / Environmental Health

Recent progress in understanding how chemical mixtures affect health is largely attributed to collaboration between scientific fields, innovation of statistical methods, and prioritization from funding agencies. Metals are an important class of chemicals to examine mixture effects because they are ubiquitous in the environment, commonly co-occur and have interactive potential. Bayesian Kernel Machine Regression (BKMR), a statistical approach developed to assess environmental mixtures, allows for the evaluation of the joint, nonlinear and interactive associations of chemicals on health. This presentation will describe the application of BKMR using our recently completed study, which used BKMR to evaluate the association of manganese (Mn), copper (Cu), lead (Pb) and chromium (Cr) measured in multiple biomatrices and children’s cognition. We measured Mn, Pb, Cu, and Cr in hair, blood, urine, nails, and saliva collected from 635 Italian adolescents ages 10-14 years. Full-scale, Verbal and Performance IQ (FSIQ, VIQ, PIQ) scores were measured using the Wechsler Intelligence Scale for Children (WISC-III). BKMR was used to estimate associations of IQ with the metal mixture. In secondary analyses we used BKMR’s hierarchical variable selection option to inform biomarker selection for Mn, Cu and Cr. Median biomarker concentrations in primary analyses were: hair Mn, 0.08 μg/g; hair Cu, 9.6 μg/g; hair Cr, 0.05 μg/g; blood Pb, 1.3 μg/dL. Adjusting for sex, age, home score, hemoglobin and socioeconomic status, we observed an inverted u-shaped association between hair Cu and VIQ, consistent with Cu as an essential nutrient that is neurotoxic in excess. When Cu was set at its 10th percentile, the mixture of Mn, Pb and Cr set at their respective 90th percentiles was associated with a 2.9 (95% CI: -5.2, -0.5) point decrease in
VIQ score, compared to their median concentrations. There was suggestive evidence of interaction between Mn and Cu. In secondary analyses, biomarkers associated most strongly with VIQ score were saliva Mn, hair Cu and saliva Cr. This metal mixture was negatively associated with IQ, especially at low Cu levels. Our work supports further investigation into the nonlinearity of Cu and the joint and interactive associations of Mn, Cu and Pb with neurobehavior.

Life Stage-Specific and Multi-Generational Effects of Environmental Stressors in Fish - Part 2

**508 Intersex development in adult fish. Are estrogenic compounds the main culprit?**

K. Hicks, Alberta Environment and Parks / Biology; H. Dhiyebi, University of Waterloo / Biology; M. Fuzen, McMaster University / Biology; N. Srikanthan, L. Bragg, P. Marjan, University of Waterloo / Biology; J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants and Research Division; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; M.R. Seros, University of Waterloo / Biology

Impacts on fish exposed to municipal wastewater treatment plant (WWTP) effluent is a concern globally. One of the most documented cases is in the Grand River of southern Ontario, where male rainbow darter (Etheostoma caeruleum) caught below the Kitchener and Waterloo WWTPs have exhibited feminization characteristics. These impacts are thought to be due to estrogenic compounds (natural and/or synthetic) present in WWTP effluents. Intersex, along with other impacts, have reduced to reference-level conditions after the Kitchener WWTP had upgraded its facility, further supporting the association of these impacts with WWTPs. Although a strong link has been established between WWTP effluent and impacts in rainbow darter, the following questions are still not well understood: i) are estrogenic compounds present in WWTP effluents responsible for the impacts observed in male rainbow darter and ii) are these impacts related to the exposure during a critical window? To address these questions, wild sexually mature male rainbow darter from a reference site were brought into the laboratory and exposed to 17α-ethinylestradiol (EE2) at nominal concentrations of 0, 1, or 10 ng/L in a flow-through system. Rainbow darter were exposed for 23 weeks (May to October), which covers the major period of recrudescence (germ cell proliferation) and is hypothesized to be a window of exposure when fish are more sensitive to EDcs. After the exposure, rainbow darter were assessed for liver vitellogenin expression, in vitro androgen production, intersex, and behavioural endpoints. Intersex was induced, with significant increases in incidence from 18% in controls to 70% in the higher dose (10 ng/L EE2). In vitro androgen production significantly decreased from 60 pg/mg tissue (in controls) to 10 pg/mg tissue at 10 ng/L EE2. The results observed in this exposure are consistent with impacts previously identified in male rainbow darter downstream of WWTPs in the Grand River providing evidence that responses observed in the field are likely due to estrogenic constituent(s) present in WWTP effluents. In addition, recrudescence may be a critical window of sensitivity; this is being further investigated. Answering these questions concerning critical constituents present in WWTP effluent and identifying sensitive windows of exposure, may help to better manage the treatment and release of WWTP effluents into aquatic receiving environments.

**509 Maternal Preconception Exposures to PFOS and PFBS Impact Zebrafish Fatty Acid Profiles and Development**

K. Annunziato, University of Massachusetts, Amherst / Environmental Health Sciences; M. Marin, University of Massachusetts, Amherst; J. Lee, University of Massachusetts, Amherst / Veterinary & Animal Sciences; W. Qi, Y. Park, University of Massachusetts, Amherst / Department of Food Science; J.M. Clark, University of Massachusetts, Amherst / Veterinary and Animal Sciences; A.R. Timme-Laragy, University of Massachusetts / Environmental Health Sciences

Perfluorobutane sulfonate, PFBS, is a perfluoralkylated substance and a shortened (4 carbon chain) alternative to PFOS, perfluorooctane sulfonate (8 carbon chain). Using the zebrafish model (Danio rerio), this study aims to compare the effects of a maternal, preconception exposure to PFBS and PFOS on reproductive and developmental endpoints. Four adult female fish, Tg(insulin:GFP) were stripped to remove existing eggs and exposed to waterborne concentrations of 0.08, 0.14, or 0.25 μg/mL PFBS or PFOS, or 0.01% DMSO. Exposures continued for 1 week for a complete cycle of oocyte maturation. Following exposures, females were bred daily with unexposed males until 5 successful embryo collections occurred. These embryos were imaged daily through 120 hours post fertilization, hpf, via live brightfield and fluorescence microscopy, and growth, yolk sac area, and pancreatic beta cell area were measured. Few significant changes in these developmental endpoints were observed in embryos from the first collection. However, in the 5th collection, significant reductions in length, yolk sac area, swim bladder inflation, and pancreatic beta cell area were measured in embryos collected from the 0.25 μg/mL PFBS treatment group. Analytical chemistry revealed that PFBS detection in freshly fertilized embryos changed over time. PFBS was measured at 120 pg PFBS/embryo in the 1st collection of 0.08 μg/mL PFBS. However, PFBS was not measured in the embryos by the 5th collection in any treatment group, nor was PFBS measured in maternal tissues. In contrast, PFOS was detected in concentrations of 4000 pg PFOS/embryo in the 1st collection. Detection persisted into the 5th collection, and PFOS was detected in maternal liver and ovary samples. Fatty acid profiles were examined in freshly fertilized embryos. In both PFOS and PFBS embryos, there was a significant decrease in the proportion of oleic acid, and significant increase in docosahexaenoic acid (DHA) in PFBS samples. PFAS exposures in female fish may impact the nutrients loaded into the egg during this process, which is evident in the effects on fatty acids and yolk sac area in the early developmental stages. This nutritional deficit, possibly coupled with loading of toxicant into the eggs, may explain the persistence of effects at 120 hpf. Together this suggests that there may be alterations in oocyte maturation and metabolic homeostasis in larvae associated with maternal, preconception exposure to PFBS and PFOS.

**510 Fathers matter: The effects of paternal exposure to pharmaceuticals on offspring reproductive health in zebrafish**

S. Fraz, McMaster University / Biology; J.Y. Wilson, McMaster University / Department of Biology

Chronic, low concentration chemical exposures may have both direct health outcomes on adults and indirect effects on their offspring. Using zebrafish, we have examined the impacts of two common environmental pharmaceutical compounds, carbamazepine and gemfibrozil, on reproductive output and a suite of male reproductive endpoints (aggression, courtship behaviour, 11-ketotestosterone levels, sperm morphology, sperm motility). Fish were exposed for 6 weeks to 10 μg/L of carbamazepine or gemfibrozil prior to assessment of reproductive endpoints. Our studies have examined the direct effects of the pharmaceuticals on the parental fish and found decreased reproductive output, lower 11-ketotestosterone levels, altered behaviour, and sperm morphology with both pharmaceuticals. The reproductive effects of these pharmaceuticals on the parental generation have been consistent and repeatable across several experimental exposures. Offspring were generated in four different lines from crosses with both parents unexposed, both parents exposed, or with only one parent exposed to distinguish between maternal and paternal effects on offspring reproductive endpoints. The impacts were the result
of parental exposure because the offspring were reared to the F_2 generation in clean water; F_2 embryos could only have been exposed via maternal deposition into the yolk. For both compounds, paternal exposure was most important for offspring reproductive health; offspring from crossing exposed mothers and unexposed fathers did not show significant effects. This rules out maternal deposition as an important exposure scenario for the F_1 embryos. Yet, reproductive output was lower in crosses with an exposed father, supporting the notion that paternal exposure was impacting offspring health. The effects of paternal gemfibrozil exposure were largely limited to the F_1 generation while the effects of paternal carbamazepine were evident into the F_2 generation, suggesting transgenerational effects. Considering that carbamazepine is a histone deacetylase inhibitor in mammals, the effects of carbamazepine are likely via an epigenetic mechanism. Recent studies in zebrafish support the role of the sperm epigenome in early development stages and major reprogramming events. Collectively, our data suggest that paternal exposures are strongly relevant to offspring reproduction and male reproductive health in fish.

511 Impacts of Embryonic Exposure to Cannabidiol or Δ9-Tetrahydrocannabinol on Zebrafish (Danio rerio) Reproduction and Behavior in F0 and F1 Generations
Z.P. Pandelides, N.M. Ashpole, University of Mississippi / BioMolecular Sciences; C.E. Thornton, University of Mississippi / Pharmacology; A. Faruque, University of Mississippi / BioMolecular Sciences; D. Carty, University of Mississippi / Biology; K.L. Willett, University of Mississippi / Department of Pharmacology of Environmental Toxicology Research Program

Cannabinoids including Δ9-tetrahydrocannabinol (THC) and cannabidiol (CBD) are being increasingly consumed for therapeutic purposes. Yet the potential adverse outcomes following exposure to cannabinoids during critical developmental periods such as embryogenesis is currently lacking. Zebrafish present a distinct advantage when studying the multigenerational effects following developmental exposure to canna-binoid compounds due to their conserved endocannabinoid system with mammals, well-characterized morphology and behavioral phenotypes, and high fecundity. The objective of this study was to assess acute, morphological, and behavioral effects following a 96-hour developmental exposure to THC or CBD and assess persistent impacts in adult fish and their offspring. Zebrafish were exposed from 6 to 96 hours post fertilization (hpf) to nominal concentrations of a solvent control (0.05% DMSO), THC (0.024 - 0.6 mg/L; 0.08 - 2 uM) or CBD (0.006 - 0.15 mg/L; 0.02 - 0.5 uM). Two and a half years following the initial larval exposure, aged F_0 (developmentally exposed) and F_1 (parents were exposed) fish were assessed for aging phenotypes such as brain and liver expression of genes involved in: neurodevelopment (bdnf), proliferation (p53), cell cycle arrest (p16, p21), and immune markers (tnfα, Il-6, Il-1b). A significant reduction in Fulton’s Condition Factor was observed for adult F_0 ZF (LOEC 39 µg/L) starting at 4 h post-fertilization (hpf) to 5 dpf post-fertilization (dpf). Neurobehavioral and molecular assays were conducted for F_0 ZF at larval, 21 dpf larvae, juvenile, adult stages as well as the subsequent larval F_1 generation. Global DNA Methylation measurements were analyzed for 5 dpf F_0 larvae, 21 dpf F_1 larvae, and 5 dpf F_1 larvae. Behavior assays assessing swimming behavior (distance traveled and velocity) of the exposed F_0 generation and F_1 larvae, and 5 dpf F_1 larvae. Behavior assays assessing swimming behavior (distance traveled and velocity) of the exposed F_0 parents or are inherited by larval F_1 progeny. Embryos were exposed to chlorpyrifos-oxon at 0.01 and 50 µg/L starting at 4 h post-fertilization (hpf) to 5 dpf post-fertilization (dpf). Neurobehavioral and molecular assays were conducted for F_0 ZF at larval, 21 dpf larvae, juvenile, adult stages as well as the subsequent larval F_1 generation. Global DNA Methylation measurements were analyzed for 5 dpf F_0 larvae, 21 dpf F_1 larvae, and 5 dpf F_1 larvae. Behavior assays assessing swimming behavior (distance traveled and velocity) of the exposed F_0 generation are conducted at 5 dpf and 21 dpf. F_0 embryos were raised to adulthood under standardized laboratory procedures in triplicates per treatment to account for differences in tank effect. Additional behavioral analyses were conducted at 11 weeks to assess juvenile shoaling interactions and adult novel tank diving. Significant decreases in swimming activity (both distance traveled and velocity) was observed for 5 dpf F_0 ZF exposed to the 50 µg/L treatment (p < 0.0001). No behavioral changes were observed for F_0 ZF at 21 dpf swimming behavior or shoaling at 11 weeks. Increased anxiety-associated behavior was observed during novel tank diving analyses for F_0 female ZF at 50 µg/L CPO exposure. Meanwhile, significant increase in Fulton’s Condition Factor was observed for adult F_0 ZF males at 50 µg/L exposure as compared to control, indicating changes in

512 Evaluation of multigenerational effects of 2-ethylhexyl 4-hydroxy-benzoate, bisphenol A, and dibutyl phthalate in Japanese medaka
S. Matten, A. Kamel, US Environmental Protection Agency / Office of Science Coordination and Policy; S.G. Lynn, US Environmental Protection Agency / Endocrine Disruption Screening Program (EDSP)

Three chemicals, 2-ethylhexyl 4-hydroxybenzoate (2-EHHB), bisphenol A (BPA), and dibutyl phthalate (DBP), were evaluated for multigenerational endocrine-mediated effects using a modified Japanese medaka (Oryzias latipes) extended one-generation reproduction test (MEOGRT) (OCSPG TEG 890.2200). Fish were exposed to five test concentrations, a water control and for DBP, triethylene glycol (solvent control), under flow-through conditions starting with adults (F_0) through the end of the second generation (F_2). Exposure to 2-EHHB significantly decreased fecundity, fertility, and growth (Lowest Observed Effect Concentration (LOEC) 5.3 µg/L) in F_0, F_1, and F_2 adults. Liver vitellogenin (vtg) mRNA increased in F_1 and F_2 subadult males (LOEC 101 µg/L) and the number of anal fin papillae were significantly decreased (LOEC 49 µg/L). Significant testicular degeneration (LOEC 5.3 µg/L) was also observed in F_1 and F_2 male adults. Findings suggest that 2-EHHB may have estrogenic effects. Results for BPA indicated that there were significant reductions in fecundity and fertility in F_0 (LOEC 2600 µg/L) and F_1 (LOEC 390 µg/L) generation adults. In F_1 subadult males, there was significant gonadal feminization (LOEC 480 µg/L), reduction in anal fin papillae (LOEC 150 µg/L), and increased liver vtg (LOEC 390 µg/L). Results may indicate an anti-androgenic and/or estrogenic mode of action leading to diminished fertility and fecundity as well as feminization of male medaka. Exposure to DBP did not significantly affect F_0 adult survival, growth or fertility, but F_1 adult fertility and fecundity was significantly decreased at the highest test concentration (LOEC 305 µg/L). Male and female growth was significantly reduced in F_1 and F_2 subadults and adults with males (LOEC 16 µg/L) being more sensitive to DBP than females (LOEC 39 µg/L). Embryo hatchability (F1 and F2) was significantly reduced (LOECs: F1 16 µg/L; F2 39 µg/L) as was the number of male anal fin papillae (F1 subadult LOEC 39 µg/L). Collectively, findings did not suggest a specific mode of action. Data from the MEOGRT can be used in a weight-of-evidence evaluation to establish dose-response relationships and potential connections to endocrine modes of action and effects. Disclaimer: The views expressed in this presentation abstract are those of the authors and should not be construed to represent any Agency determination or policy.

513 Transgenerational effects of developmental exposure to chlorpyrifos-oxon in zebrafish (Danio rerio)
C. Schmitt, K. Satbhai, Eric M. Peterson, A. Willis, N. Kumar, M. McManus, J. Crago, Texas Tech University / Department of Environmental Toxicology / TIEHH

Chlorpyrifos (CPF) is a broad-spectrum organophosphate pesticide widely used in agricultural applications in the United States, which has been attributed to a number of neurodevelopmental disorders. It is unclear if the adverse effects associated with developmental exposure to the active CPF metabolite, chlorpyrifos-oxon (CPO), persist into F_0 adulthood and future generations. The parent CPF is bio-transformed into the highly bioactive toxic CPO metabolite and travels through the body of a pregnant female to the womb. Furthermore, limited data exists on the persistent noncholinergic and DNA methylation effects of embryo-larval zebrafish (ZF) post developmental exposure to CPO. The goal of this study was to investigate if changes in ZF behavior were manifest throughout the life of the exposed F_0 parents or are inherited by larval F_1 progeny. Embryos were exposed to chlorpyrifos-oxon at 0.01 and 50 µg/L starting at 4 h post-fertilization (hpf) to 5 dpf post-fertilization (dpf). Neurobehavioral and molecular assays were conducted for F_0 ZF at larval, 21 dpf larvae, juvenile, adult stages as well as the subsequent larval F_1 generation. Global DNA Methylation measurements were analyzed for 5 dpf F_0 larvae, 21 dpf F_1 larvae, and 5 dpf F_1 larvae. Behavior assays assessing swimming behavior (distance traveled and velocity) of the exposed F_0 generation are conducted at 5 dpf and 21 dpf. F_0 embryos were raised to adulthood under standardized laboratory procedures in triplicates per treatment to account for differences in tank effect. Additional behavioral analyses were conducted at 11 weeks to assess juvenile shoaling interactions and adult novel tank diving. Significant decreases in swimming activity (both distance traveled and velocity) was observed for 5 dpf F_0 ZF exposed to the 50 µg/L treatment (p < 0.0001). No behavioral changes were observed for F_0 ZF at 21 dpf swimming behavior or shoaling at 11 weeks. Increased anxiety-associated behavior was observed during novel tank diving analyses for F_0 female ZF at 50 µg/L CPO exposure. Meanwhile, significant increase in Fulton’s Condition Factor was observed for adult F_0 ZF males at 50 µg/L exposure as compared to control, indicating changes in
growth between treatments. Separate samples were collected at 5 dpf for molecular and global DNA methylation analyses to assess long-term and generational changes due to developmental CPO exposure as compared to control. The maximum velocity observed from startle response (tapping) was significantly decreased in 5 dpf F1 ZF for the 0.01 µg/L treatment. All samples collected from F0 and F1 were analyzed to assess genetic regulation of cholinergic (AChE), dopaminergic (TH1, DAT), neurodevelompental (C-FOS, GRIN-1B, LINGO-1B), and de novo methylation genes (DNMT-3AA, DNMT-3AB, DNMT3BA). No change in AChE was observed at any treatment. Down-regulation of C-FOS, GRIN-1B, and DNMT3AA was observed in 5 dpf F0 ZF exposed to 50 µg/L chlorypyrifos-oxon. GRIN-1B (0.49 fold) and DNMT-3AB were down-regulated in 21 dpf F0 ZF at 50 µg/L exposure. However, up-regulation of GRIN-1B was observed in 21 dpf F0 ZF at 0.01 µg/L exposure. Up-regulation of DNMT3AB was the singular gene change observed for 5 dpf F1 ZF. Global DNA methylation decreased for 21 dpf F0 ZF 50 µg/L and 5 dpf F1 0.01 µg/L treatments as compared to the control ZF. No differences in TH1, DAT, or DNMT3BA were observed in any age or generation of ZF. Identification of potential noncholinergic behavioral, molecular, and epigenetic outcomes informs future investigative efforts and regulatory efforts into the persistent effects of developmental CPO insecticide exposure in ZF.

515 Multigenerational effects of endocrine disrupting compounds: Understanding population level implications using modeling approaches
S.M. Brandler, Oregon State University / Environmental and Molecular Toxicology; J.W. White, Oregon State University / Department of Fisheries and Wildlife; B. DeCourten, K. Major, Oregon State University / Environmental and Molecular Toxicology; R.E. Connolly, University of California, Davis / Anatomy, Physiology & Cell Biology; School of Veterinary Medicine; A.C. Mehinto, Southern California Coastal Water Research Project / Toxicology

Emerging research demonstrates that endocrine disrupting compounds (EDCs), which agonize, antagonize, and/or synergize the effects of endogenous hormones, can cause deleterious effects as a result of early-life exposure, as well as effects across generations. As such, we explored the effects of a suite of EDCs (ethinylestradiol, bifenthrin, levonorgestrel, and trenbolone) at low ng/L concentrations on the euryhaline model fish *Menidia beryllina*. Fish were exposed from fertilization until 21 dph, then reared through three generations in clean water. Early life exposure led to changes in sex ratio, phenotypic deformities, and differential gene expression and methylation across generations. Taken together, early life EDC exposure caused functionally relevant changes in the epigenome, transcriptome, and reproductive and immune phenotypes in directly (P0), indirectly (F1), and unexposed individuals (F2). To examine the consequences of these individual-level effects on overall population dynamics, we used these data to parameterize a size-and-age-structured integral projection model (IPM). This approach represented empirically-determined effects on growth, survival, and fecundity. Additionally, we tracked the distribution of multi- and transgenerational effects in the model. We then quantified the effects of both single and chronic exposures to a range of EDCs at environmentally relevant concentrations, both for population persistence and population variability. Accounting for multi- and transgenerational responses led to model predictions that a) single EDC exposures have longer-term effects on population variability (i.e., oscillations in abundance), and b) chronic EDC exposures were more likely to lead to population collapse. These projected effects demonstrate that EDC exposures can have far-reaching effects on unexposed generations, highlighting the need for these types of cross-generational effects to be considered in risk assessment.

Fate and Effects of Chemicals from Stormwater Runoff

516 Potentially toxic elements (PTEs) transport and accumulation in green stormwater infrastructure (GSI)
E. McKenzie, A. Behbahani, R.E. Ryan, Temple University / Civil and Environmental Engineering

Biowales are a common infiltration-based stormwater management practices (SMPs), and are touted as one the most highly recommended green stormwater infrastructure (GSI) approaches to manage both water quantity and quality. However, potentially toxic elements (PTEs) do not degrade, therefore the elevated concentrations that are observed in the runoff can accumulate in the soil and can be transported to the underlying groundwater. This study combines field data from Interstate-95 sites in Philadelphia, including highway runoff and SMP pore water concentrations, with 1-D transport modeling to understand the long term accumulation and transport of nine PTEs within the SMP media. PTE breakthrough in the soil media was observed to exhibit the following trend: Cl, Cr, Cd, As, Cu, Pb, Fe. Soil associated concentrations in the top media layer (0 - 5 cm) were compared against relevant soil screening values, and it was determined that Cl, Cr, an As would exceed the soil screening values after 20 years of SMP use. To evaluate potential risk associated with contaminating the underlying groundwater, media porewater concentrations at a depth of 5 m were compared to drinking water or aquatic life criteria; after 20 years of simulated use, only Cl concentrations exceeded regulatory values. The interactions between SMP loading ratio (i.e., the ratio between the contributing surface area and the SMP infiltration area) and SMP media solid-water distribution coefficient (Kd) were evaluated and confirmed that increased transport was associated with elevated loading ratio values and with decreased Kd values, but that the risk of PTE contamination of soil and groundwater, compared to relevant criteria, was generally fairly consistent.

517 Mitigation of stormwater toxicity with permeable pavement
B. Leonard, Washington State University, Payrallup; C. Duchet, EID Mediterranean / Department of Evolutionary and Environmental Biology; J.D. Stark, Washington State University / Dept of Entomology; J.K. McIntyre, Washington State University / School of the Environment

Permeable concrete and asphalt are engineered to allow stormwater infiltration while maintaining structural resilience under heavy vehicle loads. Adding carbon fiber to the matrix of permeable pavements increases their tensile strength. Multiple studies have focused on evaluating the engineered design performance of these permeable materials. However, it is unclear whether these materials provide chemical treatment of surface stormwater runoff and whether they contribute toxic chemicals to effluent water. We evaluated permeable concrete and asphalt cores six inches in diameter and depth with and without the addition of carbon fiber. Control water and stormwater runoff from a busy arterial road were pumped at a low flow rate (1 L/hr) through each core. The use of control water is representative of rain water while the stormwater treatment shows how these pavements may perform when exposed to diverted runoff from impermeable surfaces. After four hours of treatment influents and effluents were analyzed for water quality and chemistry (pH, dissolved oxygen, PAHs, fecal coliform bacteria, total suspended solids, dissolved organic carbon, and dissolved metals) and for toxicity on the crustacean *Ceriodaphnia dubia* and zebrafish (*Danio rerio*). Results will show (a) how permeable pavements alter clean and polluted influents; (b) whether carbon fiber alters the water quality of permeable there is a difference in treatment between permeable concrete and asphalt with and without carbon fiber additions; and (c) what effect aging over three treatments has on performance.
518 Testing Novel Bioretention Soil Media for Removal of Polycyclic Aromatic Hydrocarbons and Escherichia coli in Urban Stormwater Runoff

C. Mitchell, Washington State University / School of the Environment; A. Jayakaran, Washington State University / Puyallup Research & Extension Center; J.K. McIntyre, Washington State University / School of the Environment

Current stormwater permitting regulations in the state of Washington do not include performance goals for the treatment of pollutants like certain organic contaminants (Polycyclic Aromatic Hydrocarbons - PAHs) and bacteria (total and fecal coliforms, enterococci, Escherichia coli). As a first step in determining Best Management Practices (BMPs) for the treatment of these contaminants from stormwater runoff, a bench scale study has been conducted to assess the contaminant removal efficiencies of several emerging bioretention soil media (BSM) amendments. The following treatments have been compared in a bench scale stormwater filtration experiment: 1) sand (control), 2&3) sand amended with two different high temperature pyrolysis biochars, and 4) sand amended with alum (i.e., aluminum sulfate). These treatments have been chosen for their adsorptive properties, availability, and ability to enhance desirable hydraulic properties in stormwater bioretention systems. In a series of three dosing experiments, small bioretention columns have been dosed with 1) clean fish rearing water (to condition columns and leach potential toxicants) 2) PAH-spiked stormwater (made with used motor oil mechanically dispersed in water), and 3) E. coli spiked synthetic stormwater. Influent and effluent from the columns have been analyzed for standard parent PAH compounds and E. coli concentrations. Danio rerio (zebrafish) morphometric bioassays have been conducted to assess potential toxicity of media leachates to determine whether these novel media leach toxicants. Similar bioassays have also been conducted on the effluents from the treated PAH spike to evaluate the ability of the media to attenuate PAHs. Results indicate that the sand and alum treatments leached a mean of 0.12 and 0.14 µg/L of TPAHs respectively compared with the biochars which leached 0.079 and 0.016 µg/L. In the PAH spike experiment the sand, biochar 1, biochar 2, and alum treatments achieved mean TPAH removal rates of 32%, 99.8%, 99.8%, and 29% respectively. The D. rerio assay and E. coli spike data are not yet available, but currently available results suggest that biochar is a promising bioretention amendment for improving removal of organic contaminants, such as PAHs, from stormwater.

J. Gerads, S. Kohno, S.P. Miks, St. Cloud State University / Aquatic Toxicology Laboratory; R.L. Kiesling, US Geological Survey; C. Christen, H.L. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory

Urban landscapes are often contaminated by a complex mixture of contaminants of emerging concern (CECs). These landscapes are defined by an abundance of impermeable surfaces that act as conduits during precipitation events moving contaminants into aquatic ecosystems. Prior research on the introduction of CECs into surface waters have focused on municipal wastewater treatment plants and agricultural runoff. This study investigates the effects of urban stormwater runoff on larval fathead minnows. In addition, we examined the mitigating potential of detention ponds and iron-enhanced sand filtration (IESF) as best management practices. We collected inflow and outflow water samples following 3 cm precipitation events during snow melt, spring flush, and summer rains from seven stormwater ponds across the greater metropolitan area of Minneapolis and St. Paul, MN, USA. CECs were commonly detected in stormwater runoff with greater concentrations in inflows when compared to pond outflows. In some instances, CEC concentrations raveled those reported for treated wastewater effluent. Endpoints measured include fathead minnow hatch success, survival, growth, development, predator avoidance performance, and foraging efficiency. Our results indicate that stormwater was most detrimental to larval fathead minnows during snow melt (declining survival and foraging efficiency). For snowmelt, foraging efficiency for treated runoff was greater than untreated runoff (p=0.04). However, that effect was seasonal with summer runoff showing untreated runoff having a greater reduction in foraging efficiency than IESF treated runoff (p=0.04). Stormwater treatment performance varied by season with best management practices having the greatest impact during summer rain events. This study suggests that best management practices provide some benefit in reducing CEC presence in urban stormwater although the biological benefits are seasonally limited.

520 Concentrations of Microplastics in Urban Stormwater Runoff from the City of Calgary, Canada

M. Ross, T. Groeneveld, A. Loutan, D. Molenaar, MacEwan University / Department of Physical Sciences; K. Kroetch, MacEwan University / Department of Mathematics and Statistics; T. Bijuazek, S. Kolter, S. Moon, A. Huynh, R. Khayam, MacEwan University / Department of Physical Sciences; F. Brian, MacEwan University / Department of Mathematics and Statistics; V. Arnold, N.J. Ruecker, The City of Calgary / Water Quality Services

In urban environments, impervious surfaces, such as rooftops and roadways, prevent precipitation from soaking into the ground. This runoff flows into storm sewers and is eventually discharged into surface waters, often without treatment. Urban stormwater runoff is a source of pollutants and sediments to surface waters and is thought to be an important vector for the introduction of microplastics into the aquatic environment. However, there is a paucity of data available on the prevalence of microplastics in urban runoff, limiting assessment of its role in transporting microplastics and preventing any form of risk assessment or mitigation strategies to be implemented. This study investigates the concentration and characteristics of microplastics in urban stormwater runoff from the City of Calgary, Canada. Samples (n=75) were collected throughout the summer of 2017 from 15 sampling locations representing a range of catchment sizes and land use types. Samples were collected under both baseflow and rain event conditions using a combination of autosamplers and grab sampling. Suspected microplastics were visually characterized by microscopy and, for selected samples, further identified using Raman microspectrophotometry. Total concentrations of suspected microplastics ranged from 9 to 230 pieces/L (mean=52.9 pieces/L), with microplastics < 125 µm being the dominant size class. The predominant category of microplastics found in samples across all conditions was fibers, followed by fragments, consistent with other studies of microplastics in freshwater that have found fibers and fragments to be the dominate category of microplastic present. We also found relationships with land use and concentration, microplastic size, and morphology. This work represents one of the first studies on the occurrence of microplastics in stormwater runoff and will provide a baseline for future monitoring and mitigation studies.

521 Development of robust chemical indicators of urban runoff and sewage contamination in urban streams and an estuary in Sydney, Australia

V.J. Pettigrove, RMIT University / Sciences; C. Beasley, Sydney Water; M. Cassidy, Sydney Water Corporation; M. Allinson, The University of Melbourne / Department of Chemical Engineering; K. Kadokami, The University of Kitakyushu / Institute of Environmental Science and Technology; S. Sharp, Environment Protection Authority (Victoria) / Applied Sciences

Many organic micropollutants have been identified as indicators of specific types of pollution particularly from sewage, roads and general urban areas. There is often an assumption made that the chemical is a good indicator of a specific pollution source without evaluating whether there are other sources. If this chemical indicator is not source specific then erroneous conclusions can be made about the source of contaminants present in waters. A study was conducted on two urban creeks and in an urban estuary in Sydney, Australia to illustrate how robust indicators can be determined. To increase the range of organic micropolllutants that could be detected, two passive samplers (ChemCatches and Polar Organic Chemical Integrative Samplers) were used and compared. The
two passive samplers, along with compositd water samples from auto-
samplers were analysed by multi-residue GC-MSMS and LC-QTOF-MS 
database methods to investigate 1,393 organic chemicals, including pharma-
caceuticals and personal care products (PPCPs), pesticides, PCBs, PAHs, 
flame retardants, antioxidants and sterols such as coprostanol (a fecal indicator). A total of 255 chemicals were detected from the three urban sites surveyed: 187 using GC-MSMS and 75 using LC-QTOF-MS. Raw sewage samples were collected from sewers in the vicinity of these three urban sites to confirm what chemicals were present in sewage. Overall, 111 chemicals were detected in sewage using GC-MSMS with 73 of these 
chemicals detected at all three sites. Similarly, 73 chemicals were detected 
using LC-QTOF-MS with 59 of these samples detected at all three sites. Those chemicals that were commonly present in sewage and absent in the 
three urban sites were deemed to be potentially good indicators of sewage. Those chemicals absent in the sewage and commonly detected at 
the urban sites were deemed to be good indicators of non-sewage contami-
nated urban runoff. Many chemicals, including caffeine, were commonly 
detected in sewage and at urban sites and are poor indicators of any spec-
cific pollution source. Many chemicals, particularly pharmaceuticals have 
specific uses and can clearly be associated with sewage. However, uses 
of the remaining potentially good indicators were also were examined in 
the literature to help confirm whether they are good sources of sewage 
or urban runoff.

522 Enrichment and Attenuation of Organic Contaminants in an 
Urban Creek During a Rainfall Event 
B. Awonaike, University of Toronto, Scarborough / Physical and 
Environmental Science; Y. Lei, A. Parajulee, University of Toronto / 
Department of Physical and Environmental Sciences; C.P. Mitchell, F. 
Wania, University of Toronto, Scarborough / Department of Physical and 
Environmental Sciences

Urbanization is a global phenomenon characterized by changes in land 
use. With increased urban landcover comes the creation of more impervi-
sous surfaces, which in turn results in increased runoff generation after 
a precipitation event. Watershed urbanization provides a mechanism 
for the transport of contaminants to surface waters. Mimico Creek 
watershed is a highly urbanized watershed in Toronto, Canada, which 
drains into Lake Ontario. In this work, we monitored the concentra-
tions of four groups of organic contaminants - Polycyclic Aromatic 
Hydrocarbons (PAHs), Substituted Polycyclic Aromatic Hydrocarbons 
(SPAHs), Organophosphate Flame Retardants (OPFRs) and Benzotriazole 
Ultraviolet Stabilizers (BT-UVs) in Mimico Creek. These concentra-
tions were monitored before, during and after a major rainfall event in the 
summer of 2018. The aim of this was to explore the significance of stormwater as a source of contaminants to the river. In addition to stormwater, we 
also explore the influence of unregulated wastewater discharge. Results 
indicate that the contaminants behave differently as stormflow increases and decreases over time. Some contaminants show a sudden spike in 
concentrations, which coincides with the beginning of stormflow, while 
others show a dilution pattern. Our results suggest that during precipita-
tion events, stormwater plays a major role in the enrichment of highly 
water-soluble contaminants, while hydrophobic contaminants, which are 
more abundant in the particle phase, are mostly diluted.

523 Assessing sediment recontamination and bioaccumulation of 
metals from stormwater runoff 
I. Drygiannaki, Texas Tech University / Department of Civil, 
Environmental and Construction Engineering; M. Bejar, Texas Tech 
University; B. Rao, Texas Tech University / Department of Civil, 
Environmental and Construction Engineering; M. Rakowska, Texas

/School for Environment and Sustainability; B. Chadwick, Coastal 
Monitoring Associates / Environmental Sciences; G.H. Rosen, SPAWAR 
Systems Center San Diego / Energy and Environmental Sustainability; 
M. Colvin, Naval Information Warfare Center Pacific / Energy and 
Environmental Sustainability; R. Pitt, The University of Alabama; E. 
Strecker, B. Steets, M. Otto, Geosyntec Consultants

Effective means of evaluating the significance of the stormwater inputs 
are important when evaluating the long-term effectiveness of sediment 
remedial efforts. Here we present improved tools to assess the impact 
of stormwater runoff on metal sediment contamination, bioaccumula-
tion, and bioavailability in Paleta Creek, the San Diego Naval Base 
in California, USA. Intensive stormwater sampling was coupled with 
receiving water sediment sampling, including sediment traps and surficial 
sediment collections, ex situ bioassays, using the clam Macoma nasuta, 
and porewater sampling via DGTs during the wet and dry season. The 
effects of stormwater on receiving water were evaluated by examining 
the statistical differences by location (near stormwater discharges to far) and 
period (dry vs wet season) of concentrations in sediment cores, sediment 
traps, tissue bioaccumulation and sediment porewater. Non-parametric 
statistics using R showed strong coupling between location and period 
for Cd, THg, Ni, Pb and Zn, with concentrations of these metals increasing 
toward the stormwater discharge and during the wet season. Cu and 
As, however showed no significant increases during the wet season and 
increasing toward locations further from the stormwater, suggesting that 
other sources were important. Sediment traps were useful to confirm 
these results while reflecting only sediment depositing during a single wet 
season, whereas sediment samples inherently reflect historical discharges 
as well. Despite the significant increases in sediment concentration 
in many metals, bioassay tissues showed that concentrations of all metals 
showed significant decreases during the wet season, suggesting that 
stormwater contaminants were associated with less bioavailable forms. 
Deposition and reduction in the sediment column would normally be 
expected to lead to further reductions in bioavailability over time sugges-
ting that stormwater in this watershed is not a significant contributor to 
benthic organism impacts despite recontamination as measured by 
the bulk sediment concentration. Moreover, porewater concentration 
measurements also showed significant decreases over the wet season for 
all metals, consistent with the reductions in bioaccumulation and further 
suggesting reduced bioavailability of stormwater metals.

Alternative Approaches to Animal Testing for 
Ecotoxicity Assessments: Exploring New And Novel 
Approaches - Part 2

524 Identifying methods for the assessment of toxicant-induced 
alterations in neurological function in larval fathead minnows 
J. Krzykwa, G. Lamanteer, A. Hawkins, M.K. Sellin Jeffries, Texas 
Christian University / Department of Biology

Alterations in neurological development and/or vision have been noted 
after exposures to a variety of environmental contaminants, includ-
ing heavy metals, pesticides, pharmaceuticals, and estrogens. Despite 
the growing interest in assessing the neurotoxicity of toxicants, routine 
toxicity testing methods-such as the recently developed fish embryo toxic-
ity (FET) test-do not currently include endpoints capable of predicting
adverse impacts on neurological development. Previous studies have identified embryonic eye size as a potential FET test endpoint, and while there is limited evidence suggesting that these alterations are indicative of altered neurological development, studies validating the link between eye size and organism fitness are needed. The overarching goal of this project is to investigate whether reduced embryonic eye size at the conclusion of the FET test is predictive of altered neurological function and/or vision in larval fathead minnows. The inclusion of such an endpoint would greatly expand the utility of the FET test by allowing for the assessment of neurological teratogens. But first, assays capable of identifying toxicant-induced alterations in neurological function and/or vision in larval fathead minnows must be validated. Therefore, the objective of the present study was to validate methods to assess vision/neurological function in larval fathead minnows using a known neurotoxicant, chlorpyrifos, and the established positive control for the FET test, 3,4-dichloroaniline. Minnows were exposed for 5 or 12 d, starting at <2 hours post fertilization, then neurological function was assessed via three assays: the optomotor response assay, a feeding assay, and the e-start assay to determine which assays were sensitive to chemical exposure. The results of this project will be utilized in future studies investigating whether reductions in embryonic eye size are predictive of sublethal adverse effects.

525 Expanding the chemical footprint of the pp-LFER Target-Lipid Model (pp-LFER TLM) using Quantum-chemically estimated Abraham Parameters (QCAP)

C.W. Davis, ExxonMobil Biomedical Sciences, Inc.; T. Parkerton, ExxonMobil Biomedical Sciences, Inc. / Environmental Science; G.E. Bragin, ExxonMobil Biomedical Sciences, Inc. / Toxicology and Environmental Sciences; A. Redman, ExxonMobil Petroleum and Chemical / Toxicology and Environment Science Division

The target lipid model (TLM) has been well-established for predicting the acute and chronic toxicity of neutral organic polar and non-polar narcotic chemicals. Additionally, the TLM-derived threshold values for ecological protection (HCS) have been demonstrated to be sufficiently protective for this suite of chemicals. However, further adaptation and extension of the TLM to complex chemistries (i.e., surfactants and other ionizable chemicals) has been slow, likely in part to difficulties in obtaining reliable estimates of the octanol-water partition coefficient (Kow), which controls the relative potency (and threshold values) of the narcotic chemicals. For some classes of compounds, empirical class corrections have improved predictions, however, many classes remain data poor and consequently poorly-predicted. The development of a molecular-descriptor-based pp-LFER TLM removed the need for chemical class corrections and improved predictions for complex classes of chemistries. However, classes like surfactants are still poorly characterized with respect to their molecular descriptors, and for ionic species, only recently have methods been developed to compute these parameters. The aim of this work is two-fold: (1) to provide a standardized approach and re-calibration of the pp-TLM framework using quantum-chemically calculated Abraham descriptors; and (2) to include novel classes of chemicals - including neutral and ionic surfactants and expand the predictive domain of the TLM as a chemical hazard and risk assessment tool. Predictions for a training and calibration set of compounds (including the expanded 2018 TLM data set) are compared using (a) the traditional Kow-based TLM, (b) the pp-LFER TLM (Absolv descriptors), and the pp-LFER TLM (quantum chemical descriptors).

526 Effects of atrazine on life parameters, oxidative stress, and ecdysteroid biosynthetic pathway in the marine copepod Tigriopus japonicus

D. Yoon, Sungkyunkwan University; J. Han, Sungkyunkwan University / Department of Biological Science; J. Lee, Sungkyunkwan University

Atrazine is a widely used pesticide that is also known as endocrine disrupting chemical (EDC) for animal. The aim of this study was to investigate adverse effects of atrazine on life parameters, oxidative stress, and ecdysteroid biosynthetic pathway in the marine copepod Tigriopus japonicus. In T. japonicus, no mortality was shown in response to atrazine up to concentration 20 mg/L in acute toxicity assessment. In nauplii, retardation in the growth and prolonged molting and metamorphosis resulted under chronic exposure of atrazine at 20 mg/L. In addition, body sizes were significantly decreased (P< 0.05) in 20 mg/L atrazine-exposed T. japonicus nauplii with the generation of reactive oxygen species. Also, significant increase in the enzymatic activity of glutathione-S-transferase in adult T. japonicus was observed at low concentration of atrazine. To understand effects of atrazine on ecdysteroid biosynthetic pathway-involved genes (e.g., neverland, CYP307E1, CYP306A1, CYP302A1, CYP3022A1 [CYP355A1], CYP304A1, and CYP18D1) was examined with mRNA expressions of ecdysone receptor (EcR) and ultraspriacle (USP) in response to 20 mg/L atrazine in nauplii and adults. These genes were significantly downregulated (P< 0.05) in response to atrazine, compared to the control but not for adult T. japonicus. These results suggest that atrazine can interfere in vivo life parameters by oxidative stress-induced retrogression and ecdysteroid biosynthetic pathway in this species.

527 Toxicogenomic study using genome-wide identified glutathione S-transferases in the copepods Tigriopus japonicus and Paracyclopinula nana

J. Park, J. Lee, Sungkyunkwan University

The glutathione S-transferases (GSTs) are crucial group of enzymes in living organisms which detoxify both endogenous and exogenous compounds such as pharmaceuticals and environmental pollutants. In addition, it is also widely accepted as one of the predominant antioxidant enzyme family against reactive oxygen species (ROS) and oxidative stress by catalyzing the conjugation of glutathione (GSH) to electrophilic compounds to render them water-soluble. The genome-wide identification of GST genes in T. japonicus and P. nana resulted in 32 and 20 GSTs in total, respectively. To validate the detoxification function of the identified GSTs, both copepods were exposed to copper (Cu2+) and the reactive oxygen species (ROS) level and GST activity were measured. This study covers full identification of GST classes in two marine copepod species and their important role in marine environmental ecotoxicology. This is the first study characterizing the whole GST gene family in the copepod T. japonicus and P. nana with in-depth detailed information on the synteny analysis, which could be applied to other genetically complex organisms without currently available whole genome sequences.

528 Predictive Molecular Level Toxicity Signatures Based on Non-Targeted Analysis and QSAR modeling: A Case Study of the Lubbock Canyon Lake System

N. Kamar, Texas Tech University / Environmental Toxicology; N. Zhao, University of Washington; E.P. Kolodziej, University of Washington, Tacoma / Center for Urban Waters Interdisciplinary Arts and Sciences Civil and Environmental Engineering; J. Cropp, Texas Tech University / Department of Environmental Toxicology TIEHH

Current aquatic toxicity assessment strategies are heavily focused on targeted analysis and in vitro/in vivo toxicity data to understand the impact on aquatic organisms upon exposure to complex mixtures such as effluent. However, based on this approach alone, it is difficult to explain observed toxicity symptoms and the hidden impact on biological pathways that were not accounted during an effect analysis. The recent advances in analytical instruments (e.g., high-resolution mass spectrometry) could help us to understand chemical fingerprints of complex mixtures and this information could be integrated with the QSAR (quantitative structural activity relationships) model to understand toxicity signatures of complex mixtures in aquatic organisms. The goal of this study was to understand...
toxicity signatures in the Lubbock Canyon Lake System (LCLS) which, is an effluent dominated stream, using integrated analysis of data from non-targeted analysis of water samples and a QSAR model. Four water samples were collected from the LCLS including upstream, effluent outfall, and two downstream locations. These water samples were analyzed with non-targeted analysis and targeted analysis to understand the level of contamination in the LCLS. Furthermore, potential interactions of identified chemicals was predicted using the Similarity Ensemble Approach (SEA), which is based on the QSAR modeling concept, and a literature search (Comparative Toxicogenomic Database, CTD). Gene Ontology was used to map the predicted chemical interactions to biological pathways, and then ranked based on the number of interactions. The predicted molecular level toxicity signatures were confirmed by measuring molecular biomarkers in larval zebrafish exposed to water samples for 5 days. Based on predictions, the top pathways that could be impacted with 1-4 sites were the serotonin receptor signaling pathway, the adrenergic receptor signaling pathway, gonadotropin receptor releasing hormone pathway, and the in aquatic organisms. There was 80% agreement between the predicted toxicity signatures and the measured molecular toxicity signatures at the effluent discharge and downstream sites. Results from this study will allow researchers to choose chemical fingerprint guided biological pathways to assess adverse impacts on aquatic organisms upon exposure to complex mixtures.

529 In vitro Screening of Bisphenol A Replacement Compounds: Cytotoxicity and mRNA Expression in Chicken Embryonic Hepatocytes
T. Sharin, Environment and Climate Change Canada/University of Ottawa; D. Crump, J. O’Brien, Environment and Climate Change Canada / National Wildlife Research Centre
A market for bisphenol A (BPA) replacement compounds has emerged due to restrictions on the use and production of BPA. Some of these structural analogs have been detected in the environment, yet little is known about their toxicological properties relative to BPA. In the present study, an avian in vitro toxicogenomic model was used to compare the biological activity of five replacement compounds to BPA. Cell viability and mRNA expression were compared in primary chicken (Gallus gallus domesticus) embryo hepatocytes (CEH) exposed to BPA, bisphenol F (BPF), bis(3-allyl-4-hydroxyphenyl)sulfone (TGSIIH), 1,7-bis(4-hydroxyphenyl)-3,5-dioxahexane (DD-70), bisphenol AF (BPAF) or 4-hydroxyphenyl 4-isopropoxysulfone (BPSIP). Transcriptomic effects were determined using two PCR arrays: 1) the ToxChip, which measures the expression of several toxicologically-relevant genes; and 2) the AestroChip, which measures estrogen-responsive genes. DD-70 (LC50=32.9±7.3) and BPAF (LC50=43.1) were more cytotoxic to the embryos compared to BPA (LC50=61.7±43.1). Both BPA and the 5 replacement compounds altered the expression of genes related to xenobiotic metabolism, DNA repair, and the thyroid hormone pathway. The BPA alternative, TGSIIH, elicited the most changes in gene expression, affecting all of the pathways represented on the ToxChip array. The rank order of gene dysregulation based on the ToxChip array was TGSIIH > BPF > DD-70 > BPAF > BPSIP. All of the replacement compounds and BPA altered at least one gene on the Aestrochip array. BPA upregulated the expression of two genes, apovitellenin (3-fold) and carnitine palmitoyltransferase (2-fold). The expression of apovitellenin was also changed by two of the replacement compounds, BPSIP (3-fold) and BPF (42-fold). BPSIP altered the most estrogen-responsive genes (7/10). The rank order of Aestrochip gene dysregulation was BPSIP > BPF > BPAF > BPA > DD-70 > TGSIIH. Overall, the results suggest that certain BPA replacement compounds elicit comparable or even greater toxicity than BPA and may act via different mechanisms.

530 Metabolomic analysis reveals dysregulation of amino acid and lipid metabolism in human liver cells exposed to environmental obesogens
M.E. Franco, G.E. Sutherland, Baylor University / Environmental Science; M.T. Fernandez-Luna, Baylor University / Department of Biology; A.J. Ramirez, Baylor University / Baylor Science Facility; R. Lavado, Baylor University / Environmental Science
Obesity is considered a global pandemic affecting people of all ages and backgrounds. Environmental chemicals classified as obesogens may contribute to the promotion of obesity by altering lipid metabolism. While these obesogens are abundantly used in a wide variety of consumer products, from food packaging to fungicides, there is limited information available regarding the mechanism by which environmental exposure can contribute to the onset of obesity. In this study, potential alterations in the levels of 40 metabolites and 360 lipids in the human HepaRG liver cell line, a validated model for cellular steatosis, exposed to different concentrations of seven potential environmental obesogens were evaluated. These compounds included the pharmaceuticals rosiglitazone (ROS) and fenofibrate (FEN), the perfluorinated compounds perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), the plasticizers bisphenol-A (BPA) and di-2-ethylhexyl phthalate (DEHP), and the fungicide tributyltin (TBT). Additionally, LC50's were calculated for each compound, and immunofluorescence microscopy for cellular bioaccumulation of neutral lipids was conducted. Environmental levels of PFOS, DEHP, and TBT showed significant lipid bioaccumulation in the immunofluorescence assay. This was associated with increased levels of most of the evaluated lipids and a reduction on some amino acids. Overall, this integrated omics analysis provides mechanistic insights into the potential of these environmental pollutants to cause non-alcoholic fatty liver disease (NAFLD). Furthermore, this study actively contributes to the development of molecular signatures of toxic effects of chemicals causing fatty liver diseases and to the development of alternatives to in vivo experimentation.

531 Cell-based Lipidomics for Assessing Ecological Impacts of Environmental Surface Waters
Q. Teng, H. Zhen, Y. Yue, J.D. Mosley, USEPA / National Exposure Research Laboratory; D. Ekmak, US Environmental Protection Agency / National Exposure Research Laboratory; P. Bradley, US Geological Survey / South Atlantic Water Science Center; D. Willenueve, USEPA / Mid-Continent Ecology Division; J.E. Cavallin, G.T. Ankley, US Environmental Protection Agency / Mid-Continent Ecology Division; T. Collette, USEPA / National Exposure Research Laboratory
Chemicals released into surface waters by waste water treatment plants (WWTPs) and industrial and agricultural operations often produce adverse outcomes in both humans and wildlife. Traditional methods using live animals for conventional risk assessments are both resource- and time-intensive, and thus not sustainable in the long term. Cell-based assays have been widely used to gain information on impacted cellular pathways and relevant biomarkers of environmental exposure. In the current study, we applied a zebrafish liver (ZFL) cell-based lipidomics approach to assess the potential ecotoxicological impacts of complex contaminant mixtures in eight stream waters collected across the United States and Puerto Rico. ZFL cells were exposed to media prepared with the surface water samples for 48h. Intracellular lipophilic metabolites were detected using liquid chromatography high-resolution mass spectrometry (LC- HR MS). Untargeted lipid profiling revealed significant cellular stress resulting from exposure to several of the sites, including peroxisomal-mediated oxidative stress, endoplasmic reticulum stress, lysosomal disruption, and mitochondrial dysfunction. The results demonstrate the utility of cell-based lipidomics for environmental monitoring and risk assessments of surface waters. Detailed methods and results will be reported.
Fate, Effects, Mitigation and Monitoring of Oil and Oilfield Wastewater Spills in Freshwater Ecosystems - Part 2

532 The physical and chemical fate of diluted bitumen following experimental spills into freshwater limnocorals

S.S. Stoyanovich, J.L. Rodriguez-Gil, University of Ottawa / Department of Biology; R. Faragher, Environment and Climate Change Canada; M.L. Hanson, University of Manitoba / Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada; F. Mirnaghi, Environmental Climate Change Canada; D.M. Orihel, Queens University / Department of Biology / School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; K. Shah, Z. Yang, Environment and Climate Change Canada; J.M. Blais, University of Ottawa / Biology

Diluted bitumen (dilbit) is increasingly transported by pipeline in Canada to global markets, raising the likelihood of accidental spills. A recent report by the Royal Society of Canada concluded that more research is needed on the weathering; fate; behaviour; and environmental effects of dilbit in aquatic systems to better inform spill response countermeasures. To address this research need, the BOREAL project (Boreal-lake Oil Release Experiments by Additions to Limnocorals) was commissioned to carry out large-scale field simulations of a dilbit spills into a freshwater lake. Nine limnocorals (10 m diameter, >100 m³) were installed in Lake 260 of the International Institute for Sustainable Development’s - Experimental Lakes Area (IISD-ELA) near Kenora, Ontario. Experimental spills were carried out at oil volumes ranging from 1.5 to 179.8 L, resulting in oil:water ratios ranging from 1:100,000 to 1:1000. This presentation will report on the physical and chemical characteristics; fate; and behaviour of dilbit following its addition to water, paying special attention to major processes including evaporation, spreading, dissolution, emulsification biodegradation and submergence. Following dilbit application to water, rapid evaporation of the volatile fractions present in the dilbit was observed during the first 4 days of the study, coinciding with increases in density (0.922 g/mL to > 1 g/mL) and viscosity (181 to > 1 000 000 mPaS) of the spilled material. Dilbit’s water content rapidly increased from 0.18 to 24% during the first 8 days of the study, characteristic of the formation of a water entrained sate. The onset of submergence across all treatments progressed from low to high, with the lowest treatment beginning to sink on day 12, and the highest treatment beginning to sink on day 31. The submergence observed can be mainly attributed to increases in density of the dilbit following extensive weathering. This work provides baseline data on the environmental fate and behaviour of dilbit in a realistic freshwater environment. In particular, we are the first to demonstrate the propensity for dilbit to sink under ambient environmental conditions in fresh waters typical of many boreal lakes across the Canadian Shield.

533 Dilbit for dinner: Using stable isotope analysis to trace carbon from a diluted bitumen spill into the aquatic food web

J. Mason, Queens University / Environmental Studies; J. Séguin, J.M. Blais, University of Ottawa / Biology; M.L. Hanson, University of Manitoba / Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada; V. Palace, IISD-Experimental Lakes Area; J.L. Rodriguez-Gil, University of Ottawa / Department of Biology; D. Layton Matthews, Queens University / Geology; M. Leybourne, Queen’s University / Geology; D.M. Orihel, Queens University / Department of Biology / School of Environmental Studies

Bitumen extracted from the Canadian Oil Sands is viscous to such a degree that it must be diluted with light gas condensates to flow through pipelines, yielding diluted bitumen (dilbit). Dilbit is transported across Canada in large volumes through an intricate network of pipelines, which in the event of a rupture, can put the surrounding ecosystems at risk. We conducted a limnocorral experiment at the International Institute of Sustainable Development-Experimental Lakes Area in Northwestern Ontario, Canada. This study involved simulating a dilbit spill in 9 10-m diameter limnocorals (~100 m³) installed in the littoral zone of a boreal lake. Different volumes of dilbit were added to the limnocorals, simulating a range of environmentally realistic spill volumes. Our research involved investigating the incorporation of dilbit derived carbon into the aquatic food web by analyzing stable isotopes in periphyton and phytoplankton for 80 days. Periphyton exhibited a linear 13C depletion as a function of dilbit volume added (p=0.034). Additionally, we exposed freshwater mussels Pyganodon grandis to oil-contaminated water and analyzed their muscle tissue. By the 25th day, the limnocorals treated with 42 L and 82 L showed a 13C depletion (-36.69 ± 2.91 ‰, and -36.47 ± 1.68 ‰) statistically different from control (-33.28 ± 0.5 %) (p=0.008, and p=0.048, respectively). Stable isotopic analysis of carbon was used to track the Deepwater Horizon oil spill in marine systems, but to date, stable isotopes have not been used as a tool to track the fate of dilbit in freshwater ecosystems. Our research demonstrates the utility and power of applying isotope analysis at the site of future freshwater oil spills.

534 The stimulation of freshwater phytoplankton communities following experimental diluted bitumen spills in boreal lake limnocorals

J. Cederwall, Queens University / Biology; J.M. Blais, University of Ottawa / Biology; M.L. Hanson, University of Manitoba / Department of Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada / Emergencies Science & Technology; V. Palace, IISD-Experimental Lakes Area; J.L. Rodriguez-Gil, University of Ottawa / Department of Biology; T. Black, University of Manitoba / Department of Environment & Geography; C.W. Greer, National Research Council Canada / Energy, Mining and Environment; S.N. Higgins, IISD-Experimental Lakes Area; A.C. Ortmann, Fisheries and Oceans Canada / Bedford Institute of Oceanography; A. Zastepa, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; D.M. Orihel, Queens University / Department of Biology / School of Environmental Studies

Following highly publicized oil spills, the public has grown increasingly wary of the threat oil spills pose to aquatic ecosystems, yet the impacts of diluted bitumen in freshwater remain unclear. To address this gap, the BOREAL (Boreal lake Oil Release Experiment by Additions to Limnocorals) project seeks to give a comprehensive picture of effects for a complete ecological risk assessment of diluted bitumen by using a temperate oligotrophic lake with a natural food web for exposure. At the IISD-Experimental Lake Area in 2018, we simulated seven diluted bitumen spills—over a range of environmentally realistic spill volumes—in 10 m diameter, in-lake limnocorals, containing >100 m³ of water and natural lake sediment. We assessed diluted bitumen’s effects on the structure and function of phytoplankton communities for 80 days post-spill. Employing multiple lines of evidence, we assessed algal responses through analysis of chlorophyll-a, traditional taxonomy by light microscopy, flow cytometry, FlowCAM imaging cytometry, Pulse-Amplitude-Modulation (PAM), and genomic methods. Although there were species-specific responses, both chlorophyll-a, and photosynthetic ability increased with diluted bitumen dose by two weeks post-spill. Our preliminary interpretation is that phytoplankton may have been stimulated by diluted bitumen providing accessible carbon for growth or through a decline in grazers while also responding to reduced light under oil slicks. This research contributes to our understanding of the effects of diluted bitumen spills in freshwater ecosystems and will provide algal bioindicators of oil pollution for use after accidental spills and to monitor recovery.
535 The BOREAL Project: Changes to Freshwater Invertebrate Communities Following Simulated Diluted Bitumen Additions to Boreal Limnocorals
T. Black, University of Manitoba / Department of Environment & Geography; J. Cederwall, Queens University; S.S. Stoyanovich, University of Ottawa; M. Paterson, IISD-Experimental Lakes Area / Experimental Lakes Area; J.M. Blais, University of Ottawa / Biology; B.P. Hollebone, Environment and Climate Change Canada / Emergencies Science & Technology; D.M. Orihel, Queens University / Department of Biology / School of Environmental Studies; J. Rodriguez Gil, University of Ottawa / Department of Biology; M.L. Hanson, University of Manitoba / Department of Environment and Geography
To bring bitumen from Canada’s Oil Sands to market requires transportation over sensitive boreal environments via rail, truck, and pipeline. With proposed expansion of pipeline infrastructure in Canada, there is a clear need for whole-ecosystem based research evaluating fate, toxicity, and remediation of oil spills specific to freshwater environments. The Boreal Lake Oil Release Experiment by Additions to Limnocorals (BOREAL) aimed to specifically address the fate, behaviour, and toxicity of dilbit spills. The BOREAL study was conducted in an oligotrophic lake (Lake 260) at the IISD-Experimental Lakes Area in Summer 2018. A total of nine 10-metre diameter, ~100-m³, limnocorals were deployed. Seven limnocorals were treated with different volumes of a diluted bitumen product in a regression design accompanied by two reference limnocorals (far-field and near-field). Dilbit volumes ranged from 1.5 L to 180 L, which is representative of historical oil:water ratios for pipeline spills in North America between the 50th and 99th centile (2008-2018). The zooplankton, benthic invertebrate, and emerging insect communities were monitored for 14 days post-addition and 76 days post-addition for abundance and community composition. 48 hours following dilbit addition, zooplankton abundance had decreased in all enclosures, except for our near-field control and did not recover over the study duration to pre-treatment values. Rotifer communities became the dominant phylum within the limnocorals, while copepod communities substantially declined in all treatment limnocorals and the far-field control. No discernable or consistent impact on zooplankton community diversity (functional diversity) was observed between pre-addition and end-of-study samples. There was no clear impact observed to resident benthic invertebrate communities relative to control limnocorals and reference sites; however, a concentration-response decline was observed in total insect emergence, which was not specific to any particular insect family. Overall, invertebrate communities saw sustained declines post-addition. Sheen presence within high-treatment enclosures limited insect emergence, indicating a possible physical impact following oil exposure rather than direct toxicity to insect communities.

536 Fish embryotoxicity associated to weathered Cold Lake Blend diluted bitumen
L. Lara-Jacobo, Autonomous University of Baja California, Tijuana / Chemistry; C. Gautier, Institut National de la Recherche Scientifique (INRS) / Centre Eau Terre Environnement; Q. Xin, H. Dettman, Natural Resources Canada (NRCan) / CanmetENERGY; P. Couture, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; G. Triffault-Bouchet, MELCC / Centre d’Expertise en Analyses Environnementales du Québec (CEAEQ); V.S. Langlois, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement
For several years now, CanmetENERGY’s Devon Research Centre has been performing experiments in a 1200-L wave tank examining the physical and chemical behaviour of various crude oil/water mixtures under varying temperature regimes. Our research group at INRS has undertaken a long-term collaboration with CanmetENERGY seeking to add biological impact assessments to their physical and chemical behaviour studies. A test initiated in September of 2018 used the diluted bitumen (dilbit) Cold Lake Blend (CLB) with air and water temperatures of 15 °C. Water samples were taken from the wave tank 5 times during the 35-day experiment (times 1, 6, 14, 28, & 35) and were used to perform early life stage exposures using fathead minnows (Pimephales promelas). For each sampling time, newly fertilized embryos were exposed to a serial dilution of the original tank water samples, to non-contaminated river water (used in the tank), and to a reconstituted water control. Embryos were raised until hatching. Embryonic and larval mortality were noted as were hatching time and the incidence and type of malformations, number of heart beats/min, and in vivo EROD activity. Surviving larvae were flash frozen for subsequent gene expression analysis. Preliminary results showed that CLB exposure yielded significant negative impacts on embryonic fish, including increased rate of mortality and malformations, and alterations of the heart beat frequency and EROD activity. The highest mortality rate was found at times 1 and 6, while malformation incidence, heart beat count, and EROD activity were much more affected in the highest CLB concentrations tested for each of the time-points. Real-time RT-PCR analysis of a series of genes related to xenobiotic detoxification and oxidative stress are ongoing. This research project demonstrates the importance of testing inherent toxicity associated with more natural oil weathering conditions as fish embryotoxicity changes with changing oil chemical profiling.

537 The transcriptional responses of Japanese medaka eleutheromembryos to sublethal dibiit exposure
B.N. Madison, Queens University / Chemistry and Chemical Engineering; S.J. Wallace, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; J. Zhang, Miami University / Department of Statistics; V.S. Langlois, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement
Diluted bitumen (dibit) produced in Canada’s oil sands region is currently being transported across North America in close proximity to important watersheds and is destined to expand as demand for petroleum products to overseas markets grows. However, only limited characterization of the potential risks to aquatic ecosystems has been performed, despite increases in current volume and frequency of transcontinental movement of dibit. We expand upon our earlier dibit toxicity studies to survey the transcriptomic responses of newly-hatched Japanese medaka (Oryzias latipes) following embryonic exposure to dibit-derived water accommodated fractions at environmentally relevant levels. The central aims of this work were: 1) to pinpoint novel biomarkers of developing fish subjected to sublethal concentrations of dibit and 2) to identify gene networks altered prior to the onset of developmental malformations; including species-specific responses, e.g., abnormal swim bladder inflation. Using a custom-made microarray for medaka, we contrasted the transcriptomic profiles of control-, dispersant- (Corexit®9500A), and dibit- (Cold Lake Blend and Access Western Blend)-exposed medaka. Then, we surveyed mRNA targets demonstrating exposure-related responses with the corresponding developmental malformations observed at hatch. Of these, cytochrome P450 transcripts (e.g., cyp1) in fish from all dibit treatments (malformed, or not) ranked within the top differentially expressed genes as the superlative individual gene biomarker of exposure and toxicity; others included: fibroblast growth factor (fgf7), aryl hydrocarbon receptor (ahr), and AHDR repressor (ahrr), as well as heat shock protein 70kDa (hsp70). Gene set analysis of expression data enriched during the response to dibit exposure included: cell process-, immunological-, and metabolic pathways, lipid metabolism, steroid biosynthesis, and effects on a number of critical growth receptor signaling pathways. Differences were also noted in the response of fish exposed to combined dibit and dispersant treatments from those in the dispersant-only group. Both dibit and dispersant exposure at the embryonic stage appeared to have individual and combinative effects on the transcripts of newly hatched medaka. This is the first study to assess the mRNA responses of developing fish, including species-specific effects, to sublethal dibit exposure in order to establish dibit toxicity profiles derived from transcriptomic responses prior to the manifestation of visible signs of chronic toxicity.
538 Evaluation of the toxicity of diluted bitumen on two Canadian salmonids during their development

R. Berube, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; M. Lefebvre-Raine, C. Gauthier, T. Bourdin, Institut National de la Recherche Scientifique (INRS) / Centre Eau Terre Environnement; F. Dupont, N. Gruyer, G. Trifault-Bouchet, MEI-LCC / Centre d’Expertise en Analyses Environnementales du Québec (CEAEQ); V.S. Langlois, P. Couture, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement

Canada’s crude oil production is growing and requires an increase of transport capacity. Pipeline construction projects are being developed to transport diluted bitumen (dilbit) from Alberta, Canada to the coasts. Dilbits are a mix of bitumen and natural gas condensate, which facilitates transport by reducing bitumen’s viscosity. However, limited information is available on the toxicity of dilbits in freshwater ecosystems. This project aims to evaluate the impact and toxicity of dilbits in two salmonids found in Canadian freshwater ecosystems. Chronic exposures were performed on rainbow trout (Oncorhynchus mykiss) and Atlantic salmon (Salmo salar) at different developmental stages. One dilbit (Clearwater McMurray) and one conventional crude oil (Lloydminster) were tested. Oils were mechanically dispersed to assess the toxicity of their water accommodated fraction (WAF). The toxic components of the oils were analyzed in WAF dilutions (PAHs, VOCs, and BTEX). At exposure completion, mortality, growth, and malformations were assessed. CYP1A activity, an indicator of the detoxification capacity, was quantified along with the expression of its gene. In addition, the quantity of oxidative damage on cellular lipids (malondialdehyde) and the expression of other targeted genes (cat, sod, gst, p53, and XRC) were measured. Preliminary data suggest Clearwater McMurray dilbit to be the most toxic oil to both salmonid species as it yielded higher mortality rates than the conventional oil. CYP1A activity and cyp1a mRNA levels increased in rainbow trout larvae following an exposure from the fertilized egg stage to hatching (exposure duration of approx. 30 days), but CYP1A activity decreased once these exposed fish were returned to clean water until yolk sac resorption (deparation duration of approx. 20 days). Noteworthily, CYP1A activity was not significantly induced when the exposures started after the eyed stage. When comparing salmonid species responses to the dilbit treatment, mortality rates of the two oils were similar for both species, even if chemistry analysis demonstrated a higher level of TPAHs in the WAFs used for the salmon exposure. This research project will help understanding of the impact and toxicity of conventional and unconventional oils on the early life stages of economically important freshwater fish species for Canada.

539 The Freshwater Oil Spill Remediation Study (FOReS): Evaluation of oil spill-related toxicity using an in situ amphibian metamorphosis assay

J. Smits, R. Krohn, D. Hung, University of Calgary / Dept. of Ecosystem & Public Health, Faculty of Veterinary Medicine; V. Palace, IISD-Experimental Lakes Area

There is a major knowledge gap regarding effective remediation strategies for oil spills into freshwater environments. As one component of an oil spill remediation project on the IISD-Experimental Lakes Areas (ELA), we studied the development of local Wood frog (Lithobates sylvaticus) larvae (tadpoles). For the pilot study, experimental oil spills of 1.25 L of weathered diluted bitumen and conventional heavy crude, were applied to shoreline plots (enclosures) (2.5m x 15m) in Lake #260 at the IISD-ELA, resulting in a 0.1cm coating on the water. This was followed by standard clean-up (skimming, slushing, sorbent pads) and natural attenuation. Wood frog egg masses were collected from local wetlands and hatched in the laboratory. At Gosner stage 21-22, the tadpoles were placed into the experimental enclosures. The pilot study included 20 animals per cage, 4 cages (replicates)/enclosure, 4 enclosures (1 dilbit, 1 conventional crude, 2 controls). In year 2, the full study entailed 40 animals per cage, 3 cages (replicates)/enclosure X 18 enclosures. Tadpoles are fed, monitored every other day, and euthanized when >50% reached their metamorphic climax. Gross anatomical examinations are conducted, and samples collected for relevant biochemical, endocrinological and contaminant analyses. In year 1, tadpoles were introduced into enclosures before controlled spills of diluted bitumen or crude oil, which were then treated with physical, chemical and/or biological clean-up methods. Control replicates were carried out in the same lake and shoreline habitats, but had no exposure to the oils treatments. In year two, the acclimated tadpoles are being reintroduced into the enclosures after the controlled oil spills and experimental clean-up methods have been conducted. The pilot study confirmed that tadpoles could survive the oil applications of diluted bitumen and crude oil, continuing to develop through metamorphosis. Major endpoints that will be discussed and compared are: 1) survival, 2) size at- and time to-metamorphosis, 3) body condition (body mass: length), 4) behavioural responses, 5) thyroid hormones levels (biomarkers of endocrine disruptors) 6) triglyceride levels (indicate body energy stores), and 7) tissue metal levels. Developmental and toxicological responses in the frogs allow comparisons that will distinguish the clean-up strategies that best support the restoration of ecosystem function.

Fate and Effects of Metals: Mechanistic Knowledge of Metal Interactions With Aquatic Biota - Part 2

540 Unraveling local pH and metal speciation surrounding single phytoplankton cells: Implication for metal bioavailability

F. Liu, Imperial College London - South Kensington Campus / Department of Earth Science and Engineering; Y. Zhang, Y.E. Korchev, Imperial College London / Department of Medicine; D. Weiss, Imperial College London / Department of Earth Science and Engineering; Q. Tan, Xiamen University - College of the Environment & Ecology / College of the Environment Ecology; A. Cremazy, University of British Columbia / Department of Biological Sciences.; C. Fortin, INRS - Centre Eau Terre Environnement; P. Campbell, University of Quebec / INRS Eau Terre Environnement

Over the last 40 years, a general consensus has developed that uptake of trace metals by phytoplankton can be well predicted by metal speciation in ambient bulk water. However, an important but untested assumption of the current paradigm is that local chemical conditions such as pH and metal speciation in the boundary layer surrounding single phytoplankton cells are not distinguished from those in bulk water. A lack of knowledge on local pH and metal speciation in the micro- or nano-space (i.e., phycosphere) represents an impediment to accurately predicting metal bioavailability. Here, a novel zwitterionic label-free pH nanoprobe was developed by crosslinking glucose oxidase and polylysine at the tip of a nanopipette. This pH nanoprobe has a sensitivity greater than 0.01 pH units in the pH range from 6.0 to 9.0, a fast ~2 ms response time, a 50 nm spatial resolution, and a linear pH response in solutions up to 0.7 M ionic strength. The measured local pH in the proximity of single cells of several model phytoplankton species of cell diameter ranging from 5 to 150 um were significantly different from bulk water pH; local pH values were influenced by light intensity, ambient concentration of bicarbonate, and the distance to the cell. With this in mind, we calculated the potential influence of the local pH conditions on the speciation of dissolved essential (Co, Cu, Fe, Mn, Ni and Zn) and non-essential metals (Al, Cd, Hg, Pb, Sc and Sm) within this microenvironment in both marine and fresh waters. We propose that many of the ‘previously unexpected metal uptake’ data purely based upon metal speciation in bulk water can be successfully explained when considering local pH and metal speciation changes in the phycosphere.
541 Effects of sublethal Cd, Zn, and Cd/Zn mixtures on antioxidant defense and oxidative stress in early life stages of the purple sea urchin

C.M. Wood, University of British Columbia / Zoology; L.S. Nogueira, CAPES - Brazil; F. Valdez Domingos Moreira, Instituto Nacional de Pesquisas da Amazônia / INPA; P.G. Costa, FURG / Escola de Química e Alimentos; A. Bianchini, Federal University of Rio Grande - FURG / Instituto de Ciências Biológicas; R.D. Klein, Federal University of Rio Grande FURG / ICB

There is growing interest in the toxicity of metal mixtures, but very little information on how individual metals interact mechanistically in causing pathologies at a physiological level. Oxidative stress is now emerging as an important mechanism of metal toxicity, so we examined diagnostic indicators of ROS effects during the first 72 h of embryonic development of a marine model organism, the purple sea urchin Strongylocentrotus purpuratus. Earlier, classical EC50 testing had demonstrated that the toxicities of Cd and Zn were less than additive (i.e. antagonistic) in this system. Embryos were continuously exposed to control conditions, to Cd alone (29 μg/L), to Zn alone (9 μg/L) or to a Cd (29 μg/L) plus Zn (9 μg/L) mixture. These sublethal concentrations represent ~10% of the acute EC50 for each metal. Bioaccumulation, antioxidant capacity against peroxyl radicals (ACAP), total glutathione (GSH), glutathione-S-transferase (GST), glucose-6-phosphate dehydrogenase (G6PDH) superoxide dismutase (SOD) and lipid peroxidation (LPO) were analyzed at 24 h (blastula), 48 h (gastula), and 72 h (pluteus) stages of development. There were no changes in the whole body concentration of Zn (an essential nutrient metal) during the exposures, whereas Zn tended to reduce the marked bioaccumulation of Cd. In control animals, ACAP progressively declined from 24 h to 72 h, while LPO reciprocally increased, but other parameters did not change. Cd alone was more potent than Zn alone as a pro-oxidant, with the major effects being decreases in SOD and parallel increases in LPO throughout development; GST also increased at 24 h. Zn alone caused only biphasic disturbances of ACAP. In all cases, the simultaneous presence of the other metal prevented the effects, and there was no instance where the oxidative stress response in the presence of the Cd/Zn mixture was greater than in the presence of either Cd or Zn alone. Therefore the sublethal effects of joint exposures were always less than additive or even protective, in agreement with classical toxicity data. Furthermore, our results indicate that SOD and Zn can play important roles in protecting sea urchin embryos against Cd-induced lipid peroxidation (IDRC, International Canada Research Chairs Program).

542 Understanding Mechanisms of Bioavailability of Metal Mixture Exposures

Y. Gopalapillai, Environment and Climate Change Canada / Department of Earth & Atmospheric Sciences; B.A. Hale, University of Guelph / SES

Risk assessments for metal-elevated waters typically use environmental quality standards derived from studies of single metal toxicity thresholds. However, geologic co-occurrence in the feedstocks means that most metal-elevated sites are a mixture of metals at concentrations which individually could cause toxicity. Extensive research into the mechanisms of interactions of trace metals with water chemistry factors (pH, major cations) has contributed to the development of the Biotic Ligand Model (BLM), however little knowledge of interactions amongst co-existing trace metals exists. Here, we aim to gain mechanistic insights into the impact of mixtures on metal-BL binding in aquatic plant, Lemna minor, under alkaline conditions (pH 8.3). Metal accumulation in single metal versus ternary mixture exposures were assessed using saturation binding principles derived from enzyme kinetics. The basis is that a fixed number of BL binding sites exist, which become saturated and can be fitted to a Michaelis-Menten saturation curve. Previous studies have exploited saturation binding to explore metal-BL binding, however, none of these studies consider plants; hence the importance of the present work for ecotoxicological risk assessment of mixtures. Results show that Ni-Cu-Cd compete for uptake into organism, but once inside, their interactions are smaller. Overall, Free Ion Activity Model or BLM alone will not model bioavailability, as the organism plays a role in determining what it is exposed to.

543 Examining the relationship between metal exposure (Cd and Hg), subcellular accumulation, and physiology of juvenile Crassostrea virginica

A. Fitzgerald, New Jersey City University / Biology Department; C.B. Zarnoch, Baruch College / Department of Natural Science; W.G. Wallace, The Graduate Center, City University of New York / Earth & Environmental Science

Bivalves living in urbanized environments are subjected to a variety of pollutants, including non-essential trace metals [i.e., cadmium (Cd) and mercury (Hg)]. Accumulation of these metals in sensitive subcellular components, such as organelles and enzymes, may impact physiology at the whole-body and subcellular levels. In order to explore the their individual toxicity and associate subcellular partitioning, juvenile eastern oysters, Crassostrea virginica, were exposed to Cd or Hg [Control, Low (1x) and High (4x)] in the laboratory. Physiological endpoints were overall condition, protein content, and aerobic potential (via electron transport system assay). Subcellular fractions included an insoluble fraction (which would contain metal-rich granules), heat-stable proteins (including metallothionein-like proteins), organelles and heat-denatured proteins (including enzymes). Despite the 4-fold increase in metal concentrations, oysters from the High-Cd treatment (2.4μM Cd) attained a body burden that was only 2.4-fold greater than that of the Low-Cd treatment (0.6 μM Cd), while oysters from the High-Hg treatment (0.056μM Hg) accumulated 8.9-fold more Hg than those from the Low-Hg treatment (0.014μM Hg). The fold difference in total Cd burdens was, in general, mirrored at the subcellular level, though binding to heat-denatured proteins in the High-Cd treatment was depressed (only 1.6-fold higher than the Low-Cd treatment). Hg did not appear to appreciably partition to the subcellular fractions examined in this study, with the fold-difference in accumulation between the Low- and High-Hg treatments ranging from 1.5-fold (heat-stable proteins) to 4.6-fold (organelles). Assessment of toxicological endpoints showed that oysters exposed to High-Cd (2.4 mM) had significantly lower condition indices, proteins, and a depressed ETS activity as compared with Control and Low-Cd. Oysters exposed to Hg [Low-Hg or High-Hg] appeared to be unresponsive in terms of condition index, protein content and ETS activity. Differences in how oysters internalized and partitioned these metals, and not overall body burdens, may account for observed differences in toxicity. Additionally, environmentally realistic concentrations, mimicked by the Low-Cd (0.6 mM Cd) and Low-Hg (0.014 mM Hg) treatments, are unlikely to be hamper efforts to restore this ecosystem engineer in urbanized ecosystems (i.e., Hudson Raritan Estuary).

544 Influence of water quality on the acute toxicity of cadmium to the Florida apple snail, Pomacea paludosa

J. Sanchez, Loyola University, Chicago / Institute of Environmental Sustainability; S. Trinh, Institute for Environment and Resources; T. Hoang, Loyola University, Chicago / Institute of Environment and Sustainability

Cadmium (Cd) is a toxic metal and present in many aquatic ecosystems due to anthropogenic activities. While water quality influence metal toxicity and environmental quality guidelines have taken the influence of water quality, specially dissolved organic carbon (DOC) and pH into account for a number of metals, such as Cu, Zn, Ni, the current guidelines for Cd only consider the effect hardness as a modification factor. This study determines the influence of water quality on the bioavailability and acute toxicity of cadmium to the Florida apple snail (Pomacea paludosa) in support of development of water quality guidelines for tropical environment. 96-h acute toxicity tests were conducted with P. paludosa in waters at various hardness, DOC, and pH. Survival of snails was measured to determine lethal effect concentrations (e.g., NOEC, LOEC, LC5, LC50). Results of the present study show that the toxicity of Cd was strongly
influenced by water quality. The toxicity significantly decreased when water hardness, DOC, and pH were increased. For example, the 96-h LC50 increased from 53 to 108 µg/L Cd when hardness was increased from 45 to 277 mg/L as CaCO3 or the LC50 increased from 35 to 119 µg/L Cd when DOC concentration was increased from 5 to 20 mg/L. The decrease in Cd toxicity with increasing hardness is attributed to the competitive binding between hardness ions (i.e., Ca2+, Mg2+) and Cd2+ to the biotic ligand. The change in toxicity of Cd with DOC was explained well by the results of chemical speciation analysis for Cd in the exposure water. The percentage of Cd that bound to DOC (Cd-DOC), which is believed to be non-bioavailable Cd species increased from 8.2% to 24% while free Cd (toxic species, Cd3+) decreased from 84% to 70% when DOC concentration increased from 5 to 20 mg/L. Results of the present study are useful for development of water quality guidelines for Cd that takes the influence of water quality guidelines into account, especially for tropical aquatic ecosystems, such as the Florida Everglades.

545 Effects of waterborne chromate (Cr6+) on mRNA expression patterns in Lake Trout (Salvelinus namaycush)

J.P. Sherry, T. Neheli, J. Miller, Environment and Climate Change Canada / Water Science & Technology Directorate; D. Poirier, Ontario Ministry of the Environment; T. Watson-Leung, Ministry of the Environment, Conservation and Parks / Aquatic Toxicology Unit; R. Chung Kit, S. Maedler, Ontario Ministry of the Environment, Conservation, and Parks; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences; E.J. Reiner, Ontario Ministry of the Environment, Conservation and Parks; D. Simmons, Ontario Tech University / Faculty of Science

In anticipation of the development of chromite mining in the Ring of Fire in Northern Ontario, we assessed the effects of Cr6+ on the liver transcriptome of Lake Trout which is native to that area. Juvenile lake Trout were exposed in the laboratory to waterborne Cr6+ (0.2 ppb and 3 ppm) for 21-days (n = 6 flow-through tanks of 3 fish per tank); laboratory water was used for the control treatments. The high treatment was for 7-days due to mortality beyond 10-days in a pilot experiment. The liver transcriptomes of 2 fish per tanks were sequenced via a TruSeq/NextSeq workflow and assembled de novo via Trinity. At a false discovery rate (FDR) of 0.01 about 4,600 mRNA transcripts were differentially expressed (DE). The largest response was seen in fish from the 3 ppm Cr6+ treatment: ~2,200 transcripts were DE relative to the control and low dose treatments. In the 0.2 ppb Cr6+ treatment ~1,200 transcripts were DE relative to the control and high dose treatments. In the control treatment ~1,000 transcripts were DE relative to the high and low dose treatments. The DE transcripts were identified, curated, and functionally analyzed by means of Ingenuity Pathway Analysis (IPA). In IPA, we contrasted each Cr6+ treatment against the control fish and against one another. We also contrasted the control fish against DE transcripts that were common to both the low and high concentration treatments. Our results suggest that Cr6+ caused molecular level responses in Lake Trout at an environmentally realistic concentration of 0.2 ppb. Liver Hyperplasia/Hyperproliferation with 908 DE transcripts was significantly enriched in the 0.2 ppb dataset relative to the control fish. The most enriched molecular and cellular functions were Cell Death & Survival and Protein Synthesis with 535 and 245 DE transcripts respectively. We shall also highlight some significant effects on upstream regulators and mechanistic networks to gain insight into the effects of Cr6+ exposure on juvenile Lake Trout.

546 Sub-lethal effects and accumulation of thallium following chronic exposure to model organisms Daphnia magna and rainbow trout

A. Nagel, C. Cuss, University of Alberta / Renewable Resources; G. Goss, University of Alberta / Biological Sciences; W. Shotyk, University of Alberta / Renewable Resources; C.N. Glover, Athabasca University

Thallium (Tl) is a trace element associated with base mining effluents. In Canada, water quality guidelines for Tl exist, but are based on only a few data, most of which are acute in nature. In the current study, chronic waterborne exposures of Tl were conducted using two freshwater model species, the water flea (Daphnia magna) and rainbow trout (Oncorhynchus mykiss). Ecologically-relevant endpoints such as reproduction, growth and survival, were combined with assays examining sub-lethal mechanisms of effect on ionoregulatory enzyme activity and tissue burden, following 21 and 28 day exposures, for Daphnia and rainbow trout, respectively. Whole animal or tissue Tl burdens were also measured to establish relationships between exposure concentration, bioavailability and toxicity. Exposure of Daphnia to Tl (8ug L−1) resulted in inhibited growth, impaired reproduction and delayed time to first brood. In rainbow trout, Tl (170ug L−1) inhibited ionoregulatory enzyme activity, possibly a consequence of Tl mimicry of monovalent cations such as potassium. These effects were correlated with Tl tissue burden. Our findings show that chronic exposure to Tl can cause impairments to ecologically-relevant endpoints, albeit at concentrations at the high end of the environmental range.

547 Tissue Metal Concentrations and Anti-oxidant Enzyme Activity in Sharks

G.K. Bielmyer-Fraser, Jacksonville University / Chemistry; B. Franks, Jacksonville University / Biology and Marine Science; R. Somerville, Jacksonville University / Marine Science; J. Gelsleichter, University of North Florida

Metals occur naturally in the environment; however, anthropogenic practices have resulted in increased metal concentrations in coastal ecosystems. Sharks are important species, ecologically, recreationally and commercially. Reference levels of metal contaminants in the tissues of sharks, particularly, great whites, is lacking. In this study, concentrations of copper (Cu), cadmium (Cd), nickel (Ni), lead (Pb), selenium (Se), silver (Ag), and zinc (Zn) were measured in the muscle tissue of various shark species including Atlantic sharpnose shark collected from 12 sites along the coast of the southeastern United States, and in great white and tiger sharks, in collaboration with OCEARCH. Metal exposure in various species has been correlated with oxidative stress. Therefore, activities of antioxidant enzymes (superoxide dismutase, catalase, and glutathione peroxidase) were also examined in the shark muscle tissue with the objective of identifying a nonlethal bioindicator of metal pollution. This study provides reference levels of metal contaminants in the muscle tissue of several shark species and provides insight into oxidative stress defenses in these top-level carnivores.

Behavioral Ecotoxicology in the Lab and Beyond: Incorporating Environmental Complexity and Relevance

548 Chronic Exposure to Dietary Selenomethionine Disrupts Social Learning and Serotonergic Neurotransmission in Zebrafish

A. Attaran, A. Salahinejad, University of Saskatchewan / Biology; M. Naderi, Saskatchewan University / Biology; S. Niyogi, D.P. Chivers, University of Saskatchewan / Biology

Selenium (Se) is an essential element that has vital physiological functions as well as toxicological properties at elevated concentrations. Although the adverse neuro-behavioural effects of Se have been previously investigated in fish, very little is known about its effects on social learning behaviour in fish. In this study, we investigated the effects of environmentally relevant concentrations of Se on social learning and serotonergic neurotransmission in zebrafish. To this end, we examined whether exposure to different concentrations of dietary selenomethionine (control, 3.2, 12.6, 34.5 µg Se/g dry weight) for 90 days affected the ability of the individual observer fish to follow the demonstrator (experienced) fish escaping an oncoming trawl. Training of naive fish in this social learning paradigm occurred for 5 consecutive days in the presence of experienced demonstrator fish. Subsequently, during probing, the social learning performance of test fish was assessed in the absence of the demonstrator fish. Our results indicated that while 90% of the fish in the control and lower Se-exposure groups (3.2 and 12.6 µg/g) demonstrated a faster escape response by choosing the trained (correct) route, fish in the
highest Se-exposure group (34.5 µg/g) displayed a significantly slower escape response and only 60% of them used the trained route. In order to understand the potential mechanisms underlying these behavioural effects, oxidative stress, a key driver of Se neurotoxicity, was evaluated by measuring the lipid peroxidation (LPO) and the expression of several antioxidant enzymes genes in the zebrafish brain. In addition, since the serotoninergic neurotransmission system is known to be a key regulator of social behaviour in fish, we also evaluated the brain serotonin levels and the expression of several serotoninergic genes. Our results suggested that exposure to Se (34.5 µg/g) caused a higher LPO level and upregulation of antioxidant genes in the zebrafish brain. Moreover, high Se exposure was also found to disrupt the gene expression of serotonin receptors (htr1a, htr1b, and htr1ab), transporter (slc6a4a), synthesis (tryptophan hydroxylase-2), and degradation (monoamine oxidase) in the zebrafish brain. Overall, our study suggests that chronic Se exposure disrupts social learning in zebrafish, likely via the disruption of serotoninergic neurotransmission in the brain.

549 Hidden in the sand: Modification of burying behaviour in shore crabs and cuttlefish by antidepressant exposure

A. Chabenat, Normandie University, University of Le Havre; T. Knigge, Normandie University, University of Le Havre / UMR-I 02 INERIS-URCA-ULH Environmental Stress and Aquatic Biomonitering (SEBIO); C. Jozet-Alves, C. Bellanger, Normandie University, University of Caen / CNRS Animal and Human Ethology (EthoS)

Pharmaceuticals, such as antidepressants are constantly released into the aquatic environment. Consequently, fluoxetine (FLX) and venlafaxine (VEN), the active molecules of Prozac(C) and Effexor(C), are detected up to several ng/L in freshwater and marine coastal waters. Both compounds act on the serotoninergic system, which may result in behavioural impairment, especially of juvenile animals presumed to be more susceptible to low concentrations. The objective of this study was to determine if environmental concentrations of FLX alone or combined with VEN could have any effect on innate burying behaviour in two juvenile marine invertebrates, i.e., Sepia officinalis and Carcinus maenas. Juvenile cuttlefish were exposed from hatching to 30 days post hatch to either FLX alone (i.e. 5 ng/L) or in mixture with VEN (i.e. 2.5 ng/L as well as 5 ng/L of each antidepressant). Juvenile crabs (< 2 cm carapace width) were exposed for a period of 34 days to 5 ng/L of FLX and a mixture of 5 ng/L of FLX and VEN each. Several parameters of sand digging behaviour were assessed weekly in both species. The occurrence of sand digging behaviour decreased in cuttlefish exposed to a mixture of FLX and VEN at the lowest concentration (2.5 ng/L each). At the mixture of 5 ng/L VEN and FLX each, a better body covering in juvenile crabs was observed. In both species, innate behaviour was modified under exposure to mixtures of FLX and VEN at environmentally realistic concentrations. These alterations were observed at an early developmental stage, when animals are particularly prone to predation. Hence, the modification of behavioural traits by exposure to pseudo-persistant antidepressants may decrease the survival of these two species in the long term.

550 Summer vs. Winter: How do fish respond physiologically and behaviourally to wastewater exposure under two seasonal regimes?

H. Mehdi, S. Lau, M. Morphet, McMaster University / Biology; L. Bragg, M.R. Servos, University of Waterloo / Biology; J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; G. Scott, McMaster University / Department of Biology; S. Balshine, McMaster University / Department of Psychology, Neuroscience & Behaviour

Municipal wastewater treatment plant (WWTP) effluents are one of the largest (by volume) anthropogenic sources of aquatic pollution in Canada. Conventional WWTPs are not capable of fully removing particular water-borne contaminants, such as many pharmaceuticals and personal care products. As a result, WWTP outfalls often become major point sources of contaminants into effluent-receiving watersheds. Wastewater can impact fish and other aquatic organisms on multiple levels of biological organization, including but not limited to endocrine disruption, metabolic and behavioural dysfunction, as well as population- and community-level disturbances. However, much of the research conducted to date has not considered the effects of seasonal variation on fishes’ responses to wastewater contamination despite how relevant and overwhelming its effects can be. Our research aimed to address this issue by conducting a laboratory-based experiment, where fathead minnow (Pimephales promelas) were chronically exposed for 21 days to 0%, 25%, and 50% concentrations of wastewater under two thermal regimes (summer: 20°C; winter: 4°C). Various fitness-linked behavioural traits were examined following the exposures, including boldness, locomotor activity, sociability, foraging, and predator responses. We also assessed various whole-organism physiological traits that are strongly linked to our behavioural markers such as resting and maximal metabolic rates, aerobic scope, and critical thermal maximum. We examined behavioural and physiological impacts of wastewater exposure in tandem to gain a more holistic and ecologically-relevant understanding of how aquatic organisms respond to anthropogenically-induced stressors across different seasons. Our research will be able to further bridge the gap between controlled lab experiments and highly dynamic real-world field-based studies.

551 Behavioral consequences of per- and poly-fluorinated alkyl substances (PFAS) for crayfish species located at contaminated field sites

A. Steele, P.A. Moore, Bowling Green State University / Department of Biological Sciences

The necessity for bioindicator species to aid in the assessment of impacts on aquatic ecosystems is currently rising due to the continued anthropogenic degradation of environments. Several characteristics of crayfish make them suitable candidates for use as bioindicators: global distribution, high population densities, low migratory rate, sensitive physiology and behaviors, and easy maintenance within laboratory environments. The demonstrated sensitivity of crayfish as an established bioindicator for an array of anthropogenic toxicants, raises interest in the sensitivity of crayfish to use as a bioindicator for emerging contaminants. The emergent contaminant family, per- and poly-fluorinated alkyl substances (PFAS) such as perfluorooctyl sulfonate (PFOS) and perfluorooctanoic acid (PFOA), have gained particular research attention due their widespread detection and stability within the environment. Previous research has demonstrated exposure to PFAS causes negative effects on the reproductive, endocrine, immune and nervous systems of experimental organisms, however, behavioral effects have not been well documented. The aim of this study was to investigate the behavioral consequences of PFAS exposure on crayfish species and the utility of these organisms as a bioindicator model for PFAS contamination. Differences in the escape response of crayfish from the predatory odor of Micropterus salmoides and in plant consumption were compared between animals collected from various polluted locations in Northern Michigan. Water chemistry sampling in Northern Michigan environments performed by Tip of Mitt Watershed Council (Petoskey, Michigan) and University Michigan Biological Station Analytical Laboratory (Pellston, Michigan) provided verification of PFAS concentrations at crayfish sampling sites to determine the relationship between behavioral deficits and toxicant concentration. Behavioral responses were analyzed and resulted in differences in two ecologically relevant bioassays. Due to the prevalence and known uptake of perfluorinated compounds by aquatic organisms, a suitable bioindicator species and further study on important fitness related behaviors that may be affected by PFAS are critical.

552 Altered reproductive behaviour by male fathead minnows during a whole ecosystem EDC exposure study

P. Blanchfield, A. Majewski, Fisheries & Oceans Canada; D. Callaghan, University of Manitoba; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute

Male fathead minnows (Pimephales promelas) provide extensive parental care, and have become a model species for understanding the impacts of estrogentic compounds. Reduced nesting aggression is a common
behavioural expression of estrogen exposure for male fish in laboratory studies. However, the existence and potential repercussions of altered reproductive behaviour in the wild are unknown. We quantified the reproductive behaviour of male fathead minnows from in-lake video recordings taken before, during and after a synthetic estrogen used in birth control pills (ethynylestradiol, EE2) was added to Lake 260 at the Experimental Lakes Area. Male fatheads exposed to EE2 showed marked reductions in secondary sexual characteristics compared to males from reference lakes. Exposed males reduced time spent tending to eggs as a direct result of increasing frequency of aggressive encounters in response to greater numbers of fish surrounding the nests. These nest intruders were likely feminized male fathead minnows. Thus, the few fathead males that were able to breed during the exposure period faced increasing nest threats from conspecifics that reduced their ability to defend egg clutches and resulted in significantly fewer eggs per nest compared to pre-exposure. Observations of heightened aggression by EE2-exposed spawning male fish run counter to many previous studies. Our study highlights the complex ecological and behavioural interactions that occur in natural systems and further demonstrates the need for studies conducted at the scale of a whole ecosystem.

553 Effects of contaminants across ecosystem boundaries: a conceptual note
M. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Department of Aquatic Sciences and Assessment; J.P. Zabrod, University of Koblenz-Landau / Institute for Environmental Sciences; M. Wieczorek, University of Koblenz-Landau; R. Schulz, University of Koblenz-Landau / iES, Institute for Environmental Sciences

It is common knowledge that freshwater ecosystems are under substantial anthropogenic pressure. Contamination by organic and inorganic substances of anthropogenic origin via point and non-point sources is one of the most important factors worldwide. This fact has attracted substantial attention by researchers that are interested in the impact of chemicals at different levels of biological organization - from biomarkers to populations and even ecosystems. However, relatively little information is available on how the chemical contamination of aquatic ecosystems impacts their subsidy of adjacent terrestrial (riparian) food webs, which might either be bottom-up or top-down directed. The scarcity of data might mainly be driven by the complexity of experimental designs required to test for related hypotheses. This presentation will discuss experimental designs that support the development of this emerging field of research. We argue that experimental systems that are specifically designed (i.e., contain both an aquatic and a terrestrial model ecosystem) to assess for the aquatic subsidy of terrestrial systems will be fundamental to advance knowledge. Moreover, in addition to assessing the quantitative impact of contamination on the subsidy also qualitative measures need to be involved. In this context, stable isotope analysis and methods describing the energetic and nutritious conditions of prey and predators from aquatic and riparian systems, respectively, are imperative. The complexity of aspects associated with the stress-induced implication on the subsidy of terrestrial systems by aquatic resources opens doors for interdisciplinary collaborations of ecology and ecotoxicology.

554 Behavioural and ecological responses to chemical pollution
B. Wong, Monash University / School of Biological Sciences

Humans have brought about unprecedented changes to environments worldwide. For many species, behavioural adjustments represent the first response to altered conditions. Such behavioural modifications can potentially improve an organism’s prospects of surviving and reproducing in a rapidly changing world. However, not all behavioural responses are beneficial. Human-altered conditions, including the discharge of anthropogenic chemicals into the environment, can undermine the reliability of sexual signals used by animals to assess potential suitors. Environmental pollutants can also impair sensory systems or interfere with physiological processes needed to mount an appropriate behavioural response. An understanding of behaviour could therefore be important in helping to explain why some species are able to survive, or even flourish, under human altered conditions, while others flounder.

Concentrations and Thresholds for Effects of Current Use Pesticides in Aquatic and Terrestrial Ecosystems - Part 2

555 An Integrative Analysis of the Effects of Neonicotinoids on the Ruby-throated Hummingbird, Archilochus colubris
S.G. English, University of Toronto / Cell and Systems Biology; N. Sandovall Herrera, University of Toronto, Scarborough / Ecology and Evolutionary Biology; C.A. Bishop, Environment and Climate Change Canada / Wildlife Research Division; J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch Ecotoxicology and Wildlife Health Division; K.C. Welch, University of Toronto Scarborough / Biological Sciences

Neonicotinoids are the most widely used class of insecticides globally, due to their high efficacy and apparent target specificity. Although exposure is known to occur in a variety of non-target organisms, effects on these systems are largely unquantified. This is especially concerning for hummingbirds, which experience exposure through the floral nectar that supports their extreme metabolisms. To respond to this concern, we measured the sublethal cellular, physiological, and behavioral effects of imidacloprid, a common neonicotinoid, on ruby-throated hummingbirds (Archilochus colubris). Birds were exposed to one of three field-realistic dosing conditions (control, 0.172 mg/kg, and 2.5 mg/kg) once per day for three days prior to terminal sampling. Cholinesterase activity assays showed significant dose-dependent neurotoxic effects of imidacloprid exposure in hummingbirds. Similarly, birds’ metabolic rates (VO2) showed significant dose-dependent decreases within 2 hours after dosage. Metabolic rates did not differ between control and dosed birds 24 hours after exposure demonstrating an acute effect on activity immediately after exposure. Measurements of thermal and metabolic responses provided insight into how imidacloprid exposure affects daily energy budgets. No emergent trends arose between torpor propensity and exposure to the pesticide from preliminary data analyses, though body mass did show a significant decreasing trend in both dosage conditions. Oxidative damage biomarkers were quantified to elucidate the non-specific effects of detoxification in liver and muscle tissues. The stress-induced suppression of the humoral immune response to imidacloprid was determined through relative heterophile to lymphocyte ratios. Additionally, feeder tracking ability was tested after dosage, while hovering, preening, and feeding behaviours were indexed to evaluate how toxic effects may be expressed on a whole-organism level. This novel integrative study highlights the deleterious off-target effects of one of the most widely used agrochemical in Canada. Researching these effects is critical in the prevention and remediation of the consequences that arise from anthropogenic activities on ecosystems near and within agriculture.

556 Toxicity of agrochemicals detected on wildflowers to larval Painted Lady Butterflies (Vanessa cardui)
E. Peterson, Texas Tech University / Environmental Toxicology; K. Shaw, National Institute of Standards and Technology / Chemical Sciences Division; P.N. Smith, Texas Tech University / Environmental Toxicology

Beef cattle feed yards and row crop agriculture are the predominant sources of agrochemical usage in the Southern High Plains (SHP) of the United States. Beef cattle feed yards use large quantities of insecticides to control insect pests, and veterinary pharmaceuticals to promote cattle growth and health. To increase yields, row crop-based agriculture relies heavily upon herbicides, fungicides, and insecticides. Previous studies have documented occurrence of agrochemicals and agrichemical mixtures beyond feed yard and row crop agriculture boundaries in uncultivated, marginal areas, raising concern that migratory pollinators and pollinators...
indigenous to the SHP may become exposed to toxic agrochemicals. Painted lady butterfly (Vanessa cardui) larvae were used to investigate potential toxicity of agrochemicals quantified on wildflowers among pollinators. Moxidectin, an anti-parasiticide used on beef cattle feed yards, was determined to be extremely toxic to V. cardui larvae, with a lethal dose at which 50% of larvae died (LD₅₀) of 2.1 ± 0.1 ng/g. Additional agrochemicals, more commonly used in row crop agriculture (pyraclostrobin, clothianidin, and permethrin) delayed V. cardui development from larvae to butterfly. However, moxidectin was the only chemical that produced significant toxic effects at environmentally relevant concentrations. These results indicate that agrochemicals originating from feed yards have the potential to adversely impact development of pollinator larvae occurring in the SHP.

557 Effects of bifenthrin on the dopaminergic pathway in juvenile steelhead (Oncorhynchus mykiss)

J.T. Magnuson, University of California, Riverside / Environmental Sciences; M. Giroix, University of California, Riverside / Environmental Toxicology Graduate Program; N.E. Andrzejczyk, University of California, Riverside / Department of Environmental Sciences; G. Harraka, Z. Cryder, D. Wolf, University of California, Riverside; J. Gan, D. Schlenk, University of California, Riverside / Environmental Sciences

An increase in urban application of pyrethroids in the San Francisco Bay Estuary and Sacramento San Joaquin Delta have raised concern for salmonid populations, as several species have been classified as threatened. Bifenthrin, a type I pyrethroid, is one of the most predominant pyrethroids measured in the Bay-Delta watershed. Previous studies have shown that bifenthrin disrupts the hypothalamic-pituitary-gonadal (HPG) axis, inhibiting gonadal development and inducing estrogenic effects in juvenile salmonid species, such as steelhead. To further understand the mechanism of bifenthrin-induced toxicity to the dopaminergic system, juvenile steelhead were exposed to environmentally relevant concentrations of bifenthrin found before and after major rainfall events (60 and 120 ng/L, respectively) and assessed for the dysregulation of genes involved in the regulation of dopamine levels in the brain, catechol O-methyltransferase (COMT) and monoamine oxidase (MAO). We found that COMT and MAO expression were significantly upregulated in bifenthrin-exposed fish. Metabolomic analyses were conducted on fish brains to further understand the underlying mechanisms of toxicity to the dopaminergic system. The goal of the present study is to better understand the toxicity of bifenthrin to the dopaminergic system in fish. This research was made possible by a Proposition 1 grant from the California Department of Fish and Wildlife.

558 An investigation of the effects of Dicamba exposure on zebrafish (Danio rerio) and rainbow trout (Oncorhynchus mykiss)

J.G. Miller, University of Lethbridge / Biology; E. Vandenberg, University of Lethbridge / Biological Sciences; S. Wiseman, University of Lethbridge / Biology

Dicamba (3,6-dichloro-2-methoxybenzoic acid) is an herbicide used in industrial, domestic, and municipal applications to control woody plants and broadleaf weeds. Currently, dicamba is the second most used benzoic acid herbicide in Canadian agriculture. Because of its widespread use, dicamba is frequently detected in surface waters. In Alberta, dicamba has been found at concentrations of 0.3µg/L in irrigation canals and 2.6µg/L in storm water ponds. However, little is known regarding the effects of dicamba on freshwater aquatic vertebrates. To this end, the toxicological effects of environmental and supra-environmental concentrations of dicamba were investigated in primary cultures of rainbow trout (Oncorhynchus mykiss) hepatocytes and in early-life stages of zebrafish (Danio rerio). Hepatocytes were exposed for 48h to 22.0, 2.20, or 0.22 µg/L dicamba and zebrafish were exposed < 1h post-fertilization until hatch to 50.0, 5.0, or 0.50 µg/L dicamba. The mRNA abundances of biomarkers related to the cellular response to oxidative stress (catalase, superoxide dismutase, glutathione-s-transferase, and glutathione peroxidase) were quantified. Exposure to dicamba did not alter the mRNA abundance of biomarkers of the cellular response to oxidative stress in either species. Also, dicamba did not cause lethality or developmental malformations (edema, spinal curvature) in embryos of zebrafish. However, exposure to Dicamba did elicit an increase in concentrations of s-adenosyl methionine (SAM) in both rainbow trout hepatocytes and zebrafish larvae at 2.20 and 5.0 µg/L, respectively. S-adenosyl methionine is a critical regulator of the cellular methyl pool, and contributes methyl groups important for methylation of DNA, biotransformation of exogenous and endogenous chemicals, and the response to oxidative stress. Neither DNA methylation or expression of DNA methyltransferase enzymes were impacted in zebrafish embryos exposed to dicamba. The role of SAM in the adaptive or maladaptive responses to dicamba are being further investigated in zebrafish. Our data suggests that current environmental concentrations of dicamba do not pose a risk to freshwater fish.

559 Exposure and risk characterization of micropollutants in small streams: agricultural pesticides versus wastewater compounds

E. Carmona Martinez, Helmholtz Centre for Environmental Research - UFZ GmbH / WANA; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect-Directed Analysis; K. Foi, Helmholtz Centre for Environmental Research / System-Ecotoxicology; R. Gunold, UFZ - Helmholtz Centre for Environmental Research / Effect-Directed Analysis; S. Knillmann, Helmholtz-Centre for Environmental Research (UFZ) / System-Ecotoxicology; L. Liebmann, M. Liess, Helmholtz Centre for Environmental Research - UFZ GmbH / System-Ecotoxicology; T. Schulze, Helmholtz Centre for Environmental Research - UFZ / Effect-Directed Analysis; P. Vormeier, O. Weiwer, UFZ - Helmholtz Centre for Environmental Research / System-Ecotoxicology; M. Krauss, Helmholtz Centre for Environmental Research - UFZ / Effect-Directed Analysis

Both agricultural pesticide use and wastewater inputs might contribute to the micropolllutants burden of small and medium-sized streams in rural catchments. Several studies have shown that pesticide exposure is particularly high during discharge events. We present results from a nationwide survey for the monitoring of small streams (KgM, https://www.ufz.de/kgm/index.php?en=44480). At 69 sites from all over Germany, grab water samples were taken at base flow conditions in regular intervals and heavy rain-event triggered composite samples were collected using an automated sampler. In all samples, 385 compounds representative for agricultural use and municipal wastewater were analysed by direct injection LC-HRMS for a wide-scope target screening and quantified using a semi-automated software processing. Currently, the spectrum of analysed compounds is expanded towards 1000 potentially relevant chemicals from agricultural and urban sources. Overall, the samples showed a high spatial and temporal variation of micropollutant concentrations. More than 300 out of the 385 compounds were found in at least one sample. In the majority of the grab samples less than 25 compounds were detected, in contrast to more than 50 in two thirds of the event samples. Agricultural pesticides (majorly herbicides such as metamitron and ethofumesate) and wastewater derived compounds (such as caffeine, artificial sweeteners or the pharmaceutical metformin) were found in high concentration in both types of samples. The maximum concentrations in event samples were in general higher (up to three orders of magnitude) than in grab samples for both pesticides and wastewater-derived compounds. Current investigations aim to assess the acute toxic risk for benthic crustaceans, algae and fish to compare the impact of agricultural pesticides versus that of wastewater-derived pollutants. To this end, using a toxic unit (TU) approach based on EC50 or LC50 values from the literature or from QSAR predictions is used.
560 Current-Use Pesticides in Sediment and Biofilm “Integrative
Samplers” in Coastal California Streams and Relations to Aquatic
Invertebrate Health

B.J. Mahler, US Geological Survey / Water Mission Area; L.H. Nowell,
US Geological Survey / California Water Science Center; T.S. Schmidt,
US Geological Survey / S.O. Conte Anomalous Fish Research Center;
P.C. Van Metre, US Geological Survey / Water Mission Area; M.L.
J. May, US Geological Survey / California Water Science Center

In spring 2017, the U.S. Geological Survey (USGS) Regional Stream
Quality Assessment (RSQA) measured current-use and selected legacy
pesticides in biofilm and bed sediment from 54 small streams in Coastal
California in a range of land-use settings. One objective of the study
was to evaluate samples of biofilm colonized on deployed tiles as an
alternative to bed-sediment samples for time-integrated assessment of
current-use pesticides. Of the 96 pesticides analyzed, 25 were detected
in at least one bed sediment sample and 34 were detected in at least one
biofilm sample; the maximum number of pesticides detected at a site was
22 (in biofilm, 2 sites). Seven compounds were detected in both media at
more than 10% of sites: the legacy pesticide DDT and its degradates DDE
and DDD; the herbicides pendimethalin, oxadiazon, and oxyfluorfen; and
the pyrethroid insecticide bifenthrin. On the basis of the pesticide toxicity
index for pesticide mixtures in sediment (Sed-PTI), which sums Likely-
Effect-Benchmark Quotients for individual pesticides in the mixture,
there was potential acute toxicity to aquatic invertebrates from pesticide
mixtures in sediment (Sed-PTI=1.0) at 4 of the 52 sites. An additional 15
sites had Sed-PTI values >0.1 and <1.0. The pesticides with the largest
contribution to a Sed-PTI=0.1 were bifenthrin (12 sites), esfenvalerate (3
sites), boscalid (3 sites), and cyhalothrin (1 site). There were non-linear
relations between field-based metrics for aquatic invertebrate commu-
nity health and concentrations of boscalid, bifenthrin, and oxyfluorfen in
sediment, biofilm, or both. In general, more pesticides were detected in
biofilm than sediment at a site (63% of sites), but the difference in number
was small (medians of 4 and 3 pesticides in biofilm and sediment, respec-
tively). Each medium has advantages and disadvantages relative to the
other, but the time-integrated view of current-use pesticide occurrence in
Coastal California bed sediment was generally consistent in bed-sediment
samples and biofilm samples.

561 Sediment chemistry, sediment toxicity and aquatic communities
across an urban gradient of streams in the Northeast United States

Survey / OR WSC; B.J. Mahler, US Geological Survey / Water Mission
Area; L.H. Nowell, US Geological Survey / California Water Science
Center; P.C. Van Metre, US Geological Survey / Water Mission Area

Stream sediment contaminants are infrequently measured on broad geo-
graphic scales. As part of the US Geological Survey’s (USGS) National
Water-Quality Assessment (NAWQA) project, sediment samples were
collected from streams representing an urban gradient in the Northeast
United States; including the states of CT, MA, NH, NJ, NY, PA, RI, VT.
The study evaluated relations between sediment chemistry (metals,
pesticides, organochlorines, and polycyclic aromatic hydrocarbons),
sediment toxicity and macroinvertebrate communities across 92 sites.
Sediment toxicity was evaluated by conducting whole-sediment labora-
tory toxicity testing with the amphipod Hyalella azteca (28-d exposure)
and the midge Chironomus dilutus (10-d exposure) following ASTM
and USEPA methods. Organochlorines were the class of contaminants
most commonly measured in stream sediments; with chlordanes and
total PCBs measured at 82% of sites, dieldrin 73%, and DDXs 69%.
Of the current use pesticides, bifenthrin was measured at 71% of sites,
fipronil sulfide 49%, and chlorpyrifos 44%. However, the contami-
nants most likely to exceed their sediment benchmark for “likely” or
“probable” invertebrate effects was bifenthrin, 29% of measured sites,
followed by total chlordanes [as the sum of 5 congeners] 2% and fipronil
sulfide 2%; on an organic carbon normalized basis. Roughly half (49%)
of sites had statistically significant reduced survival or biomass in the
H. azteca or C. dilutus toxicity tests. Total PAHs (TPAHs) in sedi-
ments were the best single predictor of H. azteca survival (adj r²=0.34)
and biomass (adj r²=0.26). Stepwise regression models with up to four
contaminant classes gave minor improvements in the total variance
explained; H. azteca survival (TPAHs >bifenthrin >total chlordanes
>metals- adj.r²=0.44) and for H. azteca biomass (TPAHs >total chlordanes
>bifenthrin >metals- adj.r²=0.32). C. dilutus survival was poorly
predicted by any contaminant class and C. dilutus biomass was best
explained by metals (adj. r²=0.21), with minor improvements when total
chlordanes or bifenthrin were included. These same contaminants were
generally inversely related to common macroinvertebrate metrics (ie.
Ephemeroptera, Plecoptera, Ephemeroptera, Intolerant taxa), through
the upper 70th to 90th quantiles from quantile regression. These results,
and their relation to macroinvertebrate communities, will be discussed
in relation to parallel datasets in other regions of the U.S.

562 Evaluating Soil & Water Assessment Tool (SWAT) Capability to
Simulate Glyphosate Transport on a Watershed Scale

B.A. Asmann, S.R. Hobbs, University of Kentucky / Civil Engineering

Glyphosate (N-phosphonomethyl glycine) is an herbicide that is heavily
used in agricultural industries worldwide. Few reports have quantified
human exposure to glyphosate in rural communities, and concentrations
are not currently monitored in most areas. With growing concern for the
health effects of chronic glyphosate exposure, it is critical to understand
glyphosate transport to make informed watershed management decisions.
This presentation will present glyphosate monitoring data from rudimen-
tary water treatments systems in villages in Belize. Many rudimentary
systems rely on surface water, and may be exposing villagers to water
contaminated with glyphosate. Therefore, water and sediment samples
were collected from sites of rudimentary water treatment systems within
subcatchments where glyphosate is routinely applied. The entire water-
shed was simulated using a hydrological transport model called the Soil
and Water Assessment Tool (SWAT), and simulated concentrations were
compared to observed concentrations to evaluate model capability. A
parameter sensitivity analysis was conducted to identify the factors that
glyphosate transport is most sensitive to, and therefore how to best man-
age it within the watershed. While analyses of results are still underway,
literature has shown concentrations are typically higher with precipitation
events causing increased runoff and soil erosion, and typically higher in
sediment than in the water column. Because glyphosate is applied year-
round in this region and samples were collected during the rainy season,
glyphosate presence in surface water and sediment is expected during
the time of sampling. Other studies have demonstrated the capability of
SWAT to model complex transport and degradation processes to predict
concentrations of various pesticides, so it is expected to be capable of
modeling glyphosate. This research seeks to advance knowledge of
glyphosate transport in the environment and presents a method for simu-
lating it for the purpose of watershed management.

Advances in Passive Sampling Across Environmental
Compartments - Part 2

563 Evaluation of POM air-sampler in assessing atmospheric hydro-
phobic organic contaminants at a confined disposal facility

A. Arbidarg, Texas Tech University / Civil Engineering; D.D. Reible,
Texas Tech University / Civil and Environmental Engineering; C.
Price, D. Acevedo-Mackey, L. Thai, US Army Engineer Research and
Development Center

Volatile losses of hydrophobic organic contaminants (HOCs) such as
PCBs and PAHs from confined disposal facilities (CDFs) during place-
ment and disposal of contaminated sediments is of substantial concern
to surrounding communities. Conventional high-volume air samplers
(HVAS), are expensive to maintain and analyze, do not directly capture
long-term average concentrations of HOCs and suffer from interferences
from particle related sources not associated with local evaporation from the CDF. To overcome these problems, a passive sampling approach was developed using polyoxymethylene (POM) to absorb and quantify PAHs and PCBs in the atmosphere. Laboratory experimentation conducted by exposing POM air sampler (PAS) over a sediment slurry, showed a consistent uptake of HOCs on POM with measured $K_{\text{POM-AIR}}$ that was approximately given by the theoretical relationship of the POM-water partition coefficient and the Henry’s constant ($K_{\text{POM-w/Raw}}$). The time required for equilibration of the POM with air varied by the hydrophobicity of the compound of interest but averaged approximately 28 days for the mid-range PCBs and PAHs expected to be important in air (relative to the more hydrophobic air contaminants). Field sampling at 10 stations surrounding the CDF was conducted three times (two fall/winter and one summer) over two years. The highest concentrations ($\Sigma\text{PCB} \sim 23 \text{ ng/m}^3$) occurred during summer dredged material placement when the ambient temperature was 20-25 C. Partitioning to the POM during the fall/winter periods (temperature averaged 3-5 C) were corrected for temperature effects which may increase uncertainty in the measured concentration. ($\Sigma\text{PCB}$ ranged from 0.3 to 7 ng/m$^3$) and $\Sigma\text{PAH}$ from 3.5 to 45 ng/m$^3$ during the two winter seasons. The POM measured air concentrations were lower than measured by HVAS during the first winter sampling period which is expected due to particulate bound contaminants in the HVAS samples. PAHs, in particular, are likely dominated by particle related sources other than evaporation from the CDF and showed HVAS concentrations approximately 10 times higher than the POM.

564 A wearable polydimethylsiloxane-based passive air pollutant sampling device: Development of calibration constants

E.Z. Liu, J. Koelmel, Yale University / Environmental Health Sciences; S. Seethapathy, Thermo Fisher Scientific / GC Applications; K. Pollitt, Yale University / Environmental Health Sciences

Evaluation of cumulative exposure to air pollutant mixtures has been challenging by traditional measurement techniques to the weight, limited battery life and cost of these monitoring devices. Wearable passive air pollutant monitors have emerged as a tool for assessing personal exposure to environmental chemicals. These monitors concentrate airborne pollutants onto a substrate which can subsequently be analysed off-line for a broad range of compounds using mass spectrometry (MS). Longitudinal exposure assessment in vulnerable populations is facilitated by the lightweight, wearable form factor of these monitors. The low cost of this sampling technique further enables deployment across large populations, increasing the quantity of environmental data available for evaluating environmental risk factors for disease. We have applied a polydimethylsiloxane (PDMS) sorptive extraction technique to passively concentrate non-polar airborne compounds. Glass rods are coated with a thin PDMS film and mounted into a wristband (the Fresh Air Wristband). The wristband is worn by an individual for several hours to days depending on ambient levels. Sample analysis is performed using thermal desorption gas chromatography high resolution MS (Thermo GC Q-Exactive). Using this sampling device, time-weighted personal exposure concentrations are evaluated for a broad range of semi-volatile organic compounds, including PAHs, PCBs, and PBDEs. Calibration constants for a selection of analytes from these chemical groups were estimated from linear temperature programmed retention indices measured using a pure PDMS stationary phase GC column. This calibration approach facilitated quantification of analytes identified through nontargeted analysis. We have used the Fresh Air wristband for personal exposure assessment in several large epidemiologic studies based in the U.S., Canada, South Africa, and China. These deployments have enabled characterisation of unique exposure profiles which is a novel advancement towards identifying disease risk factors.

565 Effect of Environmental Factors on the Performance of Polyurethane Foam Sampling Column of Flow-through Atmospheric Sampler

H. Xiao, Chinese Academy of Sciences / NUEORS; Q. Cai, Institute of Urban Environment / Chinese Academy of Sciences; Z. Huang, Hanzhan Normal University; L. Tong, J. Li, J. Zheng, X. Dai, M. He, Institute of Urban Environment / Chinese Academy of Sciences

Flow-through sampler (FTS) is a novel energy-saving atmospheric sampling technology developed in recent years, which using wind energy to carry POPs through the polyurethane foam (PUF) sampling column and quantitatively absorb the target compounds. Its sampling mechanism is similar to active sampling, so the environmental factors such as temperature and wind speed have significant impacts on its sampling efficiency. In order to improve the accuracy of atmospheric sampling and quantitatively describe the environmental behavior of POPs, the adsorption properties of various compounds on the FTS sampling column under different environmental conditions were investigated. An orthogonal test design was adopted, which use active sampling pumps with different flow rates connected with an FTS sampling column to control the wind speed to sample in different seasons (at different temperature) with different sampling volumes (controlling through sampling time). Frontal chromatography theory and multi-parameter linear solvation energy relationship (LSER) was applied to analyze the breakthrough profile of each chemical on the FTS column. The quantitative correlations between the theoretical plate number and the break-through volume of the compound under different wind speed and temperature were established. These relationships were further used to develop simplified methods to estimate the loss rate for each target compound during the sampling process. The estimated loss rates were comparable with experimental values, which are obtained by integral of the breakthrough profile for each compound. It shows that the simplified formulas obtained in this study can accurately estimate the loss rate of the compound within the experimental temperature and wind speed range. For chemicals with serious breakthrough, the few PUF discs in front of the FTS sampling column can be treated as equilibrium state passive air samples. The temperature dependence of the partitioning of POPs between PUF media and air were also discussed.

566 Integrating air-, water- and porewater-phase passive sampling data for quantifying transport of polychlorinated biphenyls (PCBs) in an urban watershed

M. Bokare, N. Lombard, S. Magee, University of Maryland, Baltimore County / Department of Chemical, Biochemical and Environmental Engineering; T. Wilson, US Geological Survey; U. Ghosh, University of Maryland, Baltimore County / Chemical, Biochemical, and Environmental Engineering

Persistent organic pollutants such as polychlorinated biphenyls (PCBs) are responsible for impairment of several waterways in the Chesapeake Bay, such as the Anacostia River in District of Columbia (D.C). Previous quantitative assessments of PCB sources in this watershed are based on the Total Maximum Daily Loads (TMDL) approach, which does not account for differences in bioavailability of particulate-bound and dissolved PCBs, while also lacking quantification of diffusive exchange of PCBs across the air-water and sediment-water interfaces. These TMDLs are also limited by the difficulties in accurately measuring the low dissolved PCB concentrations in surface water and porewater, which govern the diffusive exchange of PCBs. To improve the quantitative assessment of PCB transport in this watershed, low density polyethylene passive samplers were used to measure the dissolved PCB concentrations in the surface water and sediment porewaters of the Anacostia River. Additionally, gas-phase PCB concentrations in the watershed were also measured using passive samplers. Results from our study showed that the atmosphere served as a sink for PCBs in the water column, while flux of PCBs from sediment hot-spots into surface water was nearly balanced by flux of PCBs from surface water into cleaner sediments. PCB measurements from passive samplers deployed in several major tributaries of the Anacostia River were integrated with suspended sediment sampling data from United...
States Geological Survey (USGS) to provide an improved assessment of PCB loads from these tributaries, with particular focus on the dissolved PCBs and the variation in their concentrations and loads across base and storm-flow conditions. Results from multiple sampling periods were used to evaluate seasonal variations in pollutant loads and air-water exchange of PCBs. By using passive samplers to accurately measure dissolved and gas-phase PCB concentrations which govern fate, transport, and bioaccumulation, the study aims to provide an improved TMDL framework that accounts for the significantly higher impact from dissolved PCBs.

567 Peeping at Background - Porewater Passive Sampling to Quantify Naturally Occurring Metals in Anoxic Sediment

In many areas of the Willamette Basin, elevated concentrations of naturally occurring metals such as arsenic and manganese are present and may occur in anoxic zones of sediment porewater where lower redox conditions promote solubility. As a result, there is a need to identify the influence of anoxic sediments to the porewater concentrations of metal/metalloids at the Portland Harbor Superfund Site, Portland, Oregon, to refine the conceptual site model and understanding of background conditions. Measure anoxic porewater presents a challenge since common sediment porewater sampling methods disturb the sediments, exposing them to oxygen, which provides an unrepresentative chemical characterization. Passive sampling resolves these issues by allowing the porewater to chemically equilibrate with a volume of water through a semi-permeable membrane providing little sediment disturbance and isolation from oxygen during retrieval. Additional refinement of the sampling design, such as a reverse tracer, diver-less camera deployment, and careful monitoring of ammonia and sulfides, allowed for robust data collection by eliminating some of the uncertainty associated with passive sampling. This presentation will discuss the implementation of passive porewater sampling in conjunction with innovative methods during the Portland Harbor Pre-remedial design investigation with a focus on the steps taken to demonstrate the reliability of the results to stakeholders.

568 Peepers for Sediment Porewater: Doing it Right and Doing it Better

J. Roberts, M. Healey, S. Sande, SIREM; M. Vanderkooy, J.M. Conder, C. Martin, Geosyntec Consultants

Measuring freely-dissolved chemicals in sediment porewater is a powerful technique for improving sediment assessment and management. Peepers are a reliable method to collect representative samples of hydrophilic chemicals (e.g., metals, ammonia, etc.) in sediment porewater. Peepers contain a sample of ultra-pure de-oxygenated water separated from the porewater environment by dialysis membrane. Over the deployment period, usually about 4 weeks, hydrophilic chemicals in porewater diffuse into the peeper until concentrations in the peeper water approaches concentrations in the adjacent sediment porewater. After the deployment period, the peepers are retrieved and analyzed to represent concentrations in the sediment porewater surrounding the peeper. Over the past 18 months, SIREM has successfully provided peepers for 6 project studies. Each study has included project-specific customizations that make field deployments and retrieval technically more effective and easier. This presentation will describe the scientific basis for how sampling with peepers works, how peepers should be properly deployed and retrieved to maintain high data quality and avoid potential low or high biases, and recent innovations to help make peepers more effective and easier to use. Details will cover: 1) the scientific basis for peepers and supporting data; 2) calibration for equilibrium with equilibration tracers; 3) procedure to avoid the impact of oxygen on samples before and during deployment and retrieval; 4) innovations to reduce and streamline field efforts, including diverless deployment.

569 Actively Shaken In Situ Deployment: An Innovative Approach to Accelerate Equilibrium in Passive Samplers

M. Jalalizadeh, J.M. Conder, Geosyntec Consultants, Inc.; U. Ghosh, University of Maryland, Baltimore County / Chemical, Biochemical, and Environmental Engineering; O. Ghosh, University of Maryland, Baltimore County; M. Healey, SIREM

Passive sampling for the measurement of freely dissolved concentrations (C_free) of organic pollutants in sediment porewater has emerged as a very promising approach, but in situ measurements are complicated by slow mass transfer of strongly hydrophobic compounds. This results in passive sampling deployment periods that are often 28 to 56 days, a time period that can delay rapid site-decision-making and jeopardize measurement. Additionally, slow mass transfer of very hydrophobic compounds can result in uncertain or highly variable results. Previous work has shown through laboratory experiments that periodic vibration greatly enhances sampling rates for passive samplers in sediment, reduces the required deployment times by at least 2 to 4 times, and improves the accuracy of estimating the porewater concentrations. We have developed a robust platform incorporating a vibration device that can be adapted to an existing commercially available passive sampler. The initial design operates in a small waterproof housing that has been tested to water pressures at 30 m depth. Initial field tests in marine sediments for 7-14 days demonstrated that periodic vibration of the passive samplers (5 second pulse every 4 hours), enhanced the mass transfer of PCBs compared to samplers deployed statically. Results suggest deployment times may be able to be reduced to 7-14 days, a marked improvement over typical deployment times for passive samplers. The initial design remained stable and waterproof, and there was no need to recharge the battery or service the device during deployment, allowing for an efficient and effective field program. In addition, as shown in previous research, closer approaches to equilibrium improves the accuracy of C_free measurements, especially for the more hydrophobic compounds. Overall, this technology is mature for application, improves the accuracy of C_free measurements, and reduces the costs and risks associated with in situ deployments. Ongoing work is further optimizing the layout of the vibration device to reduce power consumption, increase the efficiency of vibration, and increase the mass of deployable polymer to enable measurement of dioxins and furans.

570 3D printed design for remediation and monitoring of dredged material contaminants

M. Ballentini, A.J. Kennedy, US Army Corps of Engineers / ERDC; L. May, US Army Engineer Research and Development Center / Environmental Laboratory

The US Army Corps of Engineers maintains approximately 400 ports and 25,000 miles of waterways with dredging operations. Federal regulatory statutes and guidance require the US Army Corps of Engineers to evaluate direct, indirect, and cumulative environmental impacts associated with management of dredged material including the potential for release of contaminants at disposal sites. As limitations to the placement of dredge material in confined disposal facilities increase, the development of sustainable alternatives for dredged material management, are being pursued. This multi-phase effort is prototyping new materials to reduce the bioavailability of multiple contaminants of concern in dredge material and designing recoverable devices that contain both remediation capability and passive samplers that will provide long-term monitoring of the efficacy of remediation measures. Passive samplers 200 um squares were 3D printed in low-density polyethylene, polyactic acid (PLA), and acrylonitrile butadiene styrene (ABS) were tested for uptake along-side commercially purchased high-density polyethylene in a sediment slurry for 30 days to test baseline update of contaminants of concern. To follow up the baseline experiment of update, 3D filament were extruded containing 25% of SIR-300, SIR-600, and activated carbon individually added to PLA. The newly made filament was then used to 3D print a series of five paddle wheel models with increasing surface area. Sediment slurries containing the same sediment type as the baseline uptake experiments are
being carried out using the 3D printed additive enhanced paddle wheel models to test for uptake efficiency and surface area effect between the different filaments containing the additives. Future phases of this effort include gyroscopic buoyancy models will be created using the previous generated data for each of the filament additive to generate kinetics of sequestration of the contaminants of concern followed by a field demonstration using the optimized 3D printed floatable remediation technologies and gyroscopic retrievable passive sampling devices.

Chemistry and Exposure in the Indoor Environment - Part 2

571 Indoor house dust: Sources, composition and potential health impacts

A. Chan, J. Dingle, Y. Shi, University of Toronto / Department of Chemical Engineering and Applied Chemistry; L. Kohl, University of Helsinki; M. Meng, B. Green, S. Wang, University of Toronto / Department of Chemical Engineering and Applied Chemistry; L. Woo, C. Chow, University Health Network

Indoor house dust is a source of human exposure to persistent pollutants and is linked to potential health risks. The Fort McMurray, Alberta wildfire event in May 2016 raised questions about potential exposure to fire-related pollutants. To assess the long-term impacts of the wildfire emissions and any other sources on indoor air quality, dust was collected in Fort McMurray homes during four sampling campaigns in 2017-2018 and the concentrations of trace elements, organic contaminants were analyzed. Copper, zinc, cadmium and lead were found to be enriched in the indoor environment, suggesting indoor sources of these elements. Outdoor sources contribute to other elements such as arsenic and potassium. Neighbourhoods affected by the fires showed higher levels of arsenic, likely from combustion of treated wood. Polycyclic aromatic hydrocarbons were mostly associated with indoor use of wood fireplace. The potential of indoor dust to cause oxidative stress and adverse health outcomes was assessed using dithiothreitol assay, and its relationship to chemical composition will be discussed. Lastly, urinary metals from residents were measured and the association with house dust concentrations will be investigated. Overall this study provides insights into environmental exposure to house dust and subsequent health impacts.

572 Indoor Dust/Air Partitioning: Evidence for Kinetic Delay for Low-Volatility SVOCs

A. Parnis, T. Taskovic, Trent University / Department of Chemistry; A. Celzius, Queens University; D. Mackay, Trent University / Chemistry

Partitioning of Semi-Volatile Organic Chemicals (SVOCs) between an air phase and indoor dust is investigated by calculating Henry’s Law constants (HLCs) for selected SVOC’s from air to octanol and 8 organic oligomers and one inorganic oligomer similar in chemical structure to reported components of household dust. The HLCs were computed using the Henry’s law function contained in the first-principles COSMO-RS quantum chemical program and converted to values of KOA and KDust-Air, assuming an organic matter content in dust of 50%. The octanol results are compared with a large body of reported monitored partition ratios with good agreement for the more volatile SVOCs of vapor pressure (VP) exceeding 10-5 Pa and with the equivalent log KOA of less than 9.5. For less volatile SVOCs, reported values of KDust-Air are significantly lower than predicted, with the deviation increasing with reduction in VP. This effect is attributed to a kinetic delay in which characteristic times for equilibration exceed the dust-air contact time and equilibrium is not achieved. The nature of kinetic delay and the limitations for use of dust as a sampling probe for indoor air concentrations will be discussed.

573 Human activities influence exposure to semi-volatile organic compounds: a multimedia modeling experiment

J. Kvasnicka, University of Toronto / Environmental Health Sciences; E. Hubal, US Environmental Protection Agency / Computational Exposure Division; M.L. Diamond, University of Toronto / Department of Earth Sciences

Multimedia models have proven to be useful predictive tools for assessing the fate of neutral organic compounds released in indoor environments. These predictions have then been used to estimate human exposure. In these models, the representation of human occupants has been limited to passive individuals with static and continuous behaviors. However, evidence clearly shows that individuals alter their surrounding microenvironments indoors, which can influence exposure. Here, we developed and employed a multimedia model of the indoor environment for three purposes: 1) To investigate how typical human behaviors affect the multimedia distribution of phthalates indoors on a dynamic basis, 2) to determine how and why these behaviors, in turn, influence exposure by comparing the typical indoor activities and resultant exposures of an adult versus a toddler with different physical attributes and behavior patterns. For instance, more frequent movement, including hand-to-mouth contact, for the toddler can be shown to result in higher exposures per unit body weight compared to the more sedentary adult. The demonstrated framework may be an important step toward better understanding the role of human occupants as autonomous agents of chemical movement indoors with, in turn, consequences for exposure variability.

574 PCB Emissions from Paint Colorants and their Effect on Room Concentration

J. Jahnke, University of Iowa / Environmental Engineering and Science; K. C. Hornbuckle, University of Iowa / Civil and Environmental Engineering

Polychlorinated Biphenyls (PCBs) are currently produced as byproducts of pigment manufacturing. These pigments are used in consumer paints that can be purchased at many hardware and paint stores in the United States. Most of the congeners produced through these processes are the most volatile of PCBs: Monochloro- and dichlorobiphenyls associated with pigments have been measured in air worldwide. Although it is possible that the manufacturing process itself contributes to environmental contamination, we hypothesize that use of architectural paint is the major source of these congeners to air. For example, previous work has shown that paint is responsible for 0.000001% of PCB stocks in Chicago but is responsible for up to 7% of total PCB emissions. We investigated the emissions of PCB congeners from freshly applied paint colorant. We quantified the emissions of ∑PCBs over time (6 weeks) using a new polyurethane foam passive emissions sampler (PUF-PES) method. The PUF-PES method involves placing a PUF over a sample to capture any PCBs that volatilize from it. Due to the nature of the sampler, we only collect PCBs from the sample found in the air directly above it. The PCBs found in the applied colorant were detected on the PUF after one day. By the end of the experiment all PCBs found in the colorant were also found on the PUF including PCB 209, the highest chlorinated PCB. Lower chlorinated congeners (e.g., PCB 1, PCB 2, and PCB 3) were released from the colorant at a faster rate than higher chlorinated congeners (e.g., PCB 146 and PCB 147/149). We used our emissions data to predict concentration in a room using a mass-transfer model. Our results show that non-Aroclor PCBs associated with pigments readily volatilize, consistent with reports of the same compounds in ambient air. A currently manufactured source of PCBs could lead to detectable concentrations in indoor air. This work addresses an important source of toxic air pollutants in residential and school environments as well as outdoor natural environments that has only recently been recognized.
575 PCBs in Older Buildings: Measuring Levels of PCBs in Caulk and Window Glazing Materials

I. Osemwegie, US Environmental Protection Agency / Public Health Chemistry Branch

A method for the determination of polychlorinated biphenyls (PCBs) in caulk and glazing materials was developed and evaluated by application to a combination of 36 samples of caulk and glazing materials, from four older buildings. The quality control analysis of this method showed a range of 45 to 170% for spike recovery from the various samples and a range of 10.9 to 20.1% difference in measured precision. The method is useful for the evaluation of caulking materials in older buildings and has been recently published. The result for the samples analyzed showed that three of the four buildings sampled contained caulk and glazing materials with levels of PCBs in the range 54.6 μg/g to 445,000 μg/g. These results are consistent with other studies that evaluated PCBs in older buildings. The PCBs determined in the samples, exhibited characteristic chromatographic patterns similar to those of Aroclors 1242, 1248, 1254, 1260, 1262, and a 1016/1254 mix. This finding combined with the findings of studies in Finland, Germany, and Sweden, indicates that the presence of PCBs in caulk in older buildings is of potential concern. The presentation will provide information on the method development and how this new method can be used for characterizing caulking materials in older buildings.

576 Oxidative potential of inhalable engineered nanoparticles - investigating physical barrier effects through formation of secondary organic matter

P. Shahpoory, Q. Liu, T. Harner, J. Liggio, Environment and Climate Change Canada / Air Quality Research Division

In recent years, there has been a rapid increase in the production and application of engineered nanoparticles (ENPs), but the number of studies addressing the toxicity of ENPs is still limited. As to human exposure to ENPs through inhalation and related health effects, indoor exposure is expected to be more important because the ENP concentrations in ambient air are generally low. Oxidative potential (OP) is a measure of inhalation toxicity of airborne particles. The redox-active constituents of particles react with lung antioxidants in the epithelial lining fluid, resulting in oxidation of antioxidants. The excessive loss of antioxidants leads to oxidative stress, inflammation of the epithelial tissue, and chronic diseases. Some ENPs are known for their ability to pose oxidative stress; this ability depends on the ENP surface chemistry and particle-size distribution. However, it is not well known if the modification of ENP surface through coating with organic species, such as secondary organic matter (SOM), would influence their OP. In this work, we investigated three ENPs, namely TiO2, CeO2, and SiO2 - the first two ENPs are known to have OP in their bare form while SiO2 is relatively ineffective. In laboratory chamber experiments, we simulated the chemical aging of these particles in air through reaction of two volatile organic compounds (α-pinene and toluene) with OH radicals and O3 and eventual formation of SOM-coated ENPs. Different aging times and SOM coating thicknesses were considered. The OP of the samples was investigated using a recent method that we developed in-house. The method simulates the reaction of ENPs with major lung antioxidants in the simulated lung lining fluid and determines the redox state of the samples. We evaluated our results using the electrochemical reduction potentials of the studied ENPs. The results showed that the presence of organic coating on ENPs considerably reduces the OP of very redox-active ENPs, whereas continued chemical aging of the same particles leads to increase in OP. We found an opposite pattern with SiO2 samples. In addition, we found good agreements between these results and the measured values of reduction potentials. This work is particularly interesting in that it provides an insight into the dynamics of ENP physical and chemical transformation in indoor environments, and introduces a new method for evaluating the toxicity of inhalable ENPs indoors.

577 Investigating the Photoenhanced Uptake of Gaseous NOx on Indoor Surfaces

S.H. Jones, D.J. Donaldson, University of Toronto / Chemistry

Despite the significant amount of time that humans spend indoors during their lifetime, little is known about the chemistry of the indoor environment in comparison to the outdoor environment. Photochemical reactions play an integral role in the chemistry of the outdoor environment but such reactions are thought not to be important indoors owing to the lack of significant UV radiation < 320 nm. However, photosensitizing compounds are prevalent indoors in a variety of forms such as TiO2 which is present in many indoor paints and polycyclic aromatic hydrocarbons which are commonly found in household dust. The presence of such photosensitizers in combination with the high surface-to-volume ratio of the indoor environment suggests that it is important to study photosensitized heterogeneous chemistry indoors. Previous work has shown that renoxification can occur from indoor surfaces illuminated with common indoor light sources. Building on these findings, the photoenhanced uptake of gaseous NOx on illuminated substrates painted with commercial paints has been explored using a custom experimental set-up combined with a NOx analyser. Gaseous NOx is present in the indoor environment from a number of sources including cooking and cleaning emissions as well as from infiltration of outdoor air. The effects of relative humidity, different paint pigments and the addition of an organic film to the substrates have been investigated to better understand chemical transformations indoors. Initial results suggest that the presence of an organic film on an illuminated painted substrate compared to an organic film on an illuminated plain glass substrate significantly alters NOx uptake which could have implications for the chemistry occurring in different types of indoor environment.

578 Selective High Surface Area Scrubbers: Metal-Organic Frameworks for Decontamination of Harmful Indoor Air Pollutant Nitrous Acid

D. McGrath, Memorial University of Newfoundland / Chemistry; C. Young, York University / Department of Chemistry; M. Katz, Memorial University of Newfoundland / Chemistry

A variety of nitrogen oxides (NOx) are present in both indoor and outdoor air. The NOx species posing the most significant threat to both the environment and human health are nitrous oxide (NO) and nitrogen dioxide (NO2). NO2 can interact with other compounds present indoors to produce a wide array of secondary pollutants. An example of this is the reaction of NO2 with water on surfaces (e.g., paint) to produce nitrous acid (HONO). In the absence of light, HONO builds up via these reaction pathways. Upon exposure to light from the sun or from indoor light sources, HONO undergoes photolysis to form NO and hydroxyl (OH) radicals, which can be oxidized to form other dangerous compounds (e.g., ground-level ozone). Posing a threat to indoor air quality, levels of HONO are over 20x higher than outdoors. HONO can react with amines, such as those from cigarette or cooking smoke, to form carcinogenic nitrosamines (e.g., third hand smoke). Due to the constant flux of NOx from various sources, there is a necessity for a material to selectively decontaminate NOx and its reaction products. Metal-organic frameworks (MOFs) are porous materials known for their wide-spread applications such as chemical sensing, separations, gas storage, and chemical reactivity. The advantage of MOFs, versus other porous or high-surface area materials, is that every reactive site in the MOF is readily accessible. With this in mind, this presentation will report the successful employment of a functionalized MOF for improved quantitative measurements and selective decontamination of average indoor concentrations of HONO.
Micro- and Nano-Plastic Methods Research: Harmonizing Methods and Addressing Challenges - Part 2

579 How to sample microplastics in streams
W. Cowger, A.B. Gray, J. Guilinger, University of California, Riverside / Environmental Science

Sampling microplastics at the surface of a stream in order to derive average concentrations and estimate microplastic loading without recognition of hydrologic processes is misguided. These methods were adapted from oceanic sampling and are employed for ease. Surface sampling assumes equal concentration of microplastics within the water column. Here we show that such surface sampling methods can introduce up to eight orders of magnitude uncertainty in any assessment of average concentrations. This uncertainty is due to the potential concentration-depth profiles of plastics in the water column. To effectively monitor fluvial microplastic transport we need to assess the hydrologic mechanisms that affect our measurements, correct for them in our reporting of abundance, and develop new methods for assessing the concentration depth profile of microplastics in streams.

580 Toxicity Assessments of Micro- and Nanoplastics Can Be Confounded by Preservatives in Commercial Formulations
Q. Pikula, E. Xu, D. Berk, N. Tufenkji, McGill University / Department of Chemical Engineering

The presence of plastic debris in the aquatic environment has raised ecological concerns. The environmental weathering of large plastic debris in natural waters leads to the formation of micro- and nano-sized plastic particles that can be ingested and accumulated in aquatic organisms. Commercial formulations of micro- and nano-sized polystyrene particles (PS-NPs) are widely used as model plastics for toxicity assessment studies. However, many of these commercially available formulations contain different preservatives, antimicrobials, or surfactants such as sodium azide, Tween(R) 20, and sodium dodecyl sulfate, that may introduce artifacts in toxicity assessments. In this study, we carried out acute toxicity tests on Daphnia magna, using commercial 20 nm and 200 nm polystyrene nanoparticles (PS-NPs) containing 2 mM sodium azide as an antimicrobial preservative. The acute toxicity of non-dialyzed PS-NPs, dialyzed PS-NPs, and sodium azide alone was compared. Mortality was observed in animals exposed to non-dialyzed PS-NPs as well as in animals exposed to equivalent concentrations of sodium azide. However, no mortality was recorded for animals that were exposed to dialyzed PS-NPs after the removal of sodium azide by dialysis. Fluorescence microscopy showed visible rupture in the gastrointestinal tracts of animals exposed to non-dialyzed PS-NPs. These results suggest that the acute toxicity of the commercial formulation of PS-NPs was mainly associated with sodium azide and not the particles themselves. This study is the first to show that the observed mortality of D. magna can be directly attributed to a preservative (in this case, sodium azide) present in a PS-NP suspension. As the number of toxicity studies on micro- and nanoplastics continues to increase, the results of this study call for a more careful assessment of the toxic effects of the additives in commercial particle formulations.

582 Challenges of isolating and enumerating microplastics within the gut of a marine apex predator, the bottlenose dolphin (Tursiops truncatus)
F. Battaglia, College of Charleston; B. Beckingham, College of Charleston / Environmental Geosciences; W. McFee, NOAA/ NOS / National Centers for Coastal Ocean Science

Plastic pollution is documented to be a common and persistent problem impacting marine and estuarine ecosystems globally. An increasing number of studies report exposure of diverse biota, primarily lower trophic organisms like zooplankton, polychaetes, bivalves, crustaceans, and fish, to microplastics (< 5 mm, MP) and explore the potential physical and chemical impacts of this exposure. In contrast, research on MP ingestion at higher trophic levels is limited and presents some unique challenges. The bottlenose dolphin (Tursiops truncatus) is a long-lived apex predator and can be a sensitive gauge for environmental quality within its range. The present study aims to provide a measure for MP ingestion in T. truncatus by analyzing the gut contents of stranded dolphins recovered in South Carolina, USA. It is hypothesized that T. truncatus may be exposed to MP through ingestion of contaminated prey. A method was developed that has features which harmonize with recently published protocols for monitoring MP in cetaceans (Lusher and Hernandez-Milian, 2018: https://bio-protocol.org/e3087). The gastrointestinal tract of stranded dolphins is removed, segmented, and the contents washed into glass containers. Intact prey items and otoliths are stored for separate prey analysis while the remaining gut contents are sieved into size fractions (125-355 μm, 355 μm-1 mm, and 1-5 mm). 1M potassium hydroxide (KOH) is added to eliminate organic material and facilitate the visual identification of MP in samples, and density separation is applied as needed to samples containing sediment and calcareous organic matter. Material remaining in samples is then filtered, dried, and MP are visually detected under a stereomicroscope with the aid of hot needle test. Unlike with other taxa, acquiring samples for cetaceans is restricted to stranded animals, which vary greatly in decomposition state. In addition, their large size and heterogeneous gut contents comprised of various prey hard parts (e.g. bones, otoliths, cephalopod beaks) and soft tissues, and in some cases plant material and sediment, present challenges for isolation of microplastics. For instance, a relatively large volume of MP-free pressurized rinse water is required, and MP size measured by image analysis software indicated that sieving was ineffective for fibers. Findings from this investigation will aid future studies examining MP in marine apex predators like T. truncatus.

583 What are the current frontiers and recommendation for the study of microplastics in seafood: proposition of the “MIMS” concept
L. Hermabessiere, University of Toronto / Ecology and Evolutionnary Biology; A. Dehaut, G. Duflos, Agence nationale de sécurité sanitaire de lalimentation, de l'environnement et du travail (Anses) / Laboratoire de sécurité des aliments LSA

Since the 1950’s, mass plastic production and waste mismanagement have resulted in significant contamination of the global environment, including the marine environment. The first mention of seafood contaminated with microplastics (size < 5 mm) was recorded in the early 1970’s, and to date numerous studies have been carried out on fish, shellfish and crustaceans. Using published studies, the goal of the current work consists of reporting the numerous methodologies and practices described so far. By examining multiple aspects including problems related to the definition of the term microplastic, contamination of the laboratory environment, sampling, extraction, quantification and identification, the objective of the present work was to point out current limitations and research needs to reach reliable and reproducible practices for future studies on microplastics in seafood. A final part is devoted to the minimum information for publication of microplastics studies (MIMS). Globally, practices and methodologies are improving as of recently. However, some gaps remain. Indeed, information on the prevention of contamination, blank management and the identification of unknown particles are still missing in some studies. Based on the aspects discussed, MIMS can act as a starting point for harmonisation of analyses of microplastics in seafood and other matrices.

584 A First Open International Interlaboratory Study on Microplastics Analysis
H. Leslie, Vrije University Amsterdam / Environment & Health; B. Van Bavel, NIVA; S. Crum, Alterra Wageningen UR / ERA team; L. van Mourik, Vrije Universiteit Amsterdam / Institute for Risk Assessment Sciences; W. Cofino, Wageningen University; J. de Boer, VU University / Environment & Health

The field of microplastics analysis in environmental samples is rapidly growing. Reports appear in the literature with sometimes alarming microplastics concentrations in the marine and freshwater environments. However, often the methods have not been validated. This is partly due...
Re-centering standardization for Indigenous, northern-led, and citizen sciences

M. Liboiro, Memorial University / Department of Geography

Calls for standardizing methods within aquatic plastic pollution research have been steadily increasing. While standardization allows for better comparison between studies, standardization can also make certain environments, ways of working, and ways of knowing central while pushing others to the periphery. This presentation uses case studies of Indigenous science, kitchen science (sometimes called citizen science), and northern-led science of marine plastic pollution research as case studies to highlight crucial considerations, existing pitfalls, and unexamined politics of standardization that can create unintended power dynamics and inequity in knowledge systems. At the same time, these same cases show that the ability to compare studies, be accountable to quality assurance and contamination, and share protocols are crucial for moving forward on marine plastic pollution. The presentation concludes with the types of standards cases have found work best across diverse knowledge systems and contexts, including scales of plastic identification, methods of sample collection, and practices of categorization. These findings aim to ensure that when new standards are forwarded in our scientific communities, they are accountable to the politics and best practices of standardization.

Rethinking Microplastics As A Diverse Contaminant Suite

Microplastics are not microplastics. “Microplastics,” like other classes of chemical contaminants, is a catch-all term for a variety of unique chemical compounds. Yet, many scientific publications, policy reports, and media articles present microplastics as if they are simply a single compound or type of material. Such simple communications have consequences, leading to simplified studies and protocols that may be inadequate to inform us of the sources and fate of microplastics, as well as their biological and ecological implications. Moreover, not recognizing the diversity of materials in a microplastics sample may overlook the complexity necessary to inform robust quality analysis and quality control (QA/QC) needed in sampling and analytical measurement techniques. For instance, some methods are better at recovering specific sizes, shapes, or types of microplastics. Simplifying microplastics as a single compound has also led to confusion around the need for new policies and strategies to reduce future emissions of microplastics. For example, some policy makers and scientists are under the impression that banning microbeads from rinse-off personal care products has eliminated future releases of microplastics in general to the environment. In reality, such bans eliminate only one source of the diverse and complex emerging global contaminant suite that is “microplastics.” This can be compared to banning one specific use of a pesticide (e.g., in the home), leaving the market full of other applications of diverse pesticides that need to continue to be assessed for environmental persistence, bioavailability, and toxicity. We make the case that it is necessary to rethink microplastics (plastic particles < 5 mm in size) and consider them a suite or class of contaminants, in the same way we do for pesticides, trace metals, or flame retardants. Microplastics are diverse; they come from many different product types; incorporate a broad range of sizes, colors, and morphologies; are composed of various polymers; and include a broad array of chemical additives. This diversity is important to consider, and thinking of them like we do other classes of contaminants may help us advance methods for sampling and analysis and help us better understand the sources from which they enter the environment; their fate in water, sediment, and organisms; their toxicity; and relevant policies for mitigation.

Incorporating New Approach Methodologies to Improve Ecological Risk Assessment - Part 2

Exploiting new approach methodologies in risk assessment: Towards more holistic chemical safety decisions

B. Campos, G. Hodges, E. Butler, Unilever / Safety and Environmental Assurance Centre SEAC; I. Muller, Unilever; C. Rivetti, Unilever / Safety and Environmental Assurance Centre SEAC

In recent years there has been a paradigm shift towards gaining more mechanistic toxicological insights in risk assessments (RA). The drivers for this shift are a desire to move away from the animal testing requirement of conventional risk assessment as well as to move towards more transparent and robust approaches to toxicology. Whilst recent advances in technology have resulted in an explosion of mechanistic data being generated across multiple species, there is little evidence of it being used in chemical risk assessment or for making risk-based decisions. However, there is a growing recognition that mechanistic approaches to understanding cross species target and pathway conservation/homology provide significant opportunities in RA for both Human Health (HH) and environmental safety. Specifically, it has been recognized that a more comprehensive and reliable understanding of pathways will better enable the extrapolation of potential adverse impacts across species. Ultimately, this would allow a mutual exploitation for HH and Ecological RA to coherently and more efficiently characterize overall hazard. Given the broad inter-species differences occurring at multiple levels of biological organization, there is unlikely to be a “one-size-fits-all” solution that can effectively characterize species similarities/dissimilarities completely. Nevertheless, there are some pragmatic first steps that can be taken using New Approach Methodologies (NAMs). Thus, there is a need for NAMs to identify, characterise and (ideally) quantify those differences and how mechanisms of action may differ across species. Motivated by these questions, we show how we can make better use of existing data and
how to efficiently generate new data to derive an improved mechanistic understanding between humans and environmentally relevant species, ultimately aiming at more efficient, holistic chemical safety decisions. We will highlight gaps, key challenges, and identified research priorities for the future within the risk assessment arena. NAMs can be included in risk assessments either on their own or alongside conventional data as part of a WoE approach to gain better mechanistic insight. Here we also propose a framework to demonstrate how new mechanistically derived data can complement our current approaches to deliver a robust risk assessment applicable across both human health and the environment.

588 Novel Cell-Based Toxicokinetic Toxicodynamic Models to Improve Ecological Risk Assessment of Endangered Species

J.D. Pierro, Texas Tech University / Environmental Toxicology; A.L. Peace, Texas Tech University / Department of Mathematics and Statistics; C. Witmaack, Texas Tech University / Department of Environmental Toxicology; B.M. Higgins, NOAA National Marine Fisheries Service; C.A. Godard, Texas Tech University / Environmental Toxicology/TIEHH

Little toxicological data is available for endangered megafauna, such as sea turtles, due to inherent restrictions in in vivo toxicity testing. This study provides in vitro toxicity testing of Benzo[a]pyrene (BaP), Polychlorinated Biphenyls 77 (PCB 77), Perfluorooctanoic Acid (PFOA) on loggerhead sea turtle cells, as well as mathematical models, based on this empirical data, that allow for prediction of toxicity over time. All three chemicals are common marine contaminants found in loggerhead tissues, prey items, and ocean waters. BaP is a prototypical polycyclic aromatic hydrocarbon commonly produced through incomplete combustion. PCBs were components of dielectric fluid used in capacitors. PFOA is commonly found in non-stick wares and fire-fighting foam. In a number of animal studies, including those with reptiles, these toxicants have been proven to have adverse effects on cell viability, renal and hepatic systems, and are considered mutagenic. We examine the cytotoxic effects of BaP, PCB 77, PFOA on loggerhead skin fibroblasts using the MTT viability assay. Cells are exposed to each contaminant for standard toxicological periods of 24, 48, 72, and 96 hours, using exposure concentrations based on scientific precedent. This toxicological data was then used in the General Unified Threshold Model of Survival (GUTS) to predict loggerhead sea turtle cell survivability overtime. GUTS is a toxicokinetic toxicodynamic (TKTD) modeling tool, that identifies the sensitivity of the cells to the contaminants. There are two types of survivability models encompassed by GUTS—the individual tolerance (IT) and the stochastic death (SD) models. With the IT approach, survivability is based on individual sensitivity of each cell to the contaminant; the SD perspective presupposes that survivability rates decrease at the same rate for all cells, without consideration of individual sensitivity. Both SD and IT models were examined for effectiveness using confidence intervals and parameter sensitivity analysis. Standard ecological risk assessments can use these models as a tool, due to their standardized provision of fifty percent lethal concentration (LC50) predictions. These are the first TKTD models to look at toxicological effects of common contaminants on loggerhead sea turtles and is the first application of GUTS to cell populations. This research provides precedence for future ecological risk assessment of endangered species using novel cell-based TKTD models.

589 Assessing potential risk to data-poor species: Applying Dynamic Energy Budget theory for interspecies extrapolations

N. Galic, J.D. Maul, R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety

Ecological risk assessments are typically based on apical endpoints related to survival, growth, and reproduction (i.e., lethal and sub-lethal effects) in standard test species. Although there is a wealth of toxicological and life-history information on standard test species, it is not yet fully understood how representative they are as surrogates for other species, particularly those that are data-poor or listed under the Endangered Species Act (ESA). There is often a considerable lack of basic toxicological and life history information for listed species, further challenged by regulatory limitations on data collection. One approach to address the lack of detailed life history and toxicological information for listed species is to apply biological theory in order to identify commonalities across species. Applying common physiological principles, such as those in the Dynamic Energy Budget (DEB) theory, may enable extrapolation of physiological traits across species. It may also highlight why and how sensitivities to different chemicals vary across species. In its simplest form, DEB theory suggests that the metabolic organization, emerging from specific rules on resource acquisition and allocation, is shared across all species. Differences among species mainly occur in the magnitudes of different processes (rather than in the processes themselves) allowing for comparisons across species. Here we illustrate this approach based on two case studies: freshwater fish and avian species. We show how applying DEB theory allows identification of similarities and informing data gaps in many species, including those that are listed. Finally, we highlight the challenges of such an approach and ways forward for the assessment of data-poor species.

590 The importance of differential life stage susceptibility and population structure at time of toxicant exposure to population viability

J.D. Stark, Washington State University / Dept of Entomology

Pesticides and other toxicants may be more toxic to certain life stages of a species than to others. When this occurs, the population structure or the percentage of individuals in each life stage should play a major role in how the population responds to the exposure. Differential susceptibility and population structure is rarely if ever considered when developing risk assessments for chemicals. In this talk, examples of differential stage susceptibility of species to toxicants will be presented followed by population models showing how these variables affect population viability. Consideration of incorporating these variables into ecological risk assessment will be discussed.

591 Using Integral Projection Models for Estimating Impacts of Chemical Exposure in Aquatic Populations

N. Pollesch, M. Etterton, US Environmental Protection Agency / ORD/NHEERL/ Mid-Continent Ecology Division; S. Kadlec, NRC Research Associateship Programs; K. Flynn, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division

Wildlife populations are challenged by a variety of natural and anthropogenic stressors. In the aquatic environment, size plays a critical role in the factors that determine population vital rates. Ecologically, size influences accessible prey, predator avoidance, the onset of reproduction, mating success, and over-winter survival. In aquatic toxicology, size is a non-destructive and readily quantified attribute of individuals; it is the natural way to measure growth effects, and is a reasonable currency for understanding and incorporating differential effects of chemical exposure on survival and reproduction within a population. Integral projection models (IPMs) have emerged as a flexible and powerful approach for linking size specific effects to demography. In this paper, we present a novel application of size-structured IPMs to explore the effects of chemical and non-chemical stressors to survival, growth, and reproduction endpoints using the fathead minnow (Pimephales promelas) to develop our case studies. We demonstrate the utility of IPMs for use in ecotoxicology. By linking our IPM to existing aquatic exposure and effect models, we demonstrate how IPMs can be used to explore complex exposure scenarios and their value in modeling the impact of chemical and non-chemical stressors.
592 The missing piece in the eel puzzle? New evidence indicates dioxin-like compounds might be responsible for recruitment failure in European eels

M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre; M. Freese, J. Pohlmann, Thünen-Institute of Fisheries Ecology; J.A. Doering, US Environmental Protection Agency / Mid-Continent Ecology Division; M. Damerau, L. Marohn, R. Hanel, Thünen-Institute for Fisheries Ecology; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

European eels (Anguilla anguilla) have seen a dramatic stock decline over the past decades, and recruitment failure as a result of maternally transferred contaminants has been proposed as one of several potential causes. Dioxin-like chemicals (DLCs) have been identified as a class of chemicals of concern as they tend to bioaccumulate, are highly embryotoxic, and maternally transferred in eels. However, to date researchers have been unable to locate reproducing adult eels or developing embryos in their natural spawning grounds, and embryotoxicity data to identify causative chemicals are thus unavailable. In this study, we isolated and sequenced isoforms of the aryl hydrocarbon receptor (AhR) from eels and constructed a species-specific in vitro luciferase reporter gene assay using transfected COS-7 cells. A previously developed quantitative adverse outcome pathway (qAOP) based on the relationship between AhR activation and embryo lethality across nine species of fishes exposed to DLCs was used to predict eel-specific relative potencies of DLCs. Using this data, mortality of early-life stages of eels was estimated based on measured internal concentrations in artificially matured eels or levels predicted using a physiologically-based toxicokinetic (PBTK) model. Based on our results, European eels appear to be among the most sensitive species to DLCs and exposure levels are likely sufficient to significantly contribute to the observed decline in recruitment of eels.

593 An Approach for Assessing and Managing Underwater Sound Risks Associated with Dredging Operations

A.D. McQueen, US Army Corps of Engineers / ERDC/EL; B. Suedel, US Army Corps of Engineers / ERDC; F. Thomsen, DHI; C. de Jong, TNO

There is an increasing international focus to understand and quantify the potential ecological risks of low-frequency underwater sounds produced from anthropogenic activities (e.g., commercial shipping, dredging, construction, and offshore energy production). For dredge operations, a risk-based approach has been proposed for identifying, assessing, and managing risks; however, specific details of the framework and demonstration of the approach are lacking. Thus, the goal of this study was to provide a practical, concise, and reliable framework for assessing the effects of dredging sounds on aquatic life. The specific objectives were to: 1) outline a risk-assessment approach for assessing underwater sounds from dredging operations, 2) demonstrate the approach using a real-world dredge operation case study, and 3) document the strengths and limitations of the approach. The risk framework was adapted for underwater sounds to include a problem formulation step, an analysis step where characteristics of exposure and biological responses are assessed, a risk characterization process where the preceding steps are integrated and uncertainty is addressed, and lastly a risk management step. A key beneficial component of this framework is the use of a tiered approach, whereby a screening-level step offers a process that utilizes existing or readily available information to evaluate risk. In general, a limitation of evaluating risks to dredge operations is the degree of uncertainty surrounding effect thresholds for many marine species; however, this approach emphasizes the importance of documenting and communicating uncertainty to regulators, stakeholders, and practitioners in the decision making process. A case study example is included to illustrate how the framework can be applied in practice. The primary strength of this method is the intrinsic flexibility of the framework to adapt as the scientific understanding improves and new data become available in the rapidly evolving field of underwater acoustics.

594 Don’t Ditch All Animal-based Testing Just Yet; Remember the Critters in the Field

L.V. Tannenbaum, US Army Public Health Center

Where reasonable arguments can be put forth for minimizing animal-based testing approaches in support of terrestrial ecological risk assessment work, this amounts to concerns for what transpires in the laboratory. Chemical dosing studies in the lab bear little resemblance to the chemical exposures experienced by ecological receptors in the wild. Further, for all of the interest that forays into computational modeling and in vitro methods may be generating these days, we are only removing ourselves more from the actual exposures that occur in the field. With the proper direct assessment methodologies applied, the most minimal numbers (perhaps only 10!) of small rodents of both a contaminated environment and a matched reference location, can well inform on the overall health of all mammal species inhabiting the former. Properly conducted hands-on field methods, not all of which are destructive, and involving minimal animal numbers, can fully address the chemical mixtures concern, and illustrate that contaminated sites do not support sufficiently large populations to warrant concerns in the first place.

595 What does “translational science” mean in the environmental sciences?

A. LeHuray, Chemical Management Associates, LLC

Translational science has developed as a means to adapt new findings in basic medical and pharmaceutical research into improved patient outcomes and better public understanding. Similarly, translating and communicating research in the wide range of disciplines that together comprise the environmental sciences can be understood as improving public policy to reduce risk and developing new approaches to environmental protection. Unique to environmental science, however, is that public policies were often implemented with little understanding of the scientific foundations of the choices made. Environmental legislation and regulation were put in place decades before environmental research programs became common at universities and other research organizations, and before research funding mechanisms were established. Looking back, it is remarkable that many of the policy choices of the 1970s and 80s have been proven to comport well with deeper scientific knowledge. Some early policy choices, however, have fared less well. Translational environmental science should be understood as providing a mechanism for improving outcomes by reconsidering existing policy as well as introducing new regulatory initiatives. In this presentation, both successes and instances when translational methods should be applied to effect improvement will be highlighted.

596 Solutions-Driven Research: USEPA Office of Research and Development’s approach to translational science to protect the environment and public health

The USEPA’s Office of Research and Development (ORD) is committed to producing research that addresses real-world problems and helps EPA’s national and regional programs and other stakeholders to make timely decisions based on best available science. ORD recently issued its Strategic Research Action Plans for 2019-2022, focusing on Solutions-Driven Research (SDR) as an approach to help achieve these goals.
Principles of ORD’s SDR approach include 1) stakeholder engagement is critical throughout the research process, 2) solutions-oriented outputs should drive development of research plans, 3) coordination, communication, and collaboration are critical to develop integrated research outputs that meet stakeholders’ needs, 4) essential outputs from SDR identify and communicate the achievement of stakeholder goals and the implementation of solutions -- journal articles additionally provide the underlying scientific support for stakeholder solutions. ORD’s SDR approach builds on the successful model of translational science from the National Center for the Advancement of Translational Science which emphasizes a virtuous cycle of discovery, application, and evaluation. Translational science seeks to understand and overcome barriers and improve transitions between stages of translational research. ORD’s SDR model incorporates translational science concepts and is centered around stakeholder needs and involvement throughout the research process. ORD has initiated two pilot projects that apply and evaluate methods of SDR for planning, conducting, applying, and evaluating integrated research that addresses needs of stakeholders. These projects are addressing problems related to a) management of nutrients from septic systems and b) exposure to smoke from wildland fires. Through these pilots, ORD hopes to learn effective ways to 1) engage with stakeholders to build trust, maintain a dialogue to understand needs and research activities, and collaborate to develop and implement solutions, 2) integrate research efforts to deliver solutions-driven research results, 3) translate research results to inform stakeholder needs and enable solutions, 4) evaluate the effectiveness of science-based solutions. We will present the nutrients and wildfire smoke pilot projects as two examples of SDR, explore how ORD is integrating these approaches across its research programs, and discuss lessons learned and next steps.

597 A Review of 10 Years of Research and Monitoring at Environment and Climate Change Canada to Inform Chemicals Management Regulatory Decision-Making

G. Tardif, Environment and Climate Change Canada

The Government of Canada’s Chemicals Management Plan (CMP) was launched in 2006 with the primary goal of assessing approximately 4,300 priority substances by 2020, and implementing appropriate risk management measures for those deemed toxic to human health and/or the environment. Environment and Climate Change Canada (ECCC) is the federal department responsible for assessing and managing risks of substances to the environment. These regulatory activities require a wealth of data on the sources and fate of substances in the environment, their levels in various environmental compartments, their bioaccumulation potential, mode of action, and hazard to various species. To foster the generation of these data to inform regulatory decision-making, the CMP Research and Monitoring Programs were created within ECCC to fund research and monitoring activities and ensure alignment with CMP priorities. After over 10 years of activities, we examine the extent to which results from each of the CMP Research and Monitoring Programs have successfully been used and translated into regulatory outcomes. Our analysis indicates that, between 2007 and 2019, close to 100 research projects were funded to support the CMP, and over 500 substances and/or groups of substances were monitored in up to six environmental compartments (air, water, sediments, fish, wildlife, wastewater/biosolids). Results from these scientific activities have supported evidence-based regulatory decision-making by helping identify environmental compartments of concern, quantify the levels of toxicity and environmental exposure, inform the selection of appropriate risk management instruments and measure the effectiveness of these instruments, among other examples.

598 Drivers and Obstacles to the Adoption of Toxicogenomics Tools for Chemical Risk Assessment: A Review and Insights from Social Science

G. Pain, McGill University / Natural Resource Sciences; S. Maguire, The University of Sydney / Business School; G. Hickey, M. Mondou, McGill University / Natural Resource Sciences; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences

At the turn of the century, the scientific community recognized that the omics fields of biology - genomics, transcriptomics, proteomics, and metabolomics - could help to advance human health and ecological chemical risk assessment. In the two decades that followed, advances were made, some toxicogenomics solutions accepted, and their advantages over conventional toxicity testing methods acknowledged in specific cases. Yet, the breadth and speed of adoption of toxicogenomics for chemical risk assessment have not met the initial expectations of ‘omics proponents. To explore this situation, we review the literature addressing the adoption of toxicogenomics tools in chemicals management, and we assemble an inventory of drivers and obstacles described therein. Because the processes underlying the adoption of new practices have long been of interest to social scientists, we then apply frameworks from the literature on innovation adoption to analyze these drivers and obstacles. We identify 11 drivers and 12 obstacles, the most salient of which we describe, as well as how they facilitate or hinder the adoption of toxicogenomics tools in chemical risk assessment. Our analysis shows that the most common arguments in support of toxicogenomics, which point to superior and novel functionality offered by the new tools, may in fact deter potential adopters because they tend to overlook potential adopters’ primary concerns: simplicity of use and compatibility. We further identify two perspectives on ‘omics adoption and explain how over-reliance on the predominant innovation-centric (as opposed to adopter-centric) perspective may undermine efforts to promote toxicogenomics. We build on these insights to offer recommendations for policy and practice. Proponents of toxicogenomics in chemical risk assessment may need to put more emphasis on understanding the practices and routines of potential adopters and, in turn, ensuring that the new tools they are promoting fit with them. Priority should also be given to ensuring that new tools are not overly complex to use or unecessarily disruptive of established risk assessment practices. In other words, researchers working to develop more elaborate ‘omics methods should heed considerations of compatibility and simplicity, lest their efforts come short of improving risk assessment practice and undermine technology adoption. This work supports the EcoToxChip project (www.ecotoxchip.ca).

599 Acute Fish Toxicological Threshold of Concern: TTC - a Meta-Analysis

H. Plugee, Verisk 3E / Safer Chemical Analytics; J. Kostal, George Washington University

TTC’s (Toxicological Thresholds of Concern) are in vogue with certain regulatory agencies i.e. EFSA (European Food Safety Agency), to predict chemical concentrations below which effects are unlikely to occur. Derivation of accurate TTC’s would result in a drastic reduction of the need for animal testing of chemicals. All of this furthers regulatory objectives under e.g. TSCA (Toxic Substances Control Act), to provide realistic scientific data without a dependency on animal testing. TTC does assume that exposure models can adequately predict environmental concentrations under real-world exposure conditions. Here we have applied this concept to a Meta-Analysis of Acute Fish Toxicity Assay data. A TTC can be calculated by determining the statistical distribution of as large a dataset as can possibly be derived. Calculation of confidence intervals provides a 95/99 percentile confidence limit (lower confidence interval 2.5 or 0.5% resp.) Application of a safety factor of 10 (or 100) then results in a prediction of a .25 or 0.05 (0.025 or 0.005) percentile concentration below which chemicals are predicted to have no effect. It is then postulated that no or very few effects from chemical exposure can be observed below this concentration. Obviously this requires a large database to
accurately predict statistical parameters with as broad a scope and as small a confidence interval as can be achieved. Verisk 3E has a database of 70,000 acute fish assays for 7400 plus chemicals. Approximately 30% of the data is provided by 180 plus of the chemicals, all with LC50 counts of greater than 50 after normalization of the main database. Not only can we thus derive statistical parameters for the overall database but we can also calculate TTC’s for individual species and (sub) classes of chemicals, albeit it of lower statistical confidence limits (due to reduced sample size, even at higher concordance). Based on preliminary data analysis we determined that data, i.e. LC50’s (for select chemicals) even at n = 100 were not normally distributed for even a single chemical. We thus focused on non-normal distribution based statistics i.e. using geometric means, which assume a log-normal data distribution. We calculated these statistics including a geometric mean confidence interval for the overall databases including many of the individual chemicals. A novel, more sophisticated uncertainty analysis of the same data is presented elsewhere.

**600 Environmental monitoring and impact assessment guidance for marine oil spills on the Pacific coast of Canada**

P. Allard, Azimuth Consulting Group / Institute for Society and Genetics; T. Siemens Kennedy, L. Du Gas, SNC Lavalin, Inc. / Environment & Geoscience; C.E. Mackintosh, C. Bullen, Azimuth Consulting Group; E. Chiang, J. Banning, M. Herborg, Fisheries and Oceans Canada

An oil spill in the marine environment can potentially cause significant environmental impacts; the timely and efficient collection and evaluation of relevant monitoring data following a spill at sea is essential to understanding and mitigating these impacts. Fisheries and Oceans Canada (DFO) supported the development of draft interim technical guidance for environmental monitoring and impact assessment (EMIA) of marine oil spills on the coast of British Columbia (BC). The technical guidance, which builds on recent national and international work, incorporates a risk-based approach and provides users with operational procedures for developing and implementing a spill-specific monitoring plan. This presentation describes key components of the draft EMIA guidance. The first component consists of information necessary for completing the problem formulation stage of a risk assessment (i.e., identification of oil contamintants of potential concern [COPCs], human and ecological receptors of concern [ROCs] and operable exposure pathways, and development of a conceptual site model [CSM]). The second component guides decision-making during each phase of environmental monitoring post spill incident (i.e., key questions being addressed, types of data being collected, and a description of decision nodes associated with those phases). The next two components of the technical guidance present the key aspects of a scientifically-defensible monitoring program that inform environmental recovery from a spill incident (i.e., strategy development based on CSM, selection of endpoints and lines of evidence [LOEs], weight of evidence [WOE] interpretation, study designs and statistics, and characterization of reference conditions) and outline operational procedures, including a monitoring plan template, checklists for selecting COPCs and LOEs, and methodology for the collection and analysis of data related to relevant media and ROCs. This technical document is intended to contribute as a foundational first step towards building a holistic risk based approach that informs environmental monitoring, recovery and impact assessment of marine oil spills.

**601 Sustainable Fish Productivity: Effect on Sediment Remediation Goals**

D. Pfeiffer, P.D. Anderson, ARCADIS US, Inc.

Background: Fish consumption rates are one of, if not the, most critical assumptions when deriving sediment remediation goals. To be protective of the human populations that consume fish, high-end fish consumption rates are often used when deriving remediation goals with no, or at best little, consideration of whether a site can sustainably produce fish at the assumed fish consumption rate. This presentation reviews and summarizes fish productivity information and then presents examples of how sustainability information can be applied to the development of sediment remediation goals. Approach: Fisheries biologists have developed estimates of sustainable productivity for a range of waters throughout the United States. That information can be combined with the area of fishable waters at and adjacent sediment sites to estimate sustainable production of edible-sized fish. This presentation reviews and summarizes production data in geographically diverse locations that can be used to determine fish population dynamics and to develop estimates of the fraction of the standing fish biomass that can be removed sustainably. The estimates of sustainable production of edible sized fish were combined with assumptions of preparation of fish meals and the size of contaminated sediment sites to develop a range of fish consumption rates that could be sustained for the long-term (i.e., years). Results: Sustainable production findings combined with a range of fish meal preparation methods (e.g., consumption of fillets only or both fillets and whole fish) lead to sustainable consumption rates of edible portions of fish ranging from about 1 to 5 grams of fish per hectare per day. The range of sustainable consumption rates per hectare can be combined with the size of a contaminated sediment site to estimate the total amount of edible fish that can be produced and consumed from a site, leading to maximum fish consumption rates that are sustainable and upon which to base sediment remediation goals. Finally, examples of estimates of population risk (i.e., the potential number of cancers in the exposed population) were developed by combining sustainable production rates, site size, concentration of contaminants in fish and toxicity. Such estimates provide risk managers perspective about the benefits realized by cleanup of contaminated sediment sites.

**602 North American Urban Fisheries: A Public Health Analysis for the Future of Fishing and the Need for Management Policy**

D.A. Lucas, Arizona State University; R. King, Arizona State University / School of Mathematical and Natural Sciences; P. Beamer, University of Arizona / Mel and Enid Zuckerman College of Public Health; B. Polidoro, Arizona State University / School of Mathematical and Natural Sciences

As urbanization has spread across much of North America over the past century, with approximately 80% of the total population residing in urban areas throughout Mexico, Canada, and the United States, there has been an increase in efforts to preserve the tradition of fishing through the creation of urban fisheries. Every state in the U.S. has at least one urban area with a system of recreational urban fisheries, and the southwestern state of Arizona is home to the largest. Prior research indicates 58% of surveyed anglers in the major metropolitan area of Phoenix consume the fish they catch. A pilot study detected various pesticides, polycyclic aromatic hydrocarbons, phthalates, and heavy metals within fish sampled from ponds in the Phoenix-metro area. Aluminum and Mercury were detected in concentrations calculated to be potentially toxic if fish are consumed regularly. The aims of this study were to identify characteristics of the population at risk, and pinpoint deficiencies in management policy that allow such vulnerability. A survey was administered to 53 anglers fishing at four urban ponds in the Tucson, Arizona, area (another major metropolitan area) to analyze their demographic and quantitate the potential public health risk. Survey results indicate 57% of surveyed anglers consume the fish they catch, with an average of approximately 45 fish consumed per year. Anglers that consume fish and report fishing at least once per week (47% of the total sample size) consume approximately 59 fish per year. Many urban ponds are artificially constructed, which excludes them from protection and monitoring under the U.S. Clean Water Act. Through a comprehensive review, similar gaps in policy concerning urban fisheries were also found in Mexico and Canada. Utilizing EPA oral reference doses, participant weight, number of fish consumed per week, and a conservative estimated fish size of 1 pound (0.4536 kg), safety thresholds specific to each participant were calculated for metal contaminants which participants are exposed to through the consumption of fish. Assuming contaminant concentrations in fish from the Phoenix area are similar to those in the Tucson area, of the anglers that reported to consume fish: 37% are potentially at risk for toxic effects from Aluminum, Arsenic, and Mercury, 17% from Selenium, and 3% from Nickel and Zinc. Additional and more stringent management policy concerning urban fisheries is needed to minimize this current public health risk.
Benthic and Pelagic Harmful Algal Blooms and their Toxins: Detection, Fate, Effects, Monitoring and Management

603 An automated non-targeted method for the instrumental analysis of microcystins and anatoxin-A in harmful algal blooms

X. Ortíz Almirall, Ontario Ministry of the Environment, Conservation and Parks / Toxic Organic Section

Microcystins are hepatotoxins produced by cyanobacteria in marine and freshwater environments such as the Great Lakes. They have a cyclic heptapeptide structure, with different possible amino acid substitutions. Anatoxin-A is a bicyclic amine alkaloid also produced by certain cyanobacteria species with acute neurotoxicity to animals, including humans. Conventional approaches for the individual analysis of these toxins entail long sample preparation to lyse the cells, extract the toxins, and concentrate them to a small volume prior to the instrumental analysis, usually carried out by liquid chromatography coupled to a triple quadrupole (LC-MS/MS) or quadrupole time-of-flight (LC-QToF) mass spectrometer. The whole process can take up to several days, leading to a reduced sample throughput and slow response in case of emergency. To address this issue, an automated method for the analysis of cyanotoxins was developed using on-line solid phase extraction prior to the LC-QToF analysis, including 12 different microcystin variants and anatoxin-a in the same chromatographic run. Method dynamic range spans from 0.01-5.00 µg L⁻¹, with 5.14% of expanded uncertainty. Sample throughput is significantly increased to 72 samples day⁻¹, and results can be reported in less than 3 hours from the moment the sample is received in case of emergency. Over 250 different microcystin variants have been reported in literature to date, but that is only about 0.1% of the theoretical structures based on the permutations of the known amino acids. This suggests that there must be microcystin variants still unknown, and non-targeted methods for their analysis should be developed. The present study will describe an experimental workflow for the detection and structural elucidation of previously unreported structures, using data dependent acquisition, diagnostic fragment screening, and amino acid structure determination based on accurate mass measurements and fragmentation with a custom-made script. A step-by-step structural elucidation of ILe-microcystin-YR will be showcased as an example.

604 Global assessment of cylindrospermopsin in the environment: Review and analysis of environmental occurrence, bioaccumulation, and aquatic toxicity

K.R. Scarlett, L. Lovin, B.W. Brooks, Baylor University / Department of Environmental Science

Harmful algal blooms (HABs) appear to be increasing in magnitude, frequency and duration, in response to climate change and anthropogenic activities, including salinization and eutrophication. Subsequently, production of secondary products such as cyanotoxins present risks to public health and the environment. Here we examined an understudied HAB species, Cylindrospermopsis raciborskii, critically reviewed refereed literature for environmental occurrence in surface waters, and aquatic toxicity and bioaccumulation of cylindrospermopsin, its primary cyanotoxin. Lacustrine systems were the most common system type, with the majority of available data from Asia/Pacific, Europe, and North America. Interestingly, the Asia/Pacific region had the lowest number of detections, but the highest percentage exceedances. Limited data was found and used in the analyses for both Africa and South America, emphasizing need for further studies in more temperate regions where CYN may occur. Probabilistic environmental hazard assessments were then performed to identify exceedances of global guideline values (GVs). Specifically, these determined GV values were compared with the developed environmental exposure distributions (EEDs) of all identified surface water data, which included both intracellular and extracellular data. Common GVs of 0.5 µg/L (lowest drinking water), 1 µg/L (lowest recreational water), and 20 µg/L (highest drinking and recreational) were exceeded by 52.64 %, 40.60 %, and 6.04 %, respectively. Highest GV percent exceedances were for reservoir systems with 54.68 %, 44.0 %, and 9.50 %. Aquatic organism toxicity and bioaccumulation data were subsequently evaluated and critical data gaps were identified. Information from the current study will be useful for forthcoming efforts to understand cylindrospermopsin exposure and associated adverse outcomes to ecosystems and human health.

605 Development of methods for measuring total microcystins in Fish Tissue using the 2-methoxy-3-methyl-4-phenylbutyric acid (MMPB) procedure

There are limited methods for the analyses of multiple algal toxins in aquatic food waters, phytoplankton, zooplankton, periphyton, macroinvertebrates, forage fish, bottom feeders and top carnivore fish. Algal toxins in freshwater systems do not necessarily occur as single contaminants; mixtures of toxins may be produced from Cyanobacteria, Prymnesium parvum, and Euglena sanguinea, including microcystins, saxitoxins, cylindrospermopsin, anatoxin-a, prymnesins and euglenophycin. The objective of the first phase of this research was to spike existing fillet and whole fish homogenates with 3 congeners of microcystins (LR, LA and RR) individually and as mixtures, and to develop a method for their recovery and measurement using the MMPB derivatization method. The second phase of the project is to field-test this method on fish collected from water bodies experiencing algal blooms and compare results with individual congeners measurements. Extraction methods and analytical methods being developed for this research will be a starting point for developing extraction procedures for plankton, periphyton, and macroinvertebrates. Fish homogenates weighing 10 and 100 mg from fish containing 1, 4 and 14% lipids were spiked with 4 and 40 ng of each of the microcystin congeners, LR, LA and RR. Various extraction techniques and conditions were tested to optimize recovery and simplify the procedure. Overall toxin recoveries were found to range from 30 to 50%. The lipid content was found to not interfere with generation of MMPB; however, it did impact the workup/extraction procedure in ways which were quantifiable through the use of a surrogate standard and standard addition procedures. The MMPB technique can be reliably employed for microcystin quantification in fish tissue. During the second phase of the project fathead minnows that were deployed in experimental streams that were dosed with different nitrogen and phosphorus concentrations in 2017 and 2018 were analyzed as well as periphyton slurries collected from the streams in 2018. In addition, fish collected in 2018 from lakes with historic algal blooms in Utah, Florida, Connecticut and New Jersey were analyzed. For toxin quantification in tissues, the measurement of total microcystins via the MMPB method provides improvements over extraction of individual toxin congeners, particularly with very polar or hydrophobic MCs. Results from phases 1 and 2 will be presented.

606 Development of analytical techniques for qualification and quantification of Lyngbya wollei toxins

S. Putnam, M.L. Smith, T.T. Metz, University of South Carolina / Department of Chemistry and Biochemistry; G.I. Scott, University of South Carolina / Env. Health Sciences; J.L. Ferry, University of South Carolina / Department of Chemistry and Biochemistry

Lyngbya wollei is a harmful benthic algae in fresh and brackish waters with high biomass production once established. The relationship between biomass and toxin concentration is not well established, so control is difficult to predict, plan, and execute. In this study, a Lyngbya wollei bloom in Lake Wateree, SC was monitored from July 2018 to September 2019 at multiple grab sites, including three sampled every two weeks. Additional mapping of the bloom was carried out in coordination with WaterWatch,
a citizen's science group of trained volunteers. Samples were lyophilized, extracted, centrifuged, and analyzed by hydrophilic interaction liquid chromatography along with two complementary mass spectrometry techniques. High resolution mass spectrometry was applied using an Agilent quadrupole time-of-flight instrument to confirm the structure of the *Lyngbya wollei* toxins (LWTs) present. The high-resolution fragmentation analysis presented provided an unprecedented range of fragment ions that can be used to conclusively indicate the presence and retention time of LWTs even in the absence of commercial standards. A triple quadrupole instrument was used for quantification of toxins and routine analysis of the samples. This data showed a significant amount of noise deriving from the samples themselves. Grab sampling techniques were found to be susceptible to artifacts from deposited sediments on the bloom, inadvertent collection of aquatic vertebrates and invertebrates, and inadvertent harvesting of other members of the microbial community. A 16S rRNA gene sequence assay demonstrated the presence of a diverse community of microbiota present in the grab samples. Application of improved fragmentation schemes, suppression elimination studies, and sample-based correction strategies reduced error in the apparent biomass to LWT ratio, indicating that LWTs are in fact directly correlated with bloom biomass. This information is essential to planning the most risk-averse strategy for controlling this bloom in a way that minimizes worker and environmental exposure to toxins.

### 607 Use of passive samplers for the detection of extra cellular algal toxins in stream mesocosms, lakes and streams

H. Mash, US Environmental Protection Agency / ORD/NRMRL; D. Shea, Statera Environmental, Inc. / Biological Sciences; M. Howard, California State Water Resources Control Board; R. Kudela, University of California, Santa Cruz / Ocean Sciences; J. Allen, USEPA; J. Lazorchak, US Environmental Protection Agency / Ecological Exposure Research Division; T.T. Sanan, US Environmental Protection Agency / NRMRL; C.T. Nietch, US Environmental Protection Agency / Water Supply and Water Resources Division

Freshwater Harmful Algal Blooms (HABS) are occurring frequently throughout the U.S. and many parts of the world. Most of the emphasis on freshwater HABs has been on reservoirs and lakes with recreation and drinking water uses. However, there is mounting evidence that attached benthic cyanobacteria may be increasing and dominating the benthic periphyton community and may be contributing toxins to streams and rivers. Most methods for detections of HABs have been through water sampling for toxin measurements and cyanobacteria identification. Some newer methods have been developed and implemented in California to detect toxins in rivers using passive samplers called Solid Phase Adsorption Toxin Tracking (SPATT). In addition, North Carolina State University has been conducting passive sampler studies in China comparing several different passive samplers, SPATTs, Polar Organic Chemical Integrative Sampler (POCIS) and other Passive Sampler Devices (PSDs). What they found is that Large Format non-selective PSDs (LF nsPSDs) seemed to reflect water concentrations of microcystins better than other PSDs that were tested. For the past 4 years USEPA has been testing the consequences of nutrient additions to stream mesocosms. Macroinvertebrate and periphyton communities have been assessed using various measures for their responses to various concentrations of nitrates, phosphates and combination of nitrate/phosphates. At certain doses of these nutrients, cyanobacteria tend to dominate the benthic community. In addition, USEPA and their collaborators have also been studying a nearby lake that has bloomed for the past 8 years. The purpose of this study was to evaluate SPATT and LF nsPSDs to determine their performance in measuring extracellular algal toxins in stream mesocosms, Lake Harsha and in downstream habitats of Harsha lake. At the end of each of the 16 stream mesocosms and in 2 influent mesocosms both PSDs were deployed for 2-week intervals during the dosing period. Every 2 weeks during the dosing period, water samples were collected, PSDs retrieved and then replaced with fresh PSDs. For the lake a similar format was followed at the surface and at 2 different depths. Four stream locations were chosen below the outlet of the lake to see what the contribution of algal toxins to the stream community resulted for the lake blooms. The results of this study will be presented comparing the 2 PSDs and describing the pattern of algal toxins in each experimental unit.

### 608 Assessing potential human health risks from cyanotoxins in recycled water

C.A. Irvine, RBI / Ecosystem Services; E. Preece, P. Bedore, Robertson-Bryan, Inc.

Recycled wastewater is used primarily for irrigation (non-potable uses) in California and reduces the strain on freshwater and groundwater drinking water supplies in the face of climate change. This tertiary-treated, disinfected, recycled water is of high-quality, but when stored in holding ponds prior to distribution, it has the potential to promote the growth of cyanotoxin-producing blue-green algae. A harmful algal bloom (HAB) occurred in 2018-2019 at a recycled water holding pond at a municipality in California, USA, where recycled water provides irrigation for residential, public recreational, agricultural, and commercial properties. The blue-green algae *Microcystis* spp., which produces the liver toxin microcystin (MC), was detected in this HAB. We conducted a human health risk assessment according to U.S. Environmental Protection Agency guidance to identify and characterize potential risks associated with exposure to MC by users of the municipality’s recycled water. Complete and potentially complete exposure routes were identified and assessed for municipal and agricultural workers, children who might play in sprinklers, people consuming food grown in gardens or crops irrigated with recycled water, and for domestic pets. Conservative human health and dog benchmarks developed by State and Federal agencies to be protective of recreational exposures in waterbodies containing MC were used for the evaluation. No potential for human health risks from MC in 2018-2019 were identified. Conservative exposures for domestic pets (i.e., dogs) exceeded screening-level benchmarks, but a refined assessment with more realistic exposures did not exceed subchronic action levels for California. Potential risks were also uncertain for several exposure pathways (e.g., people consuming food grown in gardens or crops irrigated with recycled water) and more research is needed to refine exposure parameters for these pathways and inform the fate and transport of MC in exposure models. Results were used by the municipality to inform a HAB mitigation and prevention strategy, refine routine monitoring, and design a communications plan for public outreach. These efforts will help identify and minimize the potential for future health risks associated with exposure to MC from this recycled water system.

### 609 A quantitative methodology to address challenges in sampling of subtidal macroalgal biomass, benthic algae, sediment, and water, from small vessels

K.C. Sorensen, I.D. Rivera, Naval Information Warfare Center (NIWC) Pacific; C.E. Sosa, San Diego State University Research Foundation; K.P. Carlin, Naval Information Warfare Center (NIWC) Pacific

Eutrophication is the presence of excessive nutrients in lakes, estuaries, or other bodies of water. This results in a dense growth of plant life and death of marine life due to lack of oxygen. Regulatory requirements in the form of Total Maximum Daily Load (TMDLs) are shifting from the use of more causative/numeric stressor indicators, such as nitrogen (N) and phosphorus (P), to measurements of biological response. One of the key biological indicators being proposed for meeting TMDL objectives is macroalgal biomass. However, the use of this indicator in waterbodies where macroalgae is predominant has been hindered by a lack of standardized, quantitative methods which allow for sampling across the diversity of tidal elevation gradients. This is important in that macroalgal blooms are known to proliferate in both intertidal and shallow subtidal environments, so protocols to assess macroalgal abundance must be applicable across the tidal elevation gradient. The use of intertidal measurements alone to represent the system as a whole are complicated by the fact that nutrient effects on aquatic ecosystems are moderated in how they are expressed by many natural factors (e.g., light penetration,
hydraulic residence time, presence of herbivore grazers and other food web interactions, and habitat considerations). As a result, large portions of the waterbody, in particular the subtidal areas, go unmeasured. Protocols are therefore not well validated for quantifying the true level of algal biomass for a given waterbody. A new quantitative methodology has been developed which utilizes a small, portable device which can be mounted to a small vessel, like a kayak, and is not limited by the reach of your arm, allowing rapid (<5 min/sample), repeatable sampling at depths up to 3.66 meters. Furthermore, both current and proposed biological (biostimulatory) approaches to demonstrate compliance with TMDL monitoring requirements, mandate a multiple lines of evidence approach to demonstrate compliance. This requires multiple substrate sampling (e.g., water, algae, and sediment) which can be costly, time consuming, involve separate substrate-specific collection protocols, as well as pose site-specific, inherent challenges in collecting appropriate samples. With further calibration and validation to standardized methods, the use of this portable device has the potential to consolidate methods by allowing for simultaneous multiple substrate collection in one sample.

610 Whole transcriptome characterization of the hepatocyte response to microcystin-LR and RR

A. Biales, D.C. Bencic, US Environmental Protection Agency / ORD/NERL/EMMD; D.A. Gordon, US Environmental Protection Agency / National Exposure Research Laboratory; R. Flick, W. Huang, USEPA / ORD/NERL/EMMD; A. de la Cruz, USEPA / USEPA/ORD/NERL

Little is known about the risk posed by the majority of microcystin congeners, and knowledge gaps exist for even the most highly characterized. This may have implications for human and ecological health, as harmful algal blooms often contain mixtures of microcystin congeners. This work aims to identify potential intracellular targets and modes of action (MOA) by characterizing the early transcriptional response of HepaRG cells to microcystin-LR (MC-LR) and -RR. Transcriptome-wide responses of hepatocytes exposed to two concentrations (1000, 10 mg/L) of LR and RR for two hours were characterized using RNA-seq. Oxidative stress and the production of ROS appeared to play a central role leading to endoplasmic reticulum (ER) stress and the initiation of the unfolded protein response (UPR) and, in the case of LR, apoptosis. Evidence for ER stress was evident in both the MC-LR and -RR responses; however, the LR specifically triggered the PERK arm of the UPR and apoptosis, whereas, the ER stress response to MC-RR appeared to be less severe and was compensated for. A number of aldehyde dehydrogenases were up-regulated in response to both congeners, suggesting lipid peroxidation. Several congener specific responses were also observed. Members of the FOS family of proteins, constitutents of AP-1, were among the most highly differentially expressed in response to MC-LR. This was consistent between the 1000 and 100 mg/L exposures but was completely absent in any LR treatment. AP-1 is a central factor in many cellular pathways including apoptosis via TNF-a/JNK pathway. In the MC-RR treatments, complement was highly enriched in both the high and medium RR exposures, and not in any LR treatment. Though complement is generally associated with the inflammatory response, it has more recently been shown to respond to liver injury, where it is reduces apoptosis in hepatocytes. Congener specific differences suggest the potential for additional or uncharacterized MOA outside of the canonical inhibition of protein phosphatase (PP). These other MOA may help explain differences in the cytotoxic potential of MC congeners that cannot be explained through PP inhibition. Additionally, these non-canonical targets and MOA may need to be considered when estimating risk posed by MC mixtures.

611 Whole transcriptome characterization of the hepatocyte response to microcystin-LR and RR

A. Biales, D.C. Bencic, US Environmental Protection Agency / ORD/NERL/EMMD; D.A. Gordon, US Environmental Protection Agency / National Exposure Research Laboratory; R. Flick, W. Huang, USEPA / ORD/NERL/EMMD; A. de la Cruz, USEPA / USEPA/ORD/NERL

Little is known about the risk posed by the majority of microcystin congeners, and knowledge gaps exist for even the most highly characterized. This may have implications for human and ecological health, as harmful algal blooms often contain mixtures of microcystin congeners. This work aims to identify potential intracellular targets and modes of action (MOA) by characterizing the early transcriptional response of HepaRG cells to microcystin-LR (MC-LR) and -RR. These other MOA may help explain differences in the cytotoxic potential of MC congeners that cannot be explained through PP inhibition. Additionally, these non-canonical targets and MOA may need to be considered when estimating risk posed by MC mixtures.

Advancing the OMICS into Regulatory Frameworks: Case-Studies and Perspectives - Part 1

611 Ecogenomics based assessment of ecological effects of Selenium: a lake mesocosm study

Y. Xie, S. Graves, A. DeBofsky, University of Saskatchewan / Toxicology Centre; J. Giesy, D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; V. Palace, IISD-Experimental Lakes Area; M. Hecker, P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre

Selenium (Se) is not only an essential micronutrient but also one of the most hazardous trace elements to animals. Se is mainly bio-accumulated in primary aquatic consumers through their diet (e.g., microorganisms, detritus) and can be biomagnified concentrations able to cause reproductive failure and teratogenicity effects in vertebrates. However, important knowledge gaps remain concerning the ecological effects of Se during its bioconcentration. Here, Se was added to freshwater boreal lake mesocosms as selenite (IISD-Experimental Lake Area, Manitoba, Canada) following a regression design (concentrations: 0.5, 1, 2, 4, 7, and 10 μg Se/L) and three non-treatment control limnocorrals. Water, zooplankton, and sediment were sampled at multiple time points to study both short-term (3 and 7 days-post-exposure (dpe)) and medium-term (21 and 63 dpe) ecological responses to Se addition. Multiple communities, including bacteria, algae, protozoa, zooplankton, and macroinvertebrate, were characterized by environmental DNA (eDNA) metabarcoding. Ecogenomics based composition, alpha- and beta-diversities were compared to tracking the natural and disturbed changes to communities. This study presents comprehensive ecological responses of controlled mesocosms to Se, and highlights the power of emerging ecogenomic tools for regulators, scientists, and local communities to monitor and predict future trajectories for freshwater ecosystems.

612 Modifications to existing transcriptomics dose-response methods to help improve performance in ecological species

J. Ewald, McGill University / Natural Resource Sciences; O. Soufan, McGill University / Institute of Parastology; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; J. Xia, McGill University Macdonald Campus / Institute of Parastology; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences

Methods of measuring whole-transcriptome changes in gene expression, such as microarrays and RNA-sequencing, have great potential for applications in screening and prioritization of environmental contaminants by regulatory agencies. One emerging strategy for linking changes in gene expression to adverse outcomes of regulatory concern is through dose-response modeling. It has been shown previously that benchmark doses computed using gene expression are consistently within one order of magnitude of benchmark doses computed using apical outcomes. However, the analytical method used to generate these findings, implemented in the EPA software “BDMExpress,” was developed using mammalian species and relies on gene set libraries such as KEGG, the Gene Ontology, or Reactome. This makes it difficult to use for ecological species, which typically have limited genome annotation resources. Additionally, the method is computationally intensive because it requires fitting multiple statistical models to 1000s of individual genes. The objective of this study was to modify the transcriptomic dose-response approach implemented in BDMExpress to improve its performance in ecological species. First, whole-transcriptome data were summarized using our own gene sets, a collection of 21 “toxicity modules,” which were designed for the interpretation of toxicogenomics data and can be rapidly defined in species with no existing functional annotation. Next, benchmark doses were calculated by fitting statistical models to module-level responses. This significantly decreases the computational time because models are fit to only 21 outcomes (toxicity modules), rather than to 1000s of outcomes.
614 eDNA Shaping a New Era of Ecotoxicology

X. Zhang, Nanjing University / Environmental Science

Aquatic ecosystems, such as rivers and lakes, are exposed to multiple stressors from anthropogenic activity and changes in climate, which have resulted in a general decrease in biodiversity, alteration of community structures, and can ultimately result in reduction of resources provided by natural ecosystems. Adverse outcomes caused by pollutants to ecosystems are determined not only by toxic properties but also ecological contexts of ecosystems, including indigenous biodiversity and community composition. It is therefore important to identify key factors, such as diversity of species and traits that determine the vulnerability of structures and functions of ecosystems in response to toxic substances. Detection and quantification of biodiversity and its activities using environmental DNA (eDNA) is arguably one of the most important technical advances in ecology in recent years. A huge opportunity has appeared to allow more relevant approaches for assessments of risks posed to ecosystems by toxic substances. eDNA approaches provide effective and efficient tools to evaluate the effects of chemical pollutants on (1) the occurrences and population of wildlife, (2) communities, and (3) the function of ecosystem in the field. Here a conceptual framework of adverse outcome pathways to relate molecular initiating events to apical ecosystem-level responses is proposed to connecting laboratory-based prediction to observations under field conditions. Particularly, future research opportunities on effects on biodiversity, community structure, and ecosystem function by toxic substances will be discussed.

615 Addressing the “so what?” question: The transcriptome as an indicator of changes in fish health in a pesticide hot spot

S.E. Hook, CSIRO Oceans & Atmosphere; J.A. Mondon, Deakin University / School of Environmental Science; A. Revill, CSIRO Oceans and Atmosphere; P. Greenfield, CSIRO Digital Productivity; R.A. Smith, R.D. Turner, Queensland Government / Department of Environment and Science; P.A. Corbett, Deakin University; M.S. Warne, The University of Queensland / Centre for Agroecology, Water and Resilience

It is well known that concentrations of pesticides in the Great Barrier Reef Catchment Area exceed water quality criteria, however, whether these pesticides are having detrimental impacts on the health of the system was uncertain. To address this uncertainty, we conducted transcriptome profiling via RNASeq in Barramundi (Lates calcarifer) collected from rivers with comparatively good and from agriculturally influenced water quality. Fish from agriculturally influenced rivers showed altered transcriptomic patterns, including transcripts that regulate lipid metabolism, xenobiotic metabolism, and immune response. Further surveys showed that these changes only occurred when fish were collected during the wet season, when agricultural run-off is highest and pesticides are present, suggesting that the changes are unlikely to be occurring as a result of habitat modification. Subsequent studies examined higher levels of organisation and found that pesticide exposed fish had consistent changes in the transcriptome, gross histological alterations including lipodosis, and differences in some lipid classes. The work conducted to date shows that there may be “real world” impacts from pesticide exposure and may indicate a decrease in health of pesticide exposed fish. The findings of this and related studies are being used in stakeholder engagement to work with farmers to reduce pesticide load.

616 Developing models predictive of heart rate across a large set of compounds in the Environmental-Predictive-Information-Connectivity map

C. Iosif, University of Liverpool; P. Antczak, University of Liverpool / Institute of Integrative Biology

The adverse outcome pathway framework (AOP) has provided the ecotoxicology community with a great framework to conceptualise the knowledge generated in recent years. To date developing AOPs has focused on collecting data and knowledge and combining these into the framework. This can be time consuming and challenging particularly with more novel or less characterized stressors. To reduce the time required to develop AOPs, a data-driven approach is needed that can guide the researcher/regulator to the potential underlying molecular key events important for the adverse outcome (AO). The Environmental-Predictive-Information-Connectivity map (EPIC-map) attempts to address this need by developing a single dataset of dose response relationships across more than 150 compounds of environmental concern in Danio rerio embryos and by combining the power of OMICS, QSAR and Read-across approaches link chemical structural information to transcriptional data and to the observed AOs. The EPIC-map collected a vast amount of qualitative measures of adversities, including developmental, behavioural and morphological measures as well as a number of
quantitative measures, such as hatching success, heart rate, and rate of deformations. Transcriptional data is being generated which will be used to define a chemical classification based on molecular responses and to act as a proxy between chemical structural components and observed adverse outcomes. In this talk we will focus on the analysis of observed heart rates in zebrafish embryos and develop models linking chemical structural information to these. Our preliminary analysis shows that a highly predictive model (R² > 0.84) can be developed which includes lipophilicity and the total number of tertiary carbons. This suggests that there are chemical structural components that can be directly linked to observed changes in heart rate. With the additional transcriptional data we will then be able to associate a molecular response to the change in heart rate and provide a more comprehensive understanding of the underlying biology. Finally, we will show how we will be able to develop a data-driven AOP identifying the important key-events using this type of data.

617 Change of Reproduction Stage Differentiates Time-Course Regulation of Metabolites in Daphnia magna

T. Jeong, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences

Daphnia magna is an indicator species widely used in environmental quality assessments. Metabolic researchers have utilized the organism to investigate molecular responses to aquatic contaminants and environmental changes. However, the impact of reproduction stage on metabolic variation and regulation has not yet been studied. This study was performed to understand the relationship between metabolic variation and reproduction cycle. 54 metabolites were quantified using liquid-chromatography with tandem mass spectrometry during different reproduction stages and sampling times (hours). The variation of metabolite concentrations was compared between the variables and time-course metabolic regulation was analyzed to investigate if the metabolic regulation is dependent on reproduction stage. The results showed that the metabolite concentrations were significantly differentiated by the reproduction stage in addition to the sampling time. The most affected metabolites included nucleotides and amino acids, which implies that the differentiated metabolite concentrations are likely related to embryo development and time-dependent algae uptake. The patterns of time-course regulation were observed to be dependent on reproduction stages and the latter stages, stages 2 and 3, showed similar time patterns of metabolite abundance regulation. In summary, this study revealed that the reproduction stage is a variable affecting D. magna metabolic profiling. Considering that the whole body metabolite profile is a typical endpoint in metabolomics and the metabolic impact of reproduction cycle needs to be considered as an important variable in Daphnia metabolomics and more studies are required to further understand reproduction stage dependent regulation under stressed conditions such as poor water quality.

618 Metabolomics in Regulatory Toxicology: Use Cases, Best Practice and Reporting Standards

M.R. Viant, University of Birmingham / University of Birmingham Enterprise; T. Ebbels, Imperial College London; R. Beger, Food and Drug Administration; D. Ekman, US Environmental Protection Agency / National Exposure Research Laboratory; D. Epps, University of Birmingham; H. Kamp, BASF; P. Leonards, Vrije Universiteit Amsterdam / Environment & Health; G. Lotzou, Health Safety Laboratory / Computational Toxicology Team Mathematical Sciences Unit; J. MacRae, The Francis Crick Institute / Metabolomics; B. van Ravenzwaay, BASF SE / Experimental Toxicology and Ecology; P. Rocca-Serra, University of Oxford; R. Salek, International Agency for Research on Cancer; T. Walk, Metanomics; R. Weber, University of Birmingham

Researchers are increasingly using metabolomics to evaluate potential risks from exposure to environmental stressors. Much like the other OMICS approaches, metabolomics has proven to be a powerful tool for identifying and understanding contaminant mode(s) of action/adverse outcome pathways and discovering indicators of exposure/effects in ecologically relevant species. Despite these strengths, the application of metabolomics to regulatory toxicology has been limited. While several factors contribute to this slow translation, the roadblocks most commonly cited by chemical regulators and government and industry scientists is the lack of standardization, best practice guidelines, and data and metadata reporting formats. Here we will describe the final report of the MERIT project, which brought together a team with a wide range of expertise from multiple sectors to address this need. MERIT sought to define best practice guidelines and minimal reporting standards for designing, undertaking, reporting and assessing the quality of both untargeted metabolomics and targeted metabolite analyses for application to regulatory toxicology. To provide context, the most relevant-use cases for metabolomics in toxicology were also identified, including discovery of chemical mode(s) of action and cross-species extrapolation of toxicity pathways. The MERIT guidelines included experimental design; QA/QC; sampling and extraction; data acquisition and processing of mass spectrometry and NMR spectroscopy assays; data processing and statistical analysis; and metabolite identification. A strategy and architecture for integrated data management, sharing and exploitation in regulatory toxicology was also developed. We concluded that most steps in the regulatory toxicology application of untargeted metabolomics and targeted metabolite assays are already well established, including significant recent progress in QA/QC. These and other aspects of the MERIT project will be presented along with recommendations for critical “next steps” to advance the use of metabolomics in regulatory toxicology. The contents of this abstract neither constitute nor reflect USEPA policy.

Current Methods in Teaching at the Interface of Chemistry and Toxicology

619 Teaching Toxicology to Chemists: Exploiting Chemical Knowledge to Allow Chemists to Effectively Assess Chemical Risk

J.C. D’eon, University of Toronto / Chemistry

Understanding the end of use implications of chemical production is an increasingly important aspect of university chemistry education. This is particularly true at the University of Toronto as we are signatory to Beyond Benign’s Green Chemistry Commitment that solidifies our commitment to infuse our undergraduate curriculum with the twelve principles of Green Chemistry, of which “Design Benign Chemicals” is the fourth. This presentation will outline how we have incorporated toxicology concepts into a third-year environmental chemistry class. Time will be reserved at the end of the presentation for an open discussion on appropriate learning objectives for toxicology education within chemistry education.

620 Helping Chemists Assess Chemical Risk: Using Models to Visualize Chemical Fate

S. Baskaran, University of Toronto, Scarborough / Chemistry; J.C. D’eon, University of Toronto / Chemistry

Models can be used in environmental chemical risk assessment to visualize the environmental fate and partitioning of chemicals; however, they are underutilized in undergraduate education. We built a simplified Air-Water Model for use in a third-year environmental chemistry course to improve student comprehension of the core environmental chemistry concepts of chemical partitioning, persistence and environmental fate. The model is a component of a term project that allows students to understand how these properties can be used to assess chemical risk by performing an assessment themselves. The project is scaffolded such that students first develop a product generation scheme to identify the degradation products formed via hydroxyl reaction, hydrolysis, or photolysis. They then determine relevant physical-chemical properties for each of these chemicals, including the Henry’s law constant, using online resources such as the EPA’s CompTox Database. Finally, students edit the code for this model
in Visual Basic for Applications in Microsoft Excel with their own mass balance equations in order to predict the fate of their contaminants and degradation products over a 100-year period based on the reaction scheme and the chemical-physical properties previously identified. The environmental fate model allows students to visualize the difference in the fate and partitioning of legacy and emerging chemicals in the environment and adds to their overall learning experience in the class.

621 Project Based Learning in Environmental Chemistry: Student-led Projects Using Personal Air Samplers

M. Ross, MacEwan University / Physical Sciences; R. Zhao, S. Styler, University of Alberta / Department of Chemistry

Undergraduate laboratory experiments are often conducted under rigid experimental procedures, constraining students’ creativity and limiting their exposure to the trials and tribulations of “real-world” scientific research. With this in mind, we aimed to develop a new project-based learning (PBL) experience for undergraduate students enrolled in 3rd-year environmental chemistry courses at the University of Alberta and MacEwan University. PBL is a pedagogical approach in which students actively participate in the investigation of real-world problems and in the process gain experience in asking questions, predicting results, designing and carrying out experiments, analyzing data, and communicating results to others. The project utilized AirBeam personal air samplers, which are low-cost, portable instruments to determine PM2.5 mass concentrations in ambient air. In this project, students were asked to engage with the primary literature to discover areas of interest in urban and indoor air quality, ask a relevant research question, formulate a hypothesis testable using the AirBeam, and design and conduct an air sampling campaign or laboratory-based experiment to test their hypothesis. Students analyze and interpret their data, and present the main findings and broader implications of their experiment as both an oral presentation and a journal-style write-up. A PBL component into our courses has enriched the course considerably and has enabled students to gain experience with the entirety of the scientific research process.

622 Evaluating the Student Experience of a Student-Directed Group Project in an Interdisciplinary Capstone Environmental Analytical Chemistry Laboratory

R. Hems, University of Toronto / Department of Chemistry; J.C. D’eon, University of Toronto / Chemistry

The environmental chemistry curriculum at the University of Toronto includes a capstone laboratory course, CHM410-1410 Analytical Environmental Chemistry. In the fall of 2014, four of the structured labs were removed and a student-directed final group project was introduced. Students work in lab groups of 3-6 to plan, execute, and present an environmentally-relevant analysis of their choosing. The aim of these projects is to provide an authentic learning experience, to increase student investment, and encourage peer-to-peer learning, which is difficult to implement in single 3.5-hour lab periods. These projects offer students the chance to make decisions in the chemistry lab, to learn from their mistakes, and to deal with the ambiguity of generating “real” analytical chemistry data. In addition to the laboratory skills learned and practiced, the students gain valuable project management and communication skills. Student survey responses before and after implementation of the projects indicated increased satisfaction with the class as a whole. To investigate how the student experience of this laboratory compares to other senior chemistry laboratories and to determine if the teaching objectives were being met, we conducted a focus group from the fall 2018 cohort of students and an in-depth survey of past and present teaching assistants. The course attracts undergraduate and graduate students from both chemistry and engineering and one of the challenges has been teaching to these different backgrounds. The focus group highlighted that the projects provided an opportunity for peer-to-peer learning and skill development in students with different expertise. Responses from the focus group also indicated that students felt ownership over their project and were invested in the class. Results of this analysis will be presented in the context of the student experience of these projects, as well as the feedback received from the teaching assistants on how to best support students in this type of open-ended project-based learning experience in the chemistry laboratory.

623 Advantages of studio-style for teaching toxicology to undergraduates

A.D. Harwood, Alma College / Environmental Studies/Biology

One of the major problems teaching undergraduate science courses, particularly toxicology, is the integration of lecture content with the skills and methodologies experienced in the laboratory. Often students struggle to make connections between the two components of the course. One solution to this issue is the use of studio-style courses. In this format, rather than meet for three-one-hour lectures and a weekly three-hour separate laboratory, sections meet for two hours three times per week. This format has several advantages. Lecture content can be directly linked to experiments and students can spend more time doing hands-on activities. This also allows for 48 or 96 h experiments to be conducted without requiring time outside of class. The longer regular meeting time also allows for extended practice exercises and paper discussions. In 2017, an introductory toxicology course was taught at a small liberal arts college using a studio style format. Other modifications to the course included an emphasis on application and data analysis, teaching content through primary literature, and grouping students based on previous coursework. While less lecture content could be delivered in this format, overall student ability to interpret data, prepare laboratory reports, and design experiments was greatly improved. The complexity of examination questions and the level of understanding among students was greatly improved from previous versions of the course. The quality of student writing was also improved. Overall student feedback also reflected these observations, students felt more confident in their laboratory skills and content application. Therefore, moderate changes in course structure can have major implications on student learning.

624 Discipline-based education research: What is it and why it is important to environmental toxicology

C.M. Lee, Clemson University / Engineering and Science Education Department

In 1990, Ernest Boyer, who was President of the Carnegie Foundation for the Advancement of Teaching, called for scholarship to be reconsidered to include the scholarship of discovery, application, integration, and teaching. Others expanded the idea of the scholarship of teaching to include learning and still others have defined discipline-based education research (DBER) as the systematic investigation of questions about teaching and learning grounded in theory and in a specific discipline. Several models of DBER exist such as tenure-track researchers embedded in disciplinary departments (e.g., biology, chemistry, and mathematics) and departments devoted to education research serving as the tenure home for researchers who have joint appointments in disciplinary departments. Examples of both models and their pros and cons will be discussed with particular attention to the sciences important to environmental toxicology as well as the benefits derived for educating the environmental scientists of the future.
625 Finding Success in “Failure” of Undergraduate Research

J. Longstaffe, University of Guelph / School of Environmental Sciences

One of the benefits of teaching at a small university is the opportunity to work closely with undergraduate students on scientific research projects. In such scenarios, students are able to develop, execute, and present research projects, often of their own design, which helps prepare them for careers within the sciences. With various time commitments outside of research, however, challenges arise with undergraduate researchers, particularly in terms of completing research projects that produce publishable results. While such learning experiences are invaluable to students, success of tenure-track faculty advisors mentoring these students depends on publication of scientific literature. As such, finding a balance between independent, innovative student research and foolproof experimentation guaranteed to lead to publication can be difficult for early career faculty. Given the campfire nature of this session on Chemistry Education, the goal of this presentation will be to share stories of negative or confounding results from student led research in order to spark discussion of how to make the best of such scenarios. Should these situations be avoided until reaching tenure? Are negative results publishable, and if so, will they be valued as highly as more significant findings? Does mentorship of undergraduate research count as scholarly activity in one’s chosen field of study? These questions, and more, need to be discussed in a wider context.

626 How do we increase interest/ reduce apprehension about chemistry for students in environmental and agricultural sciences?

J. Longstaffe, University of Guelph / School of Environmental Sciences

Chemistry has a central role in nearly all aspects of environmental and agricultural sciences, including soil health, water quality, food security, and toxicology. Despite this importance, students in these disciplines often enter their upper year courses with either minimal preparation in chemistry or a significant degree of apprehension for any topic that may seem chemistry related. This impairs the ability of instructors to present more advanced and in-depth topics related to environmental chemistry, soil chemistry, and environmental toxicology. This talk will discuss ideas that the Ontario Agricultural College at the University of Guelph is exploring to improve the presentation of chemistry to environmental and agricultural science students with an effort to increase student engagement in this important subject area.

Emerging Environmental Contaminants: Human Exposure and Associated Risks - Part 1

627 Silicone pet tags associate tris(1,3-dichloro-2-isopropyl) phosphate exposures with feline hyperthyroidism

C. Poutasse, Oregon State University / Environmental and Molecular Toxicology; J. Herbstman, Columbia University / Public Health; M.E. Peterson, Animal Endocrine Clinic; J. Gordon, Oregon State University / Carlson College of Veterinary Medicine; P.H. Soboroff, New York Cat Hospital; D. Holmes, D. Gonzalez, Columbia University / Public Health; L. Tidwell, K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology

Feline hyperthyroidism is the most commonly diagnosed endocrine-related disease among geriatric housecats and is histologically identical to human toxic nodular goiter, but the causes remain unknown. Exposure to endocrine-disrupting compounds with thyroid targets, such as household flame retardants (FRs) may contribute to the disease development. Silicone passive sampling devices, or pet tags, quantitatively assessed the bioavailable fraction of FRs for 78 cats (age 7 y) in New York and Oregon using gas chromatography mass spectrometry. Pet tags were analyzed for 36 polybrominated diphenyl ethers (PBDEs), six organophosphate esters (OPEs), and two alternative brominated flame retardants (BFRs). In non-hyperthyroid cats, serum free thyroxine (fT4), total T4 (TT4), total triiodothyronine, and thyroid-stimulating hormone concentrations were compared with FR concentrations. Tris(1,3-dichloro-2-isopropyl) phosphate (TDCIPP) concentrations were higher in hyperthyroid than non-hyperthyroid pet tags (adjusted odds ratio, p< 0.07, Mantel-Cox, p< 0.02). Higher TDCIPP concentrations were associated with air freshener use (p< 0.01), residences built since 2005 (p< 0.002), and cats preferring to spend time on upholstered furniture (p< 0.05). Higher TDCIPP concentrations were associated with higher TT4 and T4 concentrations (p< 0.05). This study provides proof-of-concept data for the use of silicone pet tags with companion animals, which can act as sentinels for human FR exposure. This study further indicates that bioavailable TDCIPP exposures are associated with feline hyperthyroidism.

628 Using silicone rubber brooches and wristbands for measuring exposure of Canadian e-waste workers to flame retardants

L.V. Nguyen, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; S. Gravel, F. Labreche, Institut de Recherche Robert-Sauvé en Santé et en Sécurité du Travail; B. Bakhvii, M. Verner, University of Montreal; J. Zayed, Institut de Recherche Robert-Sauvé en Santé et en Sécurité du Travail; L. Juntunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; F.H. Arrandale, Cancer Care Ontario & University of Toronto / Occupational Cancer Research Center; M.L. Diamond, University of Toronto / Department of Earth Sciences

The mass of e-waste produced globally is growing dramatically. Flame retardants (FRs) are added to electronic and electrical equipment in order to meet flammability standards but may pose a health concern for workers in recycling facilities. Passive samplers made from silicone rubber are one option to measure workers’ exposure to flame retardants in air and dust but have previously been used to measure personal FR exposure over a week or more (Hammel et al., 2016; Okeme et al., 2018). Here we report the use of silicone brooches and wristbands for measuring FR exposure of e-waste workers over shorter deployment times. Sampling was conducted at three e-waste facilities in Quebec, Canada, during Summer 2017. E-waste workers (n=37) wore pre-cleaned silicone brooches and wristbands while working (range 6-10 hours). Samples were extracted and analysed for 42 flame retardants, including novel brominated flame retardants (NBFRs), polybrominated diphenyl ethers (PBDEs) and organophosphorus esters (OPEs), using gas chromatography mass spectrometry (GC-MS). Concentrations below the limit of detection (LOD) were substituted with LOD/√2. Fifteen PBDEs and 11 NBFRs had detection frequencies of more than 70% in both brooches and wristbands. The median amount (in ng) of \( \sum_{29} \) PBDEs and NBFRs found on wristbands were twice as high as on brooches. The profile of FRs collected from brooches and wristbands were similar. BDE-209 accounted for ~96% of PBDEs and NBFRs collected by both sampling media. Concentrations of BDE-209 in brooches, expressed as equivalent air concentrations, was 770 ng/m³, followed by decabromodiphenylethane (DBDPE) with a median value of 22 ng/m³. The median level of BDE-209 in wristbands (1,280 ng day⁻¹ sample⁻¹) was one to three orders of magnitudes higher than in silicone wristbands worn by Bangladeshi e-waste workers (156 ng day⁻¹ sample⁻¹) (Yang et al., in prep) and US students and office workers (45 ng day⁻¹ sample⁻¹) (Romanak et al., 2019). In conclusion, e-waste workers in this study had elevated exposures to flame retardants, often exceeding levels observed in some informal recycling facilities. Silicone brooches and wristbands deployed for a full workday on workers in e-waste recycling facilities accumulated sufficient mass of flame retardants to allow approximation of equivalent air concentrations.
629 Are Organophosphate Esters in House Dust a Risk Factor for Childhood Asthma?

S. Bernstein, University of Toronto; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; G. Navaranjan, University of Toronto; M.L. Diamond, University of Toronto / Department of Earth Sciences; P. Subbarao, University of Toronto and Sickkids Hospital; S.A. Harris, Cancer Care Ontario & University of Toronto / Population Health and Prevention & Occupational Cancer Research Centre & Dalla Lana School of Public Health; J. Scott, University of Toronto; T. Takaro, Faculty of Health Sciences, Simon Fraser Univ.; M. Azad, A. Becker, University of Manitoba; R. Dai, Hospital for Sick Children; D. Lefebvre, McMaster University; P. Mandhane, Univ AB; T. Moraes, University of Toronto and Hospital for Sick Children; S. Turvey, University of British Columbia; M. Sears, McMaster University; J. Brook, University of Toronto

Organophosphate esters (OPEs) are widely used in household products and building materials as flame retardants and plasticizers and are released into the indoor environment. Human exposure to OPEs is ubiquitous, and children are particularly vulnerable to exposure from indoor sources due to their frequent hand-to-mouth contact and proximity to floor dust. The Canadian Healthy Infant Longitudinal Development (CHILD) Cohort Study is a population-based birth cohort designed to examine the origins of asthma and allergy. We present results of OPEs in dust collected from a subset of CHILD homes, when infants were 3-4 months old, to assess the association between OPE exposures and development of childhood asthma. Pregnant mothers were enrolled in CHILD between 2008-2012 from 4 cities and 1 rural area in Canada. Dust samples were collected by trained research assistants from the floor of the most used living area and combined floor and bed in the child’s sleeping area. Dust samples for a subset of these subjects (n=100), included in an ongoing case-cohort study within CHILD, were analyzed for 33 OPEs using 25mg of a homogenized subsample combined from both rooms. Results from the subset show high levels of OPEs in all samples relative to those reported in the literature. The sum-OPEs range from 1-10 mg/g dust. TBOEP was generally the highest, followed by TPhP and TDGCPP. Constituents of Firemaster 550(C) (i.e. iso-propylated TPhP) and Firemaster 600(C) (tert-butyalted TPhP) were also found, but in lower concentrations. The Mann-Whitney U-test was used to identify median OPE concentrations in dust from homes of children diagnosed with asthma at 5 years to non-asthmatics. Results from this pilot analysis showed higher levels of several isopropylated TPhP compounds among children with asthma compared to those without. We will present data for a larger subset of the study subjects to confirm and strengthen our preliminary results.

630 Legacy and emerging compounds in nail salons: exposure of nail salon workers to phthalates, di(2-ethylhexyl) terephthalate and organophosphate esters

J. Craig, D.M. Ceballos, V. Fruh, Z. Petropoulos, Boston University School of Public Health / Department of Environmental Health; J.M. Allen, Formation Environmental, LLC / Department of Environmental Health; H.M. Stapleton, Duke University / Nicholas School of the Environment; S. Hammel, Duke University / Nicholas School of Environment; R. Gray, Boston University School of Public Health / Department of Environmental Health; T.F. Webster, Boston University / Dept Environmental Health

Nail salons, one of the fastest growing industries in the USA, represent a potentially important source of exposure of workers and customers to volatile and semi-volatile organic compounds as well as an emission source to the environment. Women make up 97% of nail salon employees, many of whom are of reproductive age. Little is known about exposure to volatile and semi-volatile organic compounds in nail salons since the replacement of some phthalates in nail polish began. We therefore assessed exposure to phthalates as well as phthalate alternatives such as di(2-ethylhexyl) terephthalate (DEHTP) and organophosphate esters in 10 nail salon workers in the Boston, MA (USA) area during one work day. We collected urine samples pre- and post-shift; workers also wore silicone wrist bands on their wrists and pinned to their lapsels. Silicone wrist bands were analyzed for parent compounds and urine samples for metabolites. Concentrations of analytes generally increased in urine samples from pre- to post-shift, but the largest increase was for a DEHTP metabolite, mono(2-ethyl-5-carboxypentyl) terephthalate (MECPTP), that more than tripled from 11.7 to 36.6 µg/g creatinine (p<0.05). DEHTP biomarkers were higher in post-shift urine samples than NHANES females 2015-2016. MECPTP and another DEHTP metabolite were significantly correlated (r=0.72-0.73, p<0.05) with DEHTP on the silicone wrist bands, indicating exposure while at work rather than diet or other sources. Nail technicians are exposed to a number of phthalates, phthalate alternatives and organophosphate esters. Silicone wrist bands were effective as a measure of external exposure during a one day shift.

631 Per- and Polyfluoroalkyl Substances (PFAs) in Children’s Car Seats, and in Carpets and Indoor Dust from Childcare Centers

Y. Wu, Indiana University, Bloomington / O’Neill School of Public and Environmental Affairs; K. Romanak, Indiana University - Bloomington / SPEA; T. Bruton, A. Blum, Green Science Policy Institute; G. Miller, J. Gearhart, Ecology Center; M. Venier, Indiana University / SPEA

Per- and polyfluoroalkyl substances (PFASs) have resulted in their ubiquitous presence in the environment globally. Public concern over the potential health risk posed by PFASs has triggered increasing number of studies conducted to address their environmental occurrence and associated toxic effects. However, knowledge remains limited in children exposure to PFASs, particularly the emerging analogues synthesized to substitute legacy PFASs. In this study, we examined seven PFAS classes, i.e., perfluoroalkyl carboxylic acids (PFCAs), perfluoroalkyl sulfonic acids (PFSAs), fluoroalkyl sulfonamides, fluoroalkyl sulfonamideethanols, telomer carboxylic acids, telomer alcohols, and telomer sulfonic acids, in 36 children's car seats (sold in 2018), as well as in paired carpets and indoor dust collected from 32 California childcare centers in 2018 as well. PFASs were detected in 97% of the car seat samples and in all the childcare carpets and dust. Median ∑PFASs (total PFAS concentrations) in the car seats was 16.3 ng/g, significantly lower than those observed in the carpets and in the dust samples. While the legacy PFAS compounds (e.g. C₆₋₁₀ PFASs) were still frequently detected, some of their replacements, like short-chain perfluoroalkyl acids (C₄₋₅ PFCAs and PFSAs) and telomer acids, also substantially contributed to the PFAS burdens in our samples. Young children likely spend a significant amount of time strapped in car seats, especially in big cities where commute is long, and in daycares, which result in significant exposures in a critical time of development.

632 Per- and polyfluoroalkyl substances (PFAs) in breast milk from the United States

G. Zheng, Indiana University; E. Schreder, J. Dempsey, N. Udin, C. Wells, Toxic-free Future; A. Salamova, Indiana University / SPEA

Breastfeeding is an important exposure pathway to many persistent organic pollutants in infants, including PFAS. Although occurrence of PFAS in breast milk has been documented in several studies around the world, there is only study on PFAS in breast milk from U.S. mothers. In this study, we collected breast milk samples from the first-time mothers residing in the greater Seattle area (n=50) and analyzed them for twenty-seven PFAS. Seventeen PFAS were detected in the samples. Thirteen different PFAS were identified in breast milk with detection frequencies over 70%. Mean concentrations of PFOA and PFOS in were 10.0 and 20.6 pg/mL, respectively, which were lower than those reported in Massachusetts in 2004 (PFOA: 43.8 pg/mL; PFOS: 131 pg/mL). PFAS with 10 to 14 fluorinated carbons, including PFDA, PFDoA, PFtDA and PFtDeA, were found at high detection frequencies for the first time. The results reported here suggest early-life exposure to PFAS through breastfeeding is important to consider in the broader context of PFAS exposure.
633 Synthetic Phenolic Antioxidants: Environmental Occurrence, Human Exposure, and Excretion
R. Liu, University of Toronto / Department of Chemistry; S. Mabury, University of Toronto / Chemistry

Synthetic phenolic antioxidants (SPAs) are a group of widely used anthropogenic antioxidants, whose potential for human exposure and toxicity has recently received increased interest. In this investigation, SPAs were analyzed in indoor dust and personal care products (PCPs) collected in Toronto to investigate their occurrence and human exposure in North America. Eight SPAs were detected in indoor dust with a geometric mean (GM) concentration of 1489 ng/g, among which 2,6-di-tert-butyl-4-methylphenol (BHT) was the primary congener and had a GM concentration of 642 ng/g. Nine SPAs were detected in the PCPs, of which only BHT (mean: 35,602 ng/g) was observed with a detection frequency of >50%. Preliminary calculations suggest dermal sorption via PCP use may be an important exposure pathway for BHT (mean: 565,879 ng/day), although this is a negligible exposure pathway for other SPAs. Five SPAs were quantified in human sera samples collected from donors in the United States. The measured total SPA concentrations (GM: 7.77 ng/mL) were dominated by BHT and 2,4-di-tert-butylphenol (DBP), which contributed 42% and 57% on average to the total concentrations, respectively. Four BHT metabolites were also detected in human serum (GM: 0.77 ng/mL), with concentrations lower than those of BHT (GM: 2.66 ng/mL). Interestingly, despite BHT being detected at low concentrations (GM: 0.85 ng/mL) in human urine, five of its metabolites were detected at relatively high concentrations (GM: 12.1 ng/mL), suggesting BHT in humans is excreted via urine following transformation to metabolites. DBP was unexpectedly detected at extremely high concentrations in human urine (GM: 25.8 ng/mL), although its major human exposure pathways remain unclear. This comprehensive study advances our understanding of the occurrence, human exposure, and excretion of SPAs in North America.

634 Make-up your mind: Prioritising Endocrine Disruptors in Personal Care Products
K. Kademoglou, A. Miralles-Marco, L. Melymuk, K. Hilsherova, J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment

Personal Care Products (PCPs) are often used in daily rituals of personal hygiene, toiletry and aesthetic interventions (e.g. soaps, body lotions, hair products, make-up, toothpastes, perfumes etc.), and in various stages of our lifetime. Concerns have been raised regarding consumer safety and potential adverse health effects of PCPs ingredients on humans, as a result of potential chronic human exposure from an early age through the adult life. Hence, human exposure to PCP ingredients such as antimicrobial agents, preservatives, fragrances, surfactants and formulation stabilisers can be characterised as chronic. The lack of prompt and rigorous screening of PCPs can lead to harmful and restricted chemicals re-entering the market, often exceeding the established tolerable safety doses. Our present study proposes: a) risk-based prioritisation criteria for PCP ingredients and container impurities on an evidence-based manner with a leap towards future human biomonitoring studies on chemicals of emerging concern and b) the development and optimisation of a multi-residue analytical method for the assessment of potential endocrine-disrupting ingredients present in rinse-off and leave-on PCPs with diverse and complex fatty matrices, e.g. shampoos, hair conditioners or sunscreens available in the Czech Republic, followed by dispersive SPE (dSPE) clean up and high-resolution MS/MS (Orbitrap Fusion(TM)) instrumental analysis. In the present study, we have identified and categorised PCPs and their ingredients based on: a) end consumer use (i.e. rinse-off, leave-on) and b) chemical category, respectively. Our preliminary results showed that currently restricted PCP ingredients such as low molecular weight parabens and preservatives, were found below the established safety limits, whereas, emerging PCP ingredients (e.g. bisphenols, UV filters) lacking comprehensive legislative safety thresholds could be present in the PCP matrix as compound-container impurities or oxidation by-products. The ambiguous disparities in addition to the regulatory complexity governing each PCP category (e.g. food supplements, biocides, medicines) worldwide, may result into different levels of product safety provided to the consumers (e.g. borderline products, imports of over-preserved cosmetics).

Alternatives Assessment and Informed Substitution: The Transition to Safer Chemicals, Materials, Processes and Products

635 The Nexus between Alternatives Assessment and Green Chemistry
R. Simon, University of Massachusetts, Lowell / Public Health; J.A. Tickner, University of Massachusetts, Lowell / Community Health and Sustainability; S. VanBergen, Washington State Department of Ecology

Increasing regulatory and market pressures for companies to eliminate chemicals of concern from the products they source and create may force manufacturers and retailers to respond quickly, focusing only on the removal of such chemicals without understanding their replacements. This approach can lead to the adoption of regrettable substitutes, where replacements for a chemical of concern have similar or greater health or environmental impacts or lower performance. This issue has propelled the growth of a new science-policy approach, alternatives assessment, to guide the evaluation and inform substitutions of chemicals of concern. Similar to alternatives assessment, green chemistry shares the objective of addressing the health and environmental impacts of chemicals but focuses on the design of new chemistries and chemical products that reduce or eliminate the use or generation of hazardous substances to achieve that goal. The foundations for both techniques center around the chemical function and a goal of understanding the options to achieve that function in a more sustainable manner. Both approaches also require attention to chemical toxicity, cost, and performance. Finally, both suffer from the challenge of defining the meaning of “safer” and “more sustainable.” Despite the clear connections between alternatives assessment and green chemistry, the two fields—and their respective scientific communities—have not been highly integrated. Yet, the scientific disciplines involved in sustainable chemical design (i.e., chemical engineering and chemistry) and the hazard assessment component of an alternatives assessment (i.e. toxicology and environmental health sciences) ultimately provide complementary and overlapping skills and tools to drive the transition to safer, more sustainable chemistries. To better understand the nexus between alternatives assessment and green chemistry in driving safer chemistry, as well as gaps and needs for each, this presentation provides a foundational evaluation of the two concepts and analyzes case examples where companies have utilized the tools and approaches of both disciplines in developing safer chemical solutions. The case examples and analysis illustrate how the approaches and underlying skillsets of alternatives assessment and green chemistry can be complementary in supporting the design, evaluation, application and scale of safer, more sustainable chemicals.

636 Safer alternatives by functional use: Improved informed decision-making in consumer products via Quantitative Chemical Hazard Assessment
J.P. Rinkevich, C. McLoughlin, P. Beattie, SciVera, LLC

Leading consumer products brands are driving the requirement for deeper understanding of industrial chemicals used in products and upstream manufacturing processes. Where Safety Data Sheet (SDS) disclosure, Authoritative List Checking (ALC), and chemical testing once were sufficient, these methods do not enable informed decision-making to avoid regrettable substitutions to meet brand (and market) requirements. A variety of approaches and certifications exist to support efforts to identify safer chemicals toward specific goals of regulatory compliance, industry governance initiatives, product safety, product stewardship, and corporate sustainability goals. Many methods and certification programs still
637 Facilitating Hazard Evaluation in Alternatives Assessment via an Uncertainty Scoring System that Integrates Mixed Toxicity Data Streams

J. Kostal, The George Washington University / Chemistry; H. Plugge, Verisk 3E / Safer Chemical Analytics

To systematically evaluate and identify safer alternatives to existing chemicals of concern on the market, one must reliably assess chemical hazard, considering all available measured as well as predicted data. For such a decision-making process, which necessitates combining multiple pieces of evidence from several sources, it is important to articulate the concept of uncertainty. Uncertainty invariably accompanies every qualitative or quantitative metric, whether measured, calculated or derived from an expert judgment. However, in current hazard assessment practices, controversies and uncertainties are typically assumed to be absent; they lack methodological transparency; or they poorly integrate qualitative and quantitative sources of information. To this end, the Kostal group at GWU has developed a novel Uncertainty Scoring System (USS), which allows the non-expert user to quantify uncertainty for all data under consideration in order to make the best-possible decision. The system can incorporate user’s expert judgement; furthermore, it can be trained and parametrized to reproduce a specific decision-making paradigm, so as to capture individual preferences and to ensure consistency in complex decision analyses. USS is a robust mathematical model that has been internally tested and validated on toxicological data. While designed to aid with hazard and alternatives assessments in toxicology, the system’s applicability extends to any decision-making process that calls for synthesis of incongruent data streams into a single outcome. Herein, we demonstrate the utility of our system on a dataset of approximately 70,000 acute fish assays carried out for over 7,400 chemicals. For chemicals with frequently repeated assays and those of approximately 70,000 acute fish assays carried out for over 7,400 outcome. Herein, we demonstrate the utility of our system on a dataset.

639 Bridging Life Cycle and Exposure Ontologies to Enable Integration of Data Streams for Risk-Based Alternatives Assessment

E. Hubal, US Environmental Protection Agency / Computational Exposure Division; S. Bailin, Knowledge Evolution, Inc.; P. Egeghy, USEPA / National Exposure Research Laboratory; D. E. Meyer, USEPA / National Research Management Laboratory; D. Vallerio, USEPA / National Exposure Research Laboratory

In recent years, several US States have passed laws requiring manufacturers to evaluate the use of chemicals in consumer products. Some legislation requires manufacturers to perform an alternatives analysis to identify chemical alternatives that reduce impacts to human health and the environment. The USEPA asked the NRC to recommend a framework for evaluating human health and ecological risks associated with new chemical substitutes that would foster an analytical approach for evaluating chemicals by integrating multiple and diverse data streams for a more holistic consideration of potential chemical impacts. The resulting 2014 NAS report, A Framework Guide for the Selection of Chemical Alternatives, includes an increased emphasis on comparative exposure assessment, integration of information across disciplines, and life cycle thinking. To realize the NRC vision and support emerging requirements for alternative assessments, tools are needed to access and exploit the limited available data on chemical manufacture, use, and occurrence for important chemical exposure scenarios and pathways across the product life cycle. Tools for more efficient exposure estimation have advanced, and accessible exposure information has grown significantly in recent years. Data that have been developed and curated for exposure forecasting and for life cycle assessments (LCA) provide a rich source of information to support informed substitution. The goal of this research is to extend and bridge the core ontologies in exposure science and LCA and thereby enable the use of these data to streamline and improve evaluation of safer alternatives. Application of this new ontology bridge to support life cycle human exposure calculations will be demonstrated using the case study of p-dichlorobenzene in air freshener. Integrating information from these separate knowledge domains, and more generally facilitating access to linked open data, will greatly enhance the efficiency of comparative exposure assessment and risk-based alternatives assessment for chemicals in consumer products. In particular, bridging ontologies will allow implementation of workflows tailored to specific alternatives assessment requirements.
640 High Throughput Exposure and Risks for Alternatives Assessment of Chemicals in Toys and Building Products

P. Fantke, N. Aurisano, Technical University of Denmark / Quantitative Sustainability Assessment Division; L. Huang, University of Michigan / School of Public Health; O. Jollivet, University of Michigan

Introduction: Evaluating exposure is an important component to identify viable alternatives to harmful chemicals in products. Yet, Alternatives Assessment (AA) methods lack efficient and flexible approaches to quantify exposure for the many thousand product-chemical combinations. To address this gap, we a) develop an operational matrix-based high-throughput framework efficiently coupling multi-pathway near-field (worker and consumer) with far-field (general population) exposures for use in AA, and b) apply it to case studies of chemicals in toys and in building materials. Method: We first determine the chemical mass in a product and calculated fractions transferred from toys or building product interior to other compartments and humans in a matrix. Inverting this matrix yields cumulative environmental transfer fractions and Product Intake Fractions (PiF) linking chemical mass taken in by humans to a unit mass of chemical in the product. We finally determine exposure doses expressed in mg/kgBWd or on a product function basis. Our framework was applied to generate high-throughput exposure results for commonly used chemicals in toys and in building products. Results: For chemicals in toys, exposure is restricted for pathways such as dermal contact or dust that are associated with the use of a single toy of e.g. 0.4kg, but becomes substantial when considering a total mass of 18.3 kg, toys purchased per child and per year in developing countries and the related releases to indoor air. The PiF widely ranges from a median of 0.002 to a max of 0.04 (or 4%). Resulting exposure doses for product users can vary from a median of 4E-6 to 4.9 mg/kgBWd, dominated by inhalation and dermal gaseous uptake. For each product application, we are able to determine the chemical-specific contributions of pathways and population groups to overall exposure and compare the relative exposure magnitude for all chemicals in a given product. Combining these exposures with toxicity data, we are able to calculate Hazard Quotients from a median of 4E-4 to 299, identifying main chemicals of concern and ranking alternatives. For building products, resulting exposure doses for product users range from a median of 1.3E-2 to 3.7 mg/kgBWd, and Hazard Quotients from a median of 0.7 to 222. Systematic sensitivity studies enable us to identify the most important product and chemical attributes affecting the Product Intake Fraction and produce heat maps to easily determine exposure, for use in the screening AA, as will be illustrated for chemical alternatives in several product types. The more detailed mass-balanced-based framework is readily available for use by AA practitioners to screen a wide range of product-chemical combinations.

H. He, University of California, Irvine / Materials Science and Engineering; S. Tian, University of California, Irvine / Advanced Power and Energy Program; C. Glaubensklee, University of California, Irvine / Biomedical Engineering; B. Tarroja, S. Samuelsen, University of California, Irvine / Advanced Power and Energy Program; G. Movie, School of Public Health; J. Schoenung, University of California, Irvine / School of Management; T. Ogunseitan, University of California, Irvine / School of Medicine; M.-derived Chemical Assessment Framework, has been applied to investigate the disability-adjusted life years caused by human health effects and various environmental impact categories. In this study, not only the primary materials used to manufacture the battery components are considered, the associated processing materials are also assessed. The results indicate that the some of the primary materials used in the electrolyte and cell stacks are chemicals of concern. When expanded to processing materials, many of the components currently use additional chemicals of concern in the production chain. With the combined use of the chemical hazard assessment and life cycle impact assessment, the inherent hazard potential of the chemicals as well as their relative emissions and exposures are addressed and compared in highlighting the health impacts associated with different life cycle stages. The results provide insight into the effects of material selection choices on the potential health effects of these new energy storage devices and can be applied to compare and prioritize materials and process alternatives for a safer battery system with reduced potential human health impact.

642 Exploring the Role of Decision Analysis in Chemical Alternatives Assessment

C.E. Beaudrie, Compass Resource Management, Ltd; C. Corbett, University of California, Los Angeles (UCLA) / School of Management; J. Laveland, University of California, Los Angeles / School of Law; X. Zhou, California Environmental Protection Agency / Department of Toxic Substances Control

Alternatives assessment (AA) involves the identification, assessment, and comparative evaluation of alternatives to hazardous chemicals with an aim to remove hazardous materials from consumer products. Completing an AA often requires trade-offs and value-based choices in terms of prioritizing one type of concern over another (e.g., reducing ecological impacts versus maintaining technical performance). Guidance for conducting alternatives assessment typically focuses on the data gathering and scoring of alternatives but provides less direction concerning the use of specific tools to facilitate decision making. We report on a workshop in which a group of practitioners from US corporations, government agencies, NGOs, and consulting organizations were confronted with three AA case studies. Participants were asked to select a preferred alternative in each case using a different decision analysis method: their own current default decision-making method, an individual or group multi-criteria decision analysis (MCDA) method, and a facilitated group structured decision-making (SDM) method. For the latter two methods, participants were given a brief tutorial on the underlying decision theory as well as training on the use of specific software tools. As concerns the participants’ current default decision making method, despite employing a range of approaches, we observed that a large majority of participants selected the same alternative. After instruction in MCDA and SDM, participants reported these tools substantially increased their understanding of the trade-offs between alternatives relative to their current default decision approach. Participants were personally quite positive about using more structured decision-making methods to the context of AA but were less confident their organizations would adopt such tools. It also was clear that an appropriate facilitation approach and managing group dynamics were important factors in whether MCDA and SDM are used successfully.

Overall, we find that structured decision-making methods have promise in the context of AA, but that practitioners will need more guidance to use such tools successfully. The presentation will conclude with suggestions for enhancing familiarity and understanding of decision making tools in the expanding alternatives analysis community.
**Fate and Effects of Metals: Biogeochemical Perspective**

643 The ever changing nature of DOC - possible implications for metal research

A. Holland, La Trobe University / Ecology, Environment and Evolution; J. Stauber, CSIRO / CSIRO Land and Water; D.F. Jolley, University of Technology Sydney / School of Chemistry

Dissolved organic carbon (DOC) plays an important role in the bioavailability and toxicity of metals within freshwater systems. This is highlighted by the inclusion of DOC concentration within methods such as multiple linear regressions and the biotic ligand model (BLM) to derive site specific guidelines for metals in some countries. The type and characteristics of DOC has also been shown to be important factors when considering toxicity and bioavailability of metals to aquatic organisms. However, DOC is heterogenous in nature with the concentration, type and key characteristics (aromaticity, molecular weight and abundance fulvic, humic and protein-like components) of DOC intrinsically linked to various allochthonous and autochthonous processes which differ considerably spatially and temporally within and between freshwater systems. Thus, DOC is ever changing in its concentration and characteristics and this poses a potential risk when trying to determine the bioavailability and toxicity of contaminants such as metals within these systems. This presentation will bring together data from Australia and across the globe to look at how DOC varies within and between freshwaters both temporally and spatially in regards to concentration and characteristics. It will also use case studies to highlight possible effects of these changes on toxicity of metals such as copper and nickel and the importance of considering DOC dynamics.

644 The effect of particle size on oral bioavailability/bioaccessibility of Ni from different sources

L. Vasiluk, University of Guelph / School of Environmental Sciences; N. Dai, Intertek / Food and Healthcare; J. Sowa, MTE Consultants Inc / Environmental Science; P. Sanborn, University of Northern British Columbia / Ecosystem Science and Management Program; M.D. Dutton, bpa, Ltd.; M. Bellantino-Perco, Vale Canada, Ltd.; B.A. Hale, University of Guelph / SES

Particle size can be an important source of variation in metal concentration and speciation in soils and dusts. Samples not sorted by particle size (“bulk”) may yield different metal concentrations than some or all the constituent size fractions. The objective of the present study was to correlate in vivo bioavailability with ex vivo bioaccessibility for elevated Ni in soils/dusts of different origin and explore attribution of any variation in this correlation to source’s particle size. We tested three Ni-elevated soils/dusts of different origin and explored attribution of any variation in this correlation to source’s particle size. There are additional factors that may convolute this relationship, such as Ni concentration within methods such as multiple linear regressions and the biotic ligand model (BLM) to derive site specific guidelines for metals in some countries. The type and characteristics of DOC has also been shown to be important factors when considering toxicity and bioavailability of metals to aquatic organisms. However, DOC is heterogenous in nature with the concentration, type and key characteristics (aromaticity, molecular weight and abundance fulvic, humic and protein-like components) of DOC intrinsically linked to various allochthonous and autochthonous processes which differ considerably spatially and temporally within and between freshwater systems. Thus, DOC is ever changing in its concentration and characteristics and this poses a potential risk when trying to determine the bioavailability and toxicity of contaminants such as metals within these systems. This presentation will bring together data from Australia and across the globe to look at how DOC varies within and between freshwaters both temporally and spatially in regards to concentration and characteristics. It will also use case studies to highlight possible effects of these changes on toxicity of metals such as copper and nickel and the importance of considering DOC dynamics.

645 Development of a Marine Ni BLM. Part I: Speciation, Bioaccumulation and Effects Data

S.D. Smith, W. Chen, Wilfrid Laurier University / Department of Chemistry and Biochemistry; S. Sherman, Wilfrid Laurier University / Biology; T. Blewett, University of Alberta / Biological Sciences; C. Cooper, International Zinc Association / Department of Marine Sciences; E.M. Leonard, McMaster University; J. McGeer, Wilfrid Laurier University / Biology; C.M. Wood, University of British Columbia / Zoology; R.C. Santore, Windward Environmental LLC

The Biotic Ligand Model (BLM) is a computational tool used in a range of risk-based regulatory approaches for metals, including the establishment of bioavailability-based environmental quality guidelines and chemical safety certifications. In freshwater (FW) environments the BLM approach has been successfully applied as a cost-effective means of meeting site-specific environmental protection goals for the metals industries and regulatory bodies. However, it is estimated that 70% of the world’s population live in coastal environments and metal impacts in saltwater (SW) environments are potentially significant, with sources from municipal/industrial effluent, building material runoff, plumbing, anti-fouling paints and sometimes directly from mines and auxiliary facilities operating in coastal areas. To date, metal bioavailability in SW environments has not received as much research attention as in FW environments. The chemistry and biology of both metals and organisms change as salinity increases. Previous research on Cu demonstrated that BLM approaches are valid in SW and this current project focuses on the development of a working BLM for nickel in SW. This research is presented in two parts. The first presentation focuses on the primary ecotoxicity and geochemistry data, and the second presentation applies these data to develop a computational BLM for Ni in SW. Effect concentrations were determined using urchin and mussel embryo tests, as well as a seven day mysid test, in samples ranging from laboratory solutions with model ligands to coastal samples from the Canadian Arctic to Southern Florida in the United States, with the bulk of samples obtained from Gaspe in Quebec as well as Connecticut and Rhode Island. Direct bioaccumulation of Ni on urchin embryos was determined using radiolabelled Ni and chemical speciation of Ni was determined using the Ion Exchange Technique (IET), specifically developed for application in SW. Much of the work focused on relationships between Ni toxicity and DOC quantity/quality. For bioavailability-based decision making, a tool is required to take speciation into account for Ni risk assessment in SW. Bioavailability tools that have a mechanistic basis, and account for speciation, have the most promise in terms of being accepted for making regulatory decisions. Funding provided by NSERC and NiPERA.

646 Development of a Marine Ni BLM. Part II: Model development, calibration, and application

R.C. Santore, K.E. Croteau, Windward Environmental, LLC.; S.D. Smith, W. Chen, Wilfrid Laurier University / Department of Chemistry and Biochemistry; S. Sherman, Wilfrid Laurier University / Biology; T. Blewett, University of Alberta / Biological Sciences; C.A. Cooper, Wilfrid Laurier University / Chemistry; E.M. Leonard, McMaster University; J. McGeer, Wilfrid Laurier University / Biology; C.M. Wood, University of British Columbia / Zoology

The Biotic Ligand Model (BLM) has been successfully used to explain and predict the effects that toxicity modifying factors have on the bioavailability and toxicity of a number of metals in freshwater environments. The development of a copper BLM in marine waters has demonstrated that the same conceptual model also works well for marine organisms. The marine model for copper has shown that natural organic...
matter (NOM) in marine systems is among the most important of the toxicity modifying factors to consider in saltwater environments, while salinity was of lesser importance but still could be significant factor in estuaries. The success of the marine copper model suggests that development of marine models for other metals would be feasible. However, there are far less marine speciation data available for other metals that can be used for model development and calibration. For this project, the marine copper BLM was used as a starting point for the development of a marine BLM for nickel. The marine copper model used copper titration data to determine binding strengths and binding-site concentrations for marine NOM interactions with copper. We used quantitative structure activity relationships (QSAR) to adjust the binding strengths of the copper speciation model as a preliminary estimate of the effects of marine NOM on nickel. This preliminary model was then refined using nickel speciation data from this project (described in Part I). An important difference in the marine models for copper and nickel is that application of the copper model to saltwater sites demonstrated that the quantity of NOM is more important than the quality of NOM (as defined by physicochemical and optical properties). For nickel, it appears that NOM quality has a much more significant influence on nickel speciation, bioavailability, and toxicity than it had for copper and should be considered in bioavailability modeling. After refining the Ni BLM with speciation data, the biotic ligand interactions were then calibrated to accumulation data on urchin embryos, and the resulting model was then used to predict nickel toxicity to urchins in a variety of marine water samples from Canada and the United States.

**647 Improving Life Cycle Inventory/Life Cycle Impact Assessment for Metal Mine Tailings**

The addition of human health and ecotoxicity metrics into Life Cycle Impact Assessment (LCIA) tools has increased the focus on trace amounts of metal impurities in metal mine tailings and their potential release to the environment. As a consequence, research has been undertaken to develop life cycle inventory (LCI) datasets for sulfidic metal disposal from metal ore beneficiation. The basis for these LCI datasets is an empirical model developed from a landfill leachate emission model. For this work, the tailings model was reviewed and some areas for potential improvement regarding its implementation in LCI/LCIA analyses were noted. Based on the review, it was clear that certain simplifications were made when adapting the landfill model to address tailings disposal facilities. These include continued use of first-order release kinetics and limited consideration of pH dynamics. In addition, the potential for metal attenuation through precipitation and sorption in the groundwater receiving tailings leachate is not considered in the tailings model nor in the consensus LCIA model. Finally, common tailings management practices (e.g., seepage barriers, water covers, etc.) are not considered in the tailings model. The following actions/recommendations address the above issues: (1) available geochemical models for tailings are being evaluated for use as a resource to validate/define the LCI tailings model formulation; (2) the short term and long term effect of applying the Best Available Techniques (BATs) for tailings management should be assessed and included in the model; and (3) attenuation of leachate metals in groundwater is expected but must be quantified and included in life cycle analysis. Experts in the field of mine tailings management and life cycle assessment should work collaboratively to improve the metal emission inventory estimates associated with mine tailings.

**648 Influence of Salinity on Copper-Ligand Formation Constants**

F.M. Barnawi, S.D. Smith, Wilfrid Laurier University / Department of Chemistry and Biochemistry

Natural Organic Matter (NOM) is known to reduce metal, such as copper, toxicity in aquatic environments. Copper is essential for organisms, but elevated concentrations of dissolved copper can potentially be toxic. The toxicity of copper is related to its bioavailability, which is influenced by toxicity modifying factors, such as NOM (quantified as Dissolved Organic Carbon (DOC) in mg C/L), alkalinity, pH and major cation and anion concentrations. The principles are the same for fresh and saltwater, but the influence of high salt concentrations, such as in estuaries, and associated activity corrections, can modify NOM complexation of metals (i.e., modify logK values). The magnitude of such corrections has not been systematically studied in the context of risk assessment tools such as the Biotic Ligand Model (BLM), and the mathematical tools currently used to correct logK values for salt effects have not been fully tested experimentally. The purpose of this study is to address these gaps by determining logK values across a range of salinities for copper association with salicylic acid as a proxy to NOM. This study used varying concentrations of salt, either as artificial seawater (10 to 100%) or simply as sodium sulfate (Na2 SO4). In these salt solutions, logK values for copper binding to salicylic acid were determined using fluorescence quenching titrations and nonlinear regression (the so-called Ryan-Weber method). Salicylic acid is a well-defined compound, so these logK values can be compared to certified values from the National Institute of Standards and Technology (NIST) measured at different ionic strengths. In addition, comparisons can be made to calculated logK values determined using the extended Debye-Huckel (DH) equation. These comparisons determine how well the experimental results match with both the NIST and theoretical values. Through this experimental and theoretical research, this study tries to explain the influence of ion activity on copper binding to NOM. These results will help with managing pollution in estuarine environments and will improve the chemical side of bioavailable metal models, such as the BLM.

**649 Comparison of the laboratory Toxicity Identification Evaluation (TIE) and the in situ Toxicity Diagnostic System (iTodS)**

The in situ Toxicity Diagnostic System (iTodS) is a biological, fractionation protocol that systematically identifies chemical classes of contaminants of concern frequently linked to adverse biological effects. The objective of this study was to improve the technology and evaluate its effectiveness in identifying toxicity compared to the USEPA’s laboratory TIE Phase 1 approach. The in situ test was in San Diego Harbor, California and the lab evaluation conducted concurrently in an adjacent Navy facility. Comparison studies consisted of a control holding unspiked sea water and one holding both seawater and a copper (Cu) band with an estimated leaching rate of 163 g cm² d⁻¹. Commercially available resins (3 -5 g) used in the deployment included Chelex, Oasis C18 SPE, and Oasis HLB as active resins, and glass wool as a control. The iTodS units were deployed in triplicate and pumped at 45 mL h⁻¹ for 24 h. Strongylocentrotus purpuratus, Mytilus galloprovincialis and Brachionus plicatilis were placed inside exposure chambers to assess the acute effects of water filtered through each resin. The TIE modified Phase 1 used a series of five-stage manipulations: baseline toxicity, 0.45 um filtration, aeration, metal sorption (EDTA), and organics sorption (C18 SPE). After each fractionation, organisms were assessed for acute effects. In situ results showed Chelex removed 93% of Cu, while HLB and C18 SPE removed only 6% and 16% of Cu, respectively. No rotifers were recovered from exposure chambers in Reference or Cu treatments. Urchin recovery was low in general, likely resulting from resin saturation and Cu.
breakthrough. Mussel larvae only survived in the Chelex treatment, showing Cu was the toxicant and adequately removed by the metal-specific resin. For the lab-based TIE, rotifers showed EDTA and C18 treatments reduced toxicity. Aeration and 0.45 um filtration slightly reduced toxicity. For the mussel embryo-larval development test, only the EDTA treatment had survival (97% normal development). Urchin embryo-larval development showed similar results with 88.5% normal development in the EDTA treatment. Through time, the iToDS has been more sensitive at detecting ambient toxicity than the traditional TIE and requires fewer resources. The current iToDS prototype 3 is robust, reliable, and easy to use in the field. Its applications to a wide range of contaminants of concern suggest it should become a standard diagnostic assessment technology at chemically contaminated sites.

650 Gravel Bed Reactors: Semi-Passive Water Treatment of Metals and Inorganics
S. Mancini, E. Cox, L. deVlaming, K.M. Bechard, Geosyntec Consultants, Inc.; R. James, Geosyntec Consultants, Inc. / Remediation; A. Przepiora, F. Risacher, Geosyntec Consultants, Inc.

Metal and inorganic impacts to groundwater and surface waters are a critical issue facing many industries across North America. A wide range of treatment solutions exist; however, the operational requirements of many industries make most conventional technologies expensive and difficult to comply with water quality discharge criteria. An in situ semi-passive water treatment technology called a Gravel Bed Reactor (GBR™) can provide an alternate option for treatment of a variety of water quality issues including acidity, metals and metalloids, inorganics, and organic chemicals. A GBR consists of an engineered bed of gravel/media through which water containing constituents of concern is passed and treated. For anaerobic biological treatment, required amendments such as electron donors and nutrients are added to the water at the inlet of the GBR to promote the growth and activity of natural microbes that are capable of reducing the inorganics, sequentially immobilizing the metals in the gravel bed. Denitrification is the microbially mediated mechanism by which nitrate concentrations in waste waters are reduced to nitrogen gas in GBR systems. Selenium can be removed from water by reducing the soluble forms of selenate (Se(VI)) or selenite (Se(IV)) to elemental selenium (Se(0)) which can then be sorbed onto solid phases, precipitated or incorporated into the biomass within the GBR. This presentation will present case studies and performance results from pilot and full-scale operations in which GBRs were implemented to successfully reduced concentration loading to surface water, and/or reduced the requirement for conventional treatment. The results of pilot testing and full-scale operations of GBRs indicate that this treatment system can provide several benefits in comparison to other anaerobic biological treatment approaches such as active water treatment facilities, packed bed bioreactors and fluidized bed reactors. Advantages include the use of less tankage and equipment and the ability to use waste rock from mining applications as bioreactor packing media. This facilitates the need for less infrastructure, easier installation of smaller systems in less accessible locations such as montane topography, and the potential to treat water at or near the source. This is specifically relevant to industrial and mining operations including Western Canada, where recent water quality focus has been on metals and inorganics such as selenium and nitrate.

Toronto Flood Protection and River Building Project - Part 1

651 Project Overview: Flood Protection Project Addressing Adaptability and Climate Resilience
K. Dion, Waterfront Toronto

Port Lands Flood Protection (PLFP) is a project led by Waterfront Toronto in partnership with Toronto and Region Conservation Authority (TRCA) and CreateTO, and with the support and involvement of PortsToronto. Funded by the City of Toronto, Province of Ontario and Government of Canada, this $1.25B project will protect approximately 250 hectares of urbanized land from flooding during a major storm (up to a Hurricane Hazel-sized event). This project will transform 30 hectares of industrial brownfields in the Port Lands into a naturalized, multi-outlet river valley system with associated channel spanning infrastructure. The result: unlocking the Port Lands for revitalization and facilitating billions of dollars in investment. Grass-roots visioning for this project was initiated as far back as 1989 with a large public meeting seeking to “Bring Back the Don.” From this initial meeting, years of study and consultation occurred, culminating in the undertaking of two large environmental assessments: Don Mouth Naturalization and Port Lands Flood Protection Project Environmental Assessment (DMNP EA); and the Lower Don Lands Transportation and Servicing Master Plan Class EA. With approvals of these EAs in 2014-2015, Waterfront Toronto proceeded with a Due Diligence study that consolidated both EAs into a single project, the Port Lands Flood Protection and Enabling Infrastructure Project. This Due Diligence study explored in more detail, the challenges, opportunities, costs, risk and schedule of the works identified in the two EAs. PLFP provides an “address the water and contaminated soils hazard first” solution, from which informs all other planning in the area. It relies on innovation to build resiliency due to change (e.g. climate) into an area undergoing a rapid and extensive transformation. It explores how the project would be able to respond through active and passive adaptation, to events outside of the “norms” related to higher or lower flood levels and the influences on ecology, river operations and other infrastructure related concerns. This presentation will detail the processes of merging these two EAs into a single project and provide an overview of the key project sub-components, and outline some of the passive and active adaptive components of the design.

652 Vision: Sustainable placemaking
S. Baker, Waterfront Toronto

The Port Lands Flood Protection and Enabling Infrastructure (PLFP) Project is a $1.25B project led by Waterfront Toronto, the City of Toronto, Toronto and Region Conservation Authority (TRCA) and CreateTO, and with the support and involvement of PortsToronto, and funding from the three levels of government. In addition to providing flood protection to approximately 250ha of flood vulnerable lands, this project will transform ~30 hectares of industrial brownfields into a naturalized, multi-outlet river valley system with associated channel spanning infrastructure, while unlocking the area for revitalization and facilitate billions of dollars in investment. PLFP will improve quality of life, bring nature back to an underused industrial site and better protect our neighbourhoods from extreme weather conditions. A comprehensive vision for the renaturalization of the river has been developed, recreating a river which then acts as an organizing structure for a system of new parks and public open spaces that will become catalysts for a range of memorable activities and experiences. At the intersection of two major systems - urban waterfront and natural river corridor - the project focuses on flood control, naturalization, and placemaking to bring the Don Valley and the Toronto’s public realm together in a robust and meaningful way. A sustainable approach to design has also been woven throughout the approach to the enabling infrastructure planned for the site. With the reconstruction of three major roads, Cherry Street, Commissioner’s Street and the Don Roadway, a low impact development approach has been integrated into the design to manage stormwater and provide for passive irrigation of streetscaping. Additionally, innovation solutions have been proposed to knit both the roadway and the parks together, taking a systems-based approach to design. This presentation will highlight the major project elements related to sustainable placemaking that combine to make the Port Lands Flood Protection and Enabling Infrastructure Project one of the most significant changes to the Lake Ontario shoreline in decades, and one of largest infrastructure projects in Canada.

SETAC North America 40th Annual Meeting | 185
The Regulatory Flood for this area is from flows generated in the Don River, up to and beyond the Regulator Flood. The Regulatory Flood for this area is from flows generated in the Don Watershed under a storm with the intensity of Hurricane Hazel, which would produce a discharge of approximately 1,560 m³/sec, and would far exceed a storm with a return period of the 1:500 years. The preferred alternative arising from the Don Mouth Naturalization and Port Lands Flood Protection Project EA (DMNP EA), identified a new river mouth that directs flows through three functionally different outlet sectors: a modified Keating Channel; a new river valley that discharges into Polson Slip through a meandering and naturalized river channel system; and a new naturalized spillway that connects to Lake Ontario through the Ship Channel, and only becomes activated by stormflows from the Don River during events in excess of the 1:50 to 1:100 year storm. The project also involves creation of flood protection landforms, an in-channel sediment trap and landside management area, and bridge modifications among other improvements. Two dimensional hydraulic (2D) modelling is used for the design and verification of flood protection. The hydraulic model was developed at a high-resolution in order to test multiple river configurations, bridge crossings and other infrastructure features, and in-valley surface treatments to confirm that the requisite flood conveyance conditions are being established with the new river mouth throughout the project. The location of the PLFP site at the mouth of the Don River is historically where the sediment delivered from the watershed would deposit, creating a river delta and the Ashbridges Marsh. The continuous supply of sediment from the highly urbanized watershed will require active management to ensure flood protection for the adjacent lands. A 2D coupled unsteady hydrodynamic (EFDC) and sediment transport model (SEDZLLJ) is used to predict the hydrodynamics and morphological changes to the bed in the Keating Channel, the new river valley, and the naturalized spillway to the Ship channel. This model was used to inform the design and to develop the future dredging and sediment management strategy. The presentation will discuss details of the technical studies used to address flood risk, some of the challenges of implementing flood remediation in an urban environment, some lessons learned to date, and how hydraulic modelling has been an asset throughout the entire planning and design process.

**654 Contamination and Human Health/Ecological Risk Assessment: Building the Site Strategy**

**K. Barfoot, A. Wojtyniak, Jacobs / Global Environmental Solutions**

Plans are underway to flood protect and revitalize underutilized brownfield lands in the Toronto Port Lands through re-naturalizing the mouth of the Don River and extending the river south and west; however, due to the former industrial use of the Port Lands, the planned river route and related redevelopment infrastructure traverse through a heavily contaminated area containing non-aqueous phase liquid (NAPL), as well as other contaminants. A risk-based approach was used to understand the long-term risk management requirements, and the management of excess soils for reuse in the construction of landforms and barriers. Statistical methods were used to select Contaminants of Concern incorporating the use of left-censored data, the distribution and potential outliers of observed COC concentrations and the use of a risk index (concentration/toxicity reference value). Statistical methods were also used to support development of “like-to-like” COC concentration targets for the reuse and relocation of contaminated soil. The process resulted in focusing risk assessment on dozens instead of hundreds of COCs, and developing defensible target concentrations for placement and reuse of soil.
will outline the approach and considerations used to derive sediment IVs that will be protective of both human and ecological receptors exposed to sediments in the newly designed river valley.

657 Communication and Engagement for Port Lands Flood Protection

M. Shenker, Waterfront Toronto / Communications

Port Lands Flood Protection (PLFP) is one of the biggest infrastructure projects in North America. Funded by the City of Toronto, Province of Ontario and Government of Canada, this $1.25-billion project is really dozens of sub-projects. Engineering a river that will look and act like a natural river, modelling our design to ensure we will achieve flood protection, remediating impacted soil and reusing it to raise grades...creating a new island! This project complex to say the least. Its scale and scope make it a project of regional significance. The conditions of our approved Environmental Assessments require us to conduct ongoing consultation as detailed design for new parks, bridges, roads and flood protection infrastructure advances. So, how do you explain the science behind this game-changing transformation to a GTA-wide, general audience? This can be as challenging as the engineering work itself. Communications and engagement for a project of this scope and ambition requires a strategy that accounts for multiple audiences, some with no awareness of the project, or even the project area, and others with deep project knowledge. Thanks to years of advocacy and engagement in the initiative to renaturalize the Don, this presentation will detail the communications and engagement strategies that help communicate what this project will accomplish and why it matters.

658 Citizen Advocacy and Campaign for Flood Protection and River Naturalization

J.K. Wilson, CSS, Inc.

Citizen Advocacy has inspired, defended and sustained the Toronto Port Lands Flood Protection project for almost 30 years. The concept of naturalizing the post-industrial Don River channel first appeared in Bringing Back the Don, the 1991 vision document of the citizen-led Task Force to Bring Back the Don - a dream of a clean, green, accessible river mouth as centrepiece of a transformed Toronto central waterfront. Through iterative cycles of dreaming, inventing, refining, negotiating, organizing, campaigning and advocating, this presentation will tour the high points of a determined citizen campaign. Now federal, provincial and municipal governments together have embarked on this project, which will culminate in an environmental brownfield transformation that is virtually unprecedented in scale, sustainability dividend, and public commitment. As the co-chair of the West Don Lands Committee and eleven years as the chair of the Task Force to Bring Back the Don and from a perspective of central role in CodeBlueTO citizen activist collective, the presenter will provide an overview of the role of citizen advocacy in providing support for this Don River flood protection and naturalization project.

Environmental Risk Assessment of Pharmaceuticals: Connecting Across Disciplines

659 Occurrence, distribution and risk assessment of azole antifungal drugs in wastewater treatment plants

H. Assress, UNISA / Nanotechnology and Water Sustainability Research Unit; H.H. Nyoni, B.B. Mamba, T.A. Msagati, University of South Africa / Nanotechnology and Water Sustainability Research Unit

Presence of azole antifungal drugs in the environment is an emerging concern due to their persistence, ecotoxicology as well as their contribution to the selection of drug resistant fungi in the environment. In this study, the occurrence, distribution and preliminary ecological and human health risks of eight commonly used azole antifungal drugs were seasonally investigated for the first time in three wastewater and one drinking water treatment plants in South Africa. Clotrimazole (CLZ), econazole (ECZ), fluconazole (FCZ), itraconazole (ITZ), ketoconazole (KTZ) and miconazole (MCZ) were detected at least once in either the influent or effluent water samples, while posaconazole (PCZ) and voriconazole (VCZ) were not detected (ND) in the samples of all seasons. FCZ was detected in about 78% of the samples with concentrations ranging from ND to 1303.657 ng L⁻¹. CLZ had the second highest frequency of detection (33.33%) with a concentration up to 143.315 ng L⁻¹. The maximum concentration and detection frequency for KTZ and MCZ were 66.576 ng L⁻¹ and 16.664 ng L⁻¹; about 26% and 18%, respectively, while ECZ and ITZ were detected only occasionally. The preliminary ecological risk assessment based on risk quotient (RQ) calculation indicated that CLZ, ECZ, ITZ and MCZ could pose medium to high risk to fish, while CLZ could pose low to high risk to daphnia and algae. Results of human health risk assessment revealed that FCZ can potentially pose a high risk to human health. Furthermore, risk estimates showed a potential for the detected concentrations of FCZ and ITZ in water samples to pose moderate to high risk for development of antifungal drug resistance. The study highlighted that some of the azole antifungal drugs are ubiquitous in treatment plants and future evaluation and monitoring programs should include those drugs that seem to pose human and ecological risk.

660 Occurrence and Aquatic Risk Assessment of Pharmaceuticals and Other Contaminants in Minnesota Lakes

M.L. Ferrey, Minnesota Pollution Control Agency / Environmental Outcomes; W.J. Backe, Minnesota Department of Health; S. Streets, Minnesota Pollution Control Agency / Environmental Analysis & Outcome; A. Andrews, Minnesota Pollution Control Agency

Investigations over several years demonstrate that antibiotics and antidepressants, alkyphenols, and disinfectants are common surface water contaminants. Concern is growing over the effects of these chemicals on fish and wildlife as well as human health. In 2015, 50 Minnesota lakes, selected at random, were sampled for a broad suite of pharmaceuticals, alkyphenols, hormones, illicit drugs, anti-corrosive chemicals, and disinfectants. Of the 163 chemicals tested, 55 were found in lakes at least once. All 50 lakes contained at least one contaminant. Detections included eleven antibiotics or anti-fungal medications, five antidepressants, two lipid lowering drugs, and two hormones. Estrone was detected the most frequently, at 70% of the locations, followed by DEET at 50%. The alkyphenols 4-nonylphenol and 4-octylphenol were found in 46% and 24% of the lakes, respectively. The antidepressants sertraline and fluoxetine were detected in 30% and 26% of the lakes, respectively. The anticorrosive chemicals benzothiazole, benzotriazole, and the derivatives of benzotriazole were frequently detected. Based on statistical analysis of these data, 75 percent of Minnesota lakes are likely to contain the hormone estrone, and 43 percent are likely to have detectable concentrations of nonylphenol. Thirty six percent of lakes likely contain oxycodeone and cotinine, 29 percent likely to contain DEET, and 26 percent bisphenol A. The antidepressants sertraline and fluoxetine and the x-ray contrast agent iopamidol are each likely present in 23 percent of the state's lakes. Five of the 39 chemicals that were evaluated for aquatic toxicity - the DEET, estrone, bisphenol A, nonylphenol, and octylphenol - are considered high priority aquatic contaminants. The maximum concentration at which bisphenol A was detected - 177 ng/L - exceeded the acute toxicity value of 60 ng/L. Nineteen of the 55 chemicals are considered intermediate priority at the concentrations detected in this study. Several pharmaceuticals are expected to have half-lives greater than 6 months in water. Only two of the 55 chemicals detected - the mono- and diethoxylates of nonylphenol - are predicted to readily biodegrade in the aquatic environment. However, the likely product of that biodegradation, nonylphenol, is more toxic and more persistent in the aquatic environment than the parent chemicals.
661 Transport and fate of antibiotics in the soil-plant system
R. Johnson, University of York; E. Bergstrom, J. Thomas-Oates, University of York / Chemistry Department; J.B. Sallach, University of York / Environment

Bioactive pharmaceutical compounds are commonly detected in wastewater effluent as a result of inefficient metabolism in the human body and incomplete removal in wastewater treatment facilities. Increasingly, treated wastewater has become a valuable commodity as a source of fresh water for irrigation in an effort to meet demand in water stressed regions throughout the world. The use of treated wastewater for irrigation represents a key pathway for pharmaceuticals to enter agricultural environments. Among these pharmaceuticals are antibiotics which are of high concern as a result of their bioactivity targeting microbes and their potential to select for resistance at sub-inhibitory levels typically found in the environment. Environmental compartments are increasingly recognized for their role as reservoirs for antibiotic resistance. Here we derived an environmentally relevant mixture of antibiotic compounds based upon prescription data from the United Kingdom. A synthetic wastewater effluent combined with the antibiotic mixture was used for irrigation in a 16 week mesocosm study with barley (Hordeum vulgare) as the model crop. The transport of antibiotics in the soil plant system was monitored via targeted analytical measurement of antibiotic concentrations in soil pore water and mesocosm leachate using high performance liquid chromatography with triple quadrupole tandem mass spectrometry. Preliminary findings suggest that some of the antibiotics (e.g. tetracycline, oxytetracycline) are not detectable in the soil pore water. Risk quotients were derived from the measured concentrations using recently published predicted no effect concentrations (PNECs) for the selection of antimicrobial resistance. From this it is possible to identify and prioritise antibiotic compounds posing the most significant risk in the agricultural environment. Laboratory degradation experiments are used to determine antibiotic stability, with degradants being identified using non-targeted high mass accuracy LC-MS. Further experiments to investigate the photolytic degradation products use novel gas-phase UV spectroscopic techniques. From these studies, stable degradation products were identified. The degradation products identified in hydrolysis and photolysis studies were then investigated in soil pore water using non-targeted capillary LC-MS. Results from the present work seek to provide new insights into the fate and transport of human use antibiotics in the agricultural environment.

662 Sorption Characteristics of Pharmaceutical with Soils, Sediments and Sludges
J.A. Elmoznino, Pfizer, Inc. / Environmental Sciences PDM

Adsorption/desorption studies gather information on the mobility and distribution of a chemical in solid-water compartments. These data are fundamental in determining the potential for persistence and bioavailability, for the assessment of environmental fate, and for estimation of potential risk. Since the European Medicines Agency (EMA) environmental risk assessment (ERA) testing guideline was finalized in June 2006, the OECD 106 protocol has been routinely conducted in Phase II Tier A testing for all human pharmaceutical marketing authorization applications. The OECD 106 Adsorption-Desorption Using a Batch Equilibrium protocol is designed for estimating the adsorption/desorption behavior of a chemical with a variety of soils with different physical characteristics, such as organic carbon content, clay content, texture and pH. As per EMA ERA testing guidelines, a sorption study using 2 types of sludge and 3 soil types, following OECD 106, is preferred. Given that active pharmaceutical ingredients (APIs) are introduced into surface waters mainly by discharges from wastewater treatment plants, and that relatively fewer APIs trigger Phase II Tier B terrestrial fate and effects analysis, Pfizer’s strategy since 2009 has been to include 2 sediments, 2 sludge and 2 soils in the OECD 106 study. To date, Pfizer has conducted sorption studies following the OECD 106 protocol utilizing soils, sludge and sediments for 13 APIs; using soils and sludge for 8 APIs, and using only soils for 4 APIs. The primary aim of this study is to relate the OECD 106 Tier 2 sorption kinetics and Tier 3 equilibrium isotherm sorption data obtained for 25 APIs; comparing the distribution coefficients (Kd, Koc, KP) derived, and examining relationships with sludge/soil/sediment physical characteristics. As the new 2019 EMA draft guidelines specify that in the Phase II Tier A assessment for sediment, the highest soil Kd value, should be utilized for the sediment predicted environmental concentration (PECs) calculation, an additional goal of this study is to compare the PECs derived using the highest soil Kd with the PECs derived using the sediment Kd, to ascertain if the use of the soil Kd is a suitable representative for sediment PEC calculations.

663 Sorption of organic cations to organic matter: Use of molecular dynamic simulations in determining binding interactions
S. Scott, Ohio State University / Environmental Engineering; A. MacKay, Ohio State University / Civil, Environmental and Geodetic Engineering

The development of an environmental sorption model incorporating electrostatic interactions is challenged by the lack of knowledge on the specific types of binding mechanisms. Current sorption models for organic compounds are typically derived from their octanol-water partition coefficients (Kow) but are often inaccurate for charged species as they do not adequately account for contributions from ionic interactions. Use of probe compounds in conjunction with a suite of derivatives has been suggested to offer a way to determine structural effects on binding affinities. Herein, a suite of Benzylamine derivatives with varying sizes, polarities, and structural moieties were used to evaluate structural effects to Pahokee Peat binding. Column chromatography studies were performed to obtain empirical sorption coefficients. Isothermal titration calorimetry was used to obtain the full thermodynamic parameters of the experimental systems and electrostatic potential maps were generated and normalized in Gaussian for the suite of Benzylamine derivatives. These maps, in conjunction with the above empirical findings, suggest that binding affinity tends to improve with localization of positive charge (lower amine order) as well as presence of neutral aromatic substituents to enhance the compound push from the water. These qualitative trends provide insight to shifts in the types and extents of interactions with changing compound structure. However, there is still a need to quantify such substituent-specific energy contributions as well as determine underlying binding interactions. Computational techniques may provide a way to identify specific binding mechanisms as well as calculate interaction energy contributions. Molecular docking outputs using AutoDock suggest that primary, secondary, and tertiary amines interact with organic matter carboxylic groups via hydrogen bonds with electrostatic, and van der Waals contributions from the rest of the cation structure. Quaternary amines tend to partition into hydrophobic organic matter pockets rather than participate in hydrogen bonds, and interact through electrostatic and van der Waals interactions. Molecular dynamic simulations using GROMOS and organic matter models built from the Vienna Soil Organic Matter Modeler will be performed with these Benzylamine derivatives to look for further evidence of these binding mechanisms. Understanding such systems at this level may be beneficial in the development of sorption models that can also account for charged species.

664 Using in Vitro and in Silico Data to Assess Potential (Anti-) Estrogenic Activity of Pharmaceuticals in Fish at Environmentally Relevant Concentrations
C. Pinto, R. Bloom, J. Laurenson, US Food and Drug Administration / Center for Drug Evaluation and Research

Endocrine-active pharmaceuticals can cause adverse reproductive and developmental effects in non-target organisms. Aquatic vertebrates may be susceptible to the effects of such pharmaceuticals as the structure of hormone receptors and the physiology of the endocrine system are highly conserved across vertebrates. To aid in the regulatory review of the environmental impact of pharmaceuticals, we demonstrate an approach to screen and support the prioritization for further testing of pharmaceuticals based on their ability to interact with estrogen receptors (ERs) at environmentally relevant concentrations. Tox21 high-throughput
screening in vitro results from ER agonist and antagonist assays were retrieved for 1,123 pharmaceuticals marketed in the year 2016. In silico predictions from the Collaborative Estrogen Receptor Activity Prediction Project (CERAPP) models were used to estimate ER agonist and antagonist activity for 170 pharmaceuticals which were not tested in the Tox21 assay platform. The “estrogenic effect ratio” (EER) and “anti-estrogenic effect ratio” (AEER) were calculated by comparing the activity concentration at half-maximal response (AC50) for ER agonism and antagonism, respectively, to estimated pharmaceutical concentrations in fish tissue based on bioconcentration factors and high-end estimates of environmental exposures. This approach, using in vitro and in silico data, may help determine the need for submission of environmental assessment data for new drug applications, and support the prioritization of pharmaceuticals for their potential to disrupt endocrine signaling in vertebrates.

665 Environmental risk assessment of veterinary medicinal products in the European Union

S. Hickmann, German Environment Agency (UBA)

The environmental risk assessment of veterinary medicines in the EU follows the VICH guidelines GL6 and GL 38. They inter alia specify the OECD studies for the basic data set on fate and effects in the environment. The use of the VICH guidelines for risk assessment has shown that for specific cases additional guidance or refinement options are necessary. Examples include the published EMA (European Medicines Agency) guidelines on a testing strategy for plants to better characterize the risks of antibiotics, or the assessment of risks for human health and groundwater communities from veterinary pharmaceuticals in groundwater. Work is still ongoing in other fields, such as higher tier testing for dung fauna for parasiticides. In January 2019, the European Commission has published a new regulation on veterinary medicines which will apply from 2022. The Commission has also published a strategy on pharmaceuticals in the environment in March 2019. Additional issues will have to be addressed such as the role of the environment for the development and dissemination of antimicrobial resistance and a new guideline will be developed to assess the risk for the environment from the use of veterinary medicines in aquaculture. The new veterinary legislation also asks the European Commission to investigate the feasibility of a substance based review system (monograph system) until 2022. Such a system would be of high importance to address the fact that there is still no comprehensive information available on the environmental fate and effect of the products authorized before 2005. A topic of importance in European chemicals policy are substances classified as persistent, bioaccumulative, and toxic (PBT), or very persistent and very bioaccumulative (vPvB). When the regulation applies in 2022, PBT substances in veterinary medicines cannot be authorized for food-producing animals unless they are essential to prevent or control a serious risk to animal health. An EMA guideline has been developed for the PBT assessment and a reflection paper discusses management options under the current legal framework. The presentation will provide an overview of recent developments in the environmental risk assessment of veterinary medicinal products in the EU. It will show case studies where research has been translated into regulatory guidance and identify future aspects for collaboration between research and regulatory groups.

666 Veterinary pharmaceuticals in water systems: potential health impact of waste water reuse as management strategy for water security

O.S. Fataki, Cape Peninsula University of Technology / Chemistry; B. Opeolu, Cape Peninsula University of Technology / Faculty of Applied Sciences; O.S. Olatunji, Cape Peninsula University of Technology / Department of Chemistry; B. Genthe, CSIR South Africa

South Africa is water stressed and the growing effects of climate change with its extreme weather conditions and erratic rainfall pattern is aggravating the situation with incidence of droughts in many parts of South Africa, including Cape Town in particular, which is a major tourist centre in South Africa. As a result, water security became a concern which could impact on people’s health and on the cities’ economic activity. One of the water management strategies being developed by government is wastewater reuse for both domestic and agricultural uses. However, with the increasing occurrence of some pollutants of emerging concern in the wastewater systems, there are concerns that this practice may expose people to these chemicals which may pose a health threat to them. Emerging contaminants (ECs) are substances whose presence and significance are only being recognised. Many ECs are persistent in the environment and have been associated with several disease in humans. Our studies in the Cape Town environment have indicated the presence of such chemicals in wastewater systems. Veterinary pharmaceuticals such as antibiotics, anti-parasitic agents and hormones (natural and synthetic oestrogens and androgens) are classified endocrine disruptors (EDs). High Performance Liquid Chromatography coupled to ultraviolet detector (HPLC-UV-Vis) method was optimized and validated for the separation and detection of phenols and prioritised pharmaceuticals. Multi-residue solid phase extraction (SPE) procedure was developed and validated for the recoveries of acetaminophen (AC), dichlophenac (DP), salicylic acid (SA), tetracycline (TC), chloramphenicol (CHR), ciprofloxacin (CP), bisphenol-A (BPA), 17β-estradiol (E2), estriol (E3), and ivermectin (IV). These pharmaceuticals were determined in wastewaters from agricultural wastewaters using the hydrophilic-lipophilic balance (HLB)-SPE column. The list of the 10 priority pharmaceuticals were developed by a screening programme and from information on the pattern of use in the Western Cape Province. Bioassay methods which are specifically aimed at providing information that could be related to potential human health effects of residues of the investigated pharmaceuticals were used to assess the health risks of the pharmaeuticals at the levels they occur in the water systems. The bioassays included the Ames mutagenicity test, and the YES (yeast oestrogen screen) test, for oestrogenic activity. These provide a broad indication of effluent quality and are often recommended as screening tests for wastewater reuse. Ten priority pharmaceuticals were identified from the screening programme - acetaminophen (AC), dichlophenac (DP), salicylic acid (SA), tetracycline (TC), chloramphenicol (CHR), ciprofloxacin (CP), bisphenol-A (BPA), 17β-estradiol (E2), estriol (E3) and ivermectin (IV). Recoveries of pharmaceuticals using HLB-SPE cartridges and HPLC-UV/vis varied between 76.62% for 17β-estradiol and 94.34 % for acetaminophen. Several levels of veterinary drugs were detected in the wastewater samples using HPLC-MS systems - AC, < 0.48 - 1.07 µg/l; SA, < 1.37 - 15.49 µg/l; TC, < 3.45 - 4.57 µg/l; CP, 0.45 - 2.46 µg/l; and IV, < 1.74 - 1.63 µg/l from the various livestock activities - poultry, cattle, sheep and pig. The results of the health risk assessment clearly showed mutagenic activity being observed in samples from sheep and poultry farms. Observations from quantitative health risk assessment bioassay suggested that where the concentration of 17β-estradiol approached the maximum concentration detected in the environmental samples, there was a slight indication of the risk of developing cancer through accidental ingestion via recreational activities only. The Ames test results also revealed clear mutagenic activity in samples from sheep and poultry farms, with mutation ratios ranging from 6 times, to close to 8 times the natural background mutation rate. Also, high levels of oestrogenic activity were observed in effluent from the pig farm, with considerably lower levels in the effluent from a sheep farming area. The estrogenic activity from the poultry farm effluent was below the level of detection. If the wastewater were used for domestic purposes and sufficient treatment to remove the emerging contaminants of concern was not made, or if the water was used for irrigation purposes, greater risks could be expected.
Environmental Radiation Sciences

667 Fate and transport modelling of the decommissioned Beaverlodge Uranium Mine Site
C. Lucas, S. Fernandes, H. Phillips, CanNorth; M. Webster, Cameco Corporation

Uranium-bearing minerals were first discovered in the Beaverlodge area of northern Saskatchewan in 1934. Mining and milling started in 1952 and continued for a 30-year production period. Decommissioning and reclamation were undertaken according to the approved plan; the work was completed by 1985. Since that time, monitoring of the receiving environment has continued as specified in the decommissioning plan. Measured data demonstrate that recovery in the immediate and downstream environments is occurring slowly, and generally as predicted; however, levels of radionuclides such as radium-226 and uranium, as well as other contaminants, remain above background and environmental quality guidelines. In recent years work has been undertaken to develop a final site clean-up strategy which would allow for ultimate close-out of the area. In order to aid the decision making process, contaminant dispersion modeling has been carried out in the post-decommissioning period for the immediate and downstream environment employing a tool called the Beaverlodge Quantitative Site Model (QSM). Model calibration was carried out using 13 years of water quality and occasional sediment data. This presentation will review the current state of the environment in the area of the decommissioned Beaverlodge mine site 30 years after decommissioning. The investigations and modelling of the fate and transport of Ra-226 and uranium will be discussed. This will include an examination of controlling factors, which can vary between the former mining areas and within the tailings management area. The water quality shows significant seasonal variability in smaller waterbodies due to the influence of ice cover and spring freshet. Recent fish chemistry data are available from the area including information on lake trout, lake whitefish, northern pike, and white sucker. The differences in concentrations, that relate to environmental concentrations and diet preferences, will be discussed as well as the implication on dose.

668 Evaluation of Radiation Doses for Workers in the Oil and Gas Exploration Sector
S. Landsberger, University of Texas / Nuclear and Radiation Engineering Program

Perhaps the first discovery of radioactivity in oil dates back to 1904 at the University of Toronto, just a short eight years after its discovery by Bequerel in 1896 in Paris. Burton discusses the presence of a highly radioactive gas obtained from crude petroleum. In 1904 McLeenan also at the University of Toronto University discussed the radioactivity of mineral oils and natural gases. Interestingly these samples were from Ontario oil and gas fields. While the existence of radioactivity of oil has been known for a long time, it was not till the early 1990’s that many papers and reports were published on well characterized activity levels in different oil and gases. By the early 2000’s and beyond a multitude of papers were published from many oil producing nations. At the University of Texas we have performed Monte Carlo (MCNP) simulations with the Oak Ridge National Lab human phantom to calculate the dose distribution throughout the human body and thus demonstrating radiation effects in each individual organ based on typical radioactivity levels found in west Texas oil scale. Results have shown that for the average worker in the field dosimeters should be kept at the lower ends of the body instead of the usual chest height.

669 Dynamic Modeling of Radionuclide Transfers in the Marine Environment in the English Channel from Discharges to Biota
B. Fievet, IRSN / MANCHE; P. Bailly du Bois, C. Voiseux, IRSN / PSE-ENV/SRTE; R. Dupont, ALTRAN

Radionuclide transfer parameters between water and biota recommended in the literature are generally limited to the concentration factor values (CF). So a steady state must be assumed when using them for modeling. But in the event of an accident or in the close vicinity of a regular input source where concentrations are maximal, sharp changes in seawater concentration are likely to occur and the assumption of a steady state is usually not met. Dynamic modeling requires taking into account the kinetics of the transfer, usually characterized by the radionuclide biological half-life (t1/2), but recommendations for t1/2 values are still scarce. The nuclear reprocessing plant of ORANO La Hague (France, Normandy) is the major source of liquid radioactive discharges to the marine environment in the English Channel. A hydrodynamic model has been extensively validated by matching several thousands of calculated and locally observed concentrations in seawater. It is now available to reliably predict the dispersion of radioactive discharges in this area. It is also possible to calculate the corresponding seawater radionuclide concentrations in locations where long time-series measurement in biota are available. Using the calculated signal in seawater and the observed signal in biota, it is possible to derive dynamic transfer parameters (CF, t1/2) to model radionuclide transfers between seawater and the biota. This data processing was performed with radionuclides data including Cs-137, Co-60, I-129, monitored in algae, mollusks, crustacean and fish, around La Hague Cape. In addition, a distribution analysis of the residual between the calculated and observed values was carried out. On the basis of this data processing, recommendations for dynamic transfer parameters (CF, t1/2) values are proposed for these radionuclides and these recommendations are supported by documenting the reliability of the modeling from the discharges down to the biota.

670 Impact of iron-55 and stable iron chlorides on uptake and sorption of plutonium-239 in liquid cultures of common environmental microorganisms
L. Manglass, Clemson University / Environmental Engineering and Earth Science; M. Wintenberg, M. Blenner, Clemson University / Chemical and Biomolecular Engineering; N. Martinez, Clemson University / Environmental Engineering and Earth Sciences

The mechanisms and impact of low doses of ionizing radiation on biological and environmental systems have been historically difficult to study. Modern biological tools have provided new methods for studying these mechanisms but applying these tools to a dose-response relationship may require refinement of dosimetry techniques, particularly when assessing the impact of low doses of ionizing radiation on environmental systems. In this work, Escherichia coli, Pseudomonas putida, and Saccharomyces cerevisiae grown in liquid culture were exposed to low dose rates of plutonium-239 and iron-55, both alone and in combination. The fractionation of plutonium-239 and iron-55 between the growth media and cell pellets was analyzed via liquid scintillation counting. Plutonium binds readily to many organic compounds and cell surfaces at near neutral pH, however cellular production of chelating agents, especially siderophores meant for transporting iron, has been observed to allow for direct uptake of plutonium into cells in the literature. By investigating the uptake and sorption of plutonium-239 in cells grown with and without iron-55, we can better understand the impact of cellular ligand production on plutonium uptake/sorption and improve assessments of dose and response. This work is part of a project focused on evaluating the potential of common environmental microorganisms to serve as biosensors for the field of nuclear forensics and non-proliferation. The implications of these findings, however, also provide broader insight for the investigation of low-dose radiation effects on biota.

671 Effects of in vivo exposure to tritium (HTO and OBT) in fish
B. Gagnaire, C. Adam-Guillermin, IRSN; A. Festarini, Canadian Nuclear Laboratories Limited CNL; I. Cavalie, IRSN; I. Gosselin, S. Kim, S. Walsh, F. Farrow, D. Beaton, H. Chen, A. Shkarupin, Canadian Nuclear Laboratories Limited (CNL); M. Stuart, Canadian Nuclear Laboratories Limited CNL / Environmental Technologies

Canadian Nuclear Laboratories (CNL) and France’s Institut de Radioprotection et de Surete Nucleaire (IRSN) conducted a collaborative
field study at Chalk River Laboratories (Ontario, Canada) to characterize the effects of tritium on fish health. Fathead minnows were exposed, through water and feed, to tritium activity concentrations ranging from 2 to 23,000 Bq/L for 60 days, followed by a 60-day depuration period. A battery of biological health indicators were measured and tritium effects were dissociated from confounding factors using multivariate analyses. No effects were observed on survival, fish condition or metabolic indices for internal dose rates reaching 0.15 µGy/h. It was, however, noted that tritium exposure increased DNA damage and induced changes in fatty acids of minnows. Tritium was also found to increase the responses of the immune, neural and antioxidant systems. Following the field investigation, a complementary experiment was conducted in a laboratory setting. Male fathead minnows were exposed to tritium activity concentrations up to 180,000 Bq/L for 60 days, followed by a 60-day depuration period. The highest internal dose rate was estimated to be 0.65 µGy/h. In agreement with the field study results, no effects were observed on survival, fish condition or metabolic indices and, tritium was shown to increase DNA damage and modulate the immune responses at the highest exposure levels. Changes in other markers, including the neural system, oxidative stress and fatty acid composition, were also observed. No effects were seen on anti-oxidant activities. Fish health results from the field and laboratory studies were in general agreement. It was, however, noted that immune makers did not correlate as well with DNA damage markers in a field context. In addition, the phagocytosis activity was much higher in the field compared to the laboratory.

672 Environmental radiation levels accurately predict past radiation exposure in Chernobyl birds
A. Bonisoli Alquati, California State Polytechnic University, Pomona / Department of Biological Sciences; A.P. Moller, University of Paris-Sud; D.J. Tedeschi, University of South Carolina / Department of Physics and Astronomy; G. Milinovsky, Taras Shevchenko National University of Kyiv / Space Physics Laboratory; T.A. Mousseau, University of South Carolina / Department of Biological Sciences

Ecological research in Chernobyl has shown that local populations of birds from contaminated sites are experiencing deleterious genetic, physiological and morphological effects. These effects seemingly translate in reduced reproductive success and increased mortality for local populations of birds, exerting selection pressures that might have contributed to adaptation to radiation. Some of these findings, however, have been deemed inconclusive based on the lack of direct measures of the doses received by local birds, which have been typically inferred from environmental measurements. We tested whether environmental radiation measurements using a hand-held dosimeter accurately predicted past radiation exposure in a diverse community of understory birds. To this aim, we captured birds in woodland sites and farms that differed for environmental radiation levels over more than three orders of magnitude. We then conducted gamma spectrometry of individual birds in the field using a portable SAM 940 Radioisotope Identifier (Berkeley Nucleonics, San Rafael, CA) equipped with a sodium iodide (NaI) detector. We also estimated the external dose received by birds using GR-200A LiF:Mg,Cu,P thermoluminescent dosimeters (TLDs), attached to standard aluminum bird bands. Environmental levels measured in the site of capture of each bird accurately predicted the internal dose received by the birds, as indexed by activity concentrations in their body. Environmental radiation levels also predicted the dose received by the TLDs during a month-long period between subsequent captures for a subsample of birds. For both relationships the strength of the association varied among closely-related passerine species, thus highlighting the limitation of radiological protection approaches based on reference animals. Environmental radiation levels in the site of capture of wild birds overall reliably indicate past radiation exposure. The existence of variation across species in this relationship suggests that species-specific behavioral and ecological traits are involved in determining a species’ exposure to radionuclides under realistic ecological conditions, thus calling into question the validity of dose estimation approaches based on reference organisms.
Broadening the Scope of Chemical Assessments Using Toxicokinetic Data

675 Evaluation and comparison of intrinsic metabolic clearance using isolated hepatocytes from humans, rats, and rainbow trout
S.R. Black, RTI International / Discovery Sciences; K.A. Fay, General Dynamics Information Technology / Office of Chemical Safety and Pollution Prevention; J.W. Nichols, US Environmental Protection Agency / ORD NHEERL / Mid-Continent Ecology Division; S. Matten, US Environmental Protection Agency / Office of Science Coordination and Policy; S.G. Lynn, US Environmental Protection Agency / Endocrine Disruptor Screening Program (EDSP)

The US Environmental Protection Agency (EPA) is statutorily required under the amended Toxic Substances Control Act to reduce and replace vertebrate animal testing to the extent practicable and scientifically justified. To this end, EPA conducted in vitro metabolic clearance assays using cryopreserved hepatocytes to collect chemical and species-specific data for use in in vitro to in vivo extrapolation (IVIVE) models. A total of 54 chemicals were evaluated for in vitro clearance at two concentrations using hepatocytes derived from humans, rats or rainbow trout. Hepatocytes were incubated with a test chemical and sampled over time to determine clearance rates, with heat-treated controls (HTC) run concurrently. Each dataset (live cell and HTC depletion data for each chemical/dose/species) was evaluated and binned based on HTC recovery to determine if clearance rates from the live cell assays could be reported. Of the 238 unique datasets, 75 datasets were excluded due to poor performance in HTC recoveries (< 50% or > 130%). A total of 34 datasets had HTC recovery ranging from 50 to 80%. For these datasets, the ratio of the slope derived from the live cell assays to the slope derived from the HTC assays was evaluated. A total of 21 datasets had a ratio > 20, indicating substantial hepatic clearance of the chemical above HTC loss, while the remaining 13 datasets were excluded from rate reporting. Of the 150 datasets meeting reporting criteria, a total of 22 had 2 or fewer data points above the Limit of Quantitation and were simply reported as having “Fast” clearance, leaving 128 datasets with reportable rates. Clearance rates varied among species, generally indicating slower chemical clearance by trout hepatocytes. In general, clearance rates with rat or human hepatocytes were within 2-fold agreement; however, 3,3’5,5’-tetrabromobisphenol A, mestranol, picoxytroisin, terbutylazine, and triclocarban were cleared at least 3 times more quickly by rat hepatocytes. Conversely, cerceoxib was cleared faster by human hepatocytes. Overall, this work provides a large collection of in vitro clearance data for cross-species comparisons and supports IVIVE applications such as reverse toxicokinetic modeling and bioconcentration factor predictions. The views expressed in this abstract are solely those of the authors and do not represent the policies of the USEPA. Mention of trade names or commercial products should not be interpreted as an endorsement by the EPA.

676 Using S9 clearance rates and membrane-water partitioning to predict surfactant bcf values for fish
S. Droge, University of Amsterdam / IBED Institute; M. McLachlan, Stockholm University / Environmental Science and Analytical Chemistry (ACES); J.W. Nichols, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division; J.M. Armitage, AES Armitage Environmental Sciences, Inc. / Physical and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting

Surfactants are challenging chemicals to work with, as they may: accumulate at all kinds of interfaces, occur in complex mixtures, be readily biodegraded during testing, and fall outside the applicability domain of current test guidelines and models. In particular, there are often no or highly uncertain octanol-water partition coefficients (Kow) for surfactants. In the CEFIC-ECO37 project we focused on series of individual surfactant structures and measured cell membrane-water partition coefficients (Kmw) to potentially replace Kow model parameters. In addition, we measured in vitro intrinsic clearance (CLint) using trout liver S9 fractions to determine the potential impact of biotransformation on fish bioaccumulation factors. Trends in Kmw and CLint with surfactant structure have been identified that allow for extrapolations to analogue structures within various surfactant types. In parallel, we determined in vivo fish BCF values for strategically composed mixtures of surfactants with rainbow trout, in order to evaluate and further refine model predictions based on Kmw and CLint. The model captures the influence of ionization, pH and key sorptive and biotransformation properties that influence uptake and elimination rates. Currently, a matrix of in vivo and in vitro data have become available for a set of 12 cationic surfactant structures, and 8 nonionic surfactants. BCF values increase with stronger sorptive properties, and decrease with stronger ionization. Including biotransformation appears to align the model predictions closer to observed values resulting in agreement within a factor 10 for most tested compounds. Remaining challenges of the approach, e.g. in terms of quantitative in vitro-in vivo extrapolation (QIVIVE) and surfactant chemical domains, will be discussed.

677 Measurement of unbound chemical fractions of hydrophobic chemicals in rainbow trout liver S9 fractions and blood plasma using a passive dosing method
L.J. Saunders, Simon Fraser University; G. Diaz Blanco, Polytech Nice Sophia / Department of Environmental Engineering; Y. Lee, V. Otton, F. Gobas, Simon Fraser University / Resource & Environmental Management

Recent studies demonstrate the utility of in vitro-in vivo extrapolation (IVIVE) approaches for evaluating the impact of biotransformation on chemical bioaccumulation in fish. In the IVIVE approach, a chemical biotransformation rate is measured in a hepatic in vitro system and is then extrapolated to estimate a whole-body biotransformation rate in fish, which are in turn can be used as an input in a mass balance models to predict a steady-state bioconcentration factor (BCF). Although the inclusion of in vitro biotransformation rates substantially improves BCF predictions, there remains a consistent tendency for IVIVE methods to overestimate BCFs relative to empirical BCF values. Several studies show that BCF overestimates are typically observed when hepatic clearance is assumed to be controlled by the unbound (i.e. free) chemical concentration in vitro and in vivo. Instead, improved agreement between predicted and empirical BCFs was obtained by assuming that chemical bioavailability in S9 fractions and blood plasma is effectively the same (TU = 1.0). Several studies have highlighted the uncertainty in algorithms used to estimate the fraction unbound and represents a priority research need. Here we present results from passive dosing experiments (sorbent phase dosing with ethylene vinyl acetate [EVA]) performed to obtain equilibrium partitioning measurements for several hydrophobic test chemicals (log Kow 4-8) in rainbow trout liver S9 fractions and blood plasma. For all test chemicals, equilibrium in the EVA test-system was achieved within 24h. The unbound chemical fractions in liver S9 fractions (ϕS9) and blood plasma (ϕP) were obtained for the test chemicals and were compared to predictions using available binding algorithms. Binding correction factors (TU = ϕP/ϕS9) determined for the test chemicals were always less than 1.0 and was expected given the higher lipid content of blood plasma (1.27%) compared to liver S9 fractions (0.01%). Our findings also suggest that lipid may be a more important determinant of binding for hydrophobic chemicals than protein, and should be considered when evaluating the fraction unbound in subcellular fractions.

678 Toxicokinetic Modelling of Trophic Transfer of Octylphenol between Chlorella vulgaris and Daphnia magna
J.C. Achar, J. Jung, Korea University / Environmental Science and Ecological Engineering

Octylphenol (OP) is widely used in the production of plastic additives and non-ionic surfactants, causing endocrine disruption, carcinogenicity and reproduction inhibition on aquatic organisms. The bioconcentration of OP in freshwater algae and subsequent transfer to aquatic invertebrates is very important to evaluate its ecological risk. We applied one
Evaluating the PBT potential of organic chemicals in the environment. Quantification of biotransformation rate remains a major challenge in Environmental Engineering.

Determining Biotransformation Rate Constant Using Early Biota Concentration Data

Quantification of biotransformation rate remains a major challenge in evaluating the PBT potential of organic chemicals in the environment. A simplified approach is proposed for the derivation of biotransformation rate constant (kM). It is proposed that kM can be estimated using the molar equivalent fraction of residual parent compound at early times during the uptake phase. This method requires no data fitting or model estimates on other toxicokinetic parameters. The proposed equation was tested against experimental kM's derived from data regression or optimization of kinetic data. The short-cut method performed accurately (n=42, RMSE=0.31) and superior to accuracy of typical toxicokinetic models. The proposed equation satisfies the major requirements needed for a valid kM equation. Theoretical analysis shows that the short-cut method converges with the solution of established toxicokinetic equations for biotransformation under both constant exposure and decay exposure scenarios. The behavior and limitations of the short-cut method are demonstrated by simulation results. It is found that the error in log kM estimates increase with larger depuration or transformation rate constants. This is also consistent with the expectation that kM is accurate using measurements made at early times. A general protocol for efficient characterization of large number of organic compounds in diverse biota is discussed. The proposed short-cut method will support and speed up investigation on interspecies difference on biotransformation of organic contaminants.

Toxicokinetic modeling of systematic pesticides in aquatic organisms: The impact of transformation on bioaccumulation

Pesticides have become a great threat to ecological biodiversity at a global scale and it is imperative to evaluate ecological risk related to pesticide use. Degradation and biotransformation are critical processes modifying the bioaccumulation and toxicity of organic pollutants in the environments. Compared with legacy organochlorine pesticides, current-use pesticides have a greater tendency to be transformed in abiotic environment and biota, requiring better understanding on the roles of degradation and biotransformation on their bioaccumulation. In this presentation, two systematic insecticide, fipronil and imidacloprid were selected as the representative chemicals of easily metabolizable pesticides. The study included two exposure scenarios for fipronil. One is the biotransformation and bioaccumulation of waterborne fipronil in fish (tilapia, Oreochromis niloticus). The other is the degradation, biotransformation and bioaccumulation of sediment-bound fipronil in a benthic invertebrate (blackworm, Lumbriculus variegatus). Toxicokinetic models were developed to simulate the kinetic processes of fipronil and its more toxic metabolites in both organisms. Tissue-specific accumulation, biotransformation and elimination of fipronil in tilapia were quantified by combining in vivo measurements and the newly developed multi-compartmental pharmacokinetic model. The multi-compartmental model quantitatively demonstrated the highly dynamic intercompartmental transport and rapid branchial clearance of fipronil in fish. Modelling results also suggested that uptake and biotransformation were the stronger driving forces for the inter-compartmental transport of xenobiotics in fish than the intrinsic partitioning capacity. While fipronil sulfone was the main metabolite in fish, fipronil sulfone and sulfide were detected in sediment and the lugworms. To incorporating the degradation of fipronil in sediment into toxicokinetic model of fipronil in the blackworms better explained the biotransformation and bioaccumulation of fipronil in organisms. In addition, varying toxicity of imidacloprid to four invertebrates were explained by their different toxicokinetic processes. Overall, our findings highlight the importance of degradation and biotransformation on the internal disposition and bioaccumulation of fipronil in aquatic organisms, which helps to improve the aquatic toxicity assessment of easily metabolizable pesticides.

Interpreting OECD 305 dietary bioaccumulation tests with the ADME-B calculator: BCFs, BMFs and biotransformation rates

Current OECD 305 guidelines for bioaccumulation tests include the option to conduct a dietary bioaccumulation test for assessing a chemical's bioaccumulation behaviour. However, the one-compartment toxicokinetic model that is used to analyze the results of dietary bioaccumulation tests is out-of-step with the current bioaccumulation science and experimental practices and information needs for bioaccumulation and risk assessment. This study presents (i) a two-compartment toxicokinetic modeling framework for describing the bioaccumulation of neutral hydrophobic organic chemicals in fish; and (ii) an associated toxicokinetic analysis tool (ADME-B calculator) for the analysis and interpretation of the results from dietary bioaccumulation test in terms of the adsorption, distribution, metabolism and excretion (ADME) of chemicals for the purpose of bioaccumulation (B) assessment; and (iii) an error analysis and statistical tests for comparing bioaccumulation metrics to criteria values. The model framework and ADME-B calculator were applied to the analysis of 32 OECD-305 dietary bioaccumulation tests involving 166 unique organic chemicals. Bioconcentration and biomagnification factors, as well as somatic and intestinal biotransformation rates were derived from this analysis. The findings indicate that the advantage of the two-compartment fish toxicokinetic model over the one-compartment fish model is that the effect of the exposure pathway on the bioconcentration and biomagnification factor of biotransformed chemicals can be quantitatively taken into account. This is important for the application of a weight-of-evidence based approach to bioaccumulation assessment where information from both aequous and dietary bioaccumulation tests needs to be interpreted in terms of the chemical's bioaccumulation potential in the environment.

Perfluoroalkyl acids: Aquatic food web biomagnification insights

Despite nearly two decades of environmental monitoring of perfluoroalkyl acids (PFAAs), unusual patterns in these compounds’ bioaccumulation and trophic transfer suggest incomplete understanding of these complex processes. More specifically, trophodynamic studies on aquatic food webs have found low trophic level organisms can accumulate equal or greater PFAA concentrations relative to top predators. These findings suggest that additional aspects beyond direct trophic transfer govern PFAA trophodynamics. PFAAs are essentially chlorine-substituted endogenous fatty acids, and literature has routinely highlighted the importance of protein-ligand interactions in PFAA accumulation/elimination. Work in progress seeks to gain insight regarding the potential relationship between blood protein variability and PFAA accumulation among multiple fish species of the Lake Ontario aquatic food web. To accomplish this, paired analyses
of protein content and PFAA concentrations in blood serum from alewife (
*Alosa pseudoharengus*), deepwater sculpin (*Mxyoscephalus thompsonii*),
and lake trout (*Salvelinus namaycush*) were performed with the goal of
identifying whether intra- and/or interspecies blood protein variability
may drive differences in PFAA burden.

**Integrating Pest Management, Risk Assessment and Environmental Sustainability**

*683 Effectiveness of an Integrated Wetland Treatment System in Reducing Pesticide Concentrations Associated with Agricultural Runoff*

L.B. McCalla, University of California, Davis / Marine Pollution Studies
Laboratory at Granite Canyon / Environmental Toxicology; B.M. Phillips,
B.S. Anderson, J. Voorhees, K. Siegler, University of California, Davis / Environmental Toxicology; K.R. Faulkenberry, S. Zamudio, University of California, Davis / Marine Pollution Studies Laboratory at Granite Canyon / Environmental Toxicology; R.S. Tjeerdema, University of California, Davis / Environmental Toxicology; X. Deng, California Environmental Protection Agency / Pesticide Regulation

The Salinas Valley in Monterey County, California, USA, is a highly
productive agricultural region that produces much of the country’s salad
greens, strawberries, artichokes, and cruciferous vegetables such as
broccoli, cauliflower, and Brussels sprouts. Agricultural irrigation runoff
containing pesticides at concentrations toxic to aquatic organisms poses
a threat to aquatic ecosystems within local watersheds. This study was
designed to monitor the effectiveness of a constructed wetland treatment
system with a granulated activated carbon (GAC) filter installation at
reducing pesticides associated with agricultural runoff. The addition of
pennywort (*Hydrocotyle*

 Additional samples were analyzed for 172 fungicides, herbicides and
insecticides. Input water was toxic to *H. azteca* in two trials and *C. dilutus*
in one trial, but toxicity was reduced as water moved through the treatment
system. Toxicity to *C. dilutus* occurred and persisted during the first
trial, likely influenced by elevated conductivity. Collectively, the system
reduced fungicides by 44%, herbicides by 55%, and insecticides by 60%. The GAC filtration component provided additional average concentration
reductions in all pesticide groups across all trials. Results suggest that a
wetland treatment system coupled with GAC filtration can significantly
reduce pesticide concentrations in agricultural runoff.

*684 Ants on Cucurbits: Their diversity, ecological role, and exposure
to pesticide residues*

A.D. Fairweather, J.M. Schmidt, N. Raine, University of Guelph / School
of Environmental Sciences

Ants (Hymenoptera: Formicidae) are highly abundant in terrestrial habi-
tats, in which they often provide a range of important ecosystem services.
Surprising little is currently known about the value of ants in crop-
ning systems. Here we investigated the abundance and diversity of ants
found in cucurbit crops, their role as ecosystem service providers (e.g.
biocontrol), how they are exposed to pesticides, and the impacts of that
exposure. We have documented 16 species of ants across four subfamilies
interacting with cucurbit crops on 6 major farms and 1 field test site in
southern Ontario. Two species, *Lasius alienus* and *Prenolepis imparis*,
were discovered nesting in all areas of these crop fields. *Lasius alienus*
preferentially nested in the root systems of cucurbits and was observed
feeding on major cucurbit pest species. These ants potentially provide
significant beneficial pest regulation services, while simultaneously being
exposed to pesticides via contact with soil or plant surfaces, or ingestion
of contaminated nectar. Our research is the first exploring the ant diver-
sity and ecology found on a high value crop in southern Ontario, and their
exposure to pesticides. This research has important implications for pest
control in Cucurbita fields, environmental risk assessments, and increas-
ing our ecological knowledge about these agriculturally relevant ant taxa.

*685 The Pesticide Loss from Agricultural Field Model*

S. Lyons, K.J. Hageman, Utah State University / Chemistry & Biochemistry

Global pesticide usage has been estimated to total over 6 billion pounds
annually with costs to producers exceeding $50 billion. Due to the costs
associated with pesticide usage as well as the adverse effects on human
health and sensitive, non-target ecosystems, it is vital that pesticide fate is
better understood so improved management practices can be implemented
to save money and preserve the health of the environment and its inhabit-
ants. With this in mind, the Pesticide Loss from Agricultural Field model
was developed using partition coefficients and photodegradation rates
on leaves to predict pesticide losses following application. A key model
output is the time for dissipation to half of the initial concentration (DT50)
due to volatilization plus photodegradation. The model was validated by
comparing modeled DT50 values to 40 measured values reported in the
literature that covered 7 pesticides and 23 plant types. Along with DT50,
other outputs of the model include loss contributions from volatilization
and photodegradation, the cumulative loss after 24 hours, and estimated
concentrations for the soil and plant compartments. The model was used
to probe questions related to how time of day and time of year of applica-
tion impacts dissipation. Simulations for the seven pesticides used in
validation were run to mimic a summer and autumn application. In addi-
tion, time of day of application was also varied to represent a morning,
afternoon, and evening application. The extended DT50 values predicted
for the autumn application is expected due to increased volatilization
and photodegradation occurring in the summer months when tempera-
tures and solar radiation are elevated. Time of day of application is less
important than the time of year, however, it becomes an important factor
for pesticides that dissipate rapidly as is shown by some pesticides having
their DT50 extended by over 50% when the application occurs later in the
day. All of this shows the model’s ability to represent pesticide fate for
a variety of conditions and its value in providing farmers with informa-
tion regarding the fate of pesticides on plants following application. In
the future, dissipation and photodegradation studies will be conducted to
expand and optimize the model and it will be linked with toxicity thresh-
olds to provide farmers with information on how long their pesticide is
effective against pests and when it is safe to introduce pollinators.

*686 Digital tools and data science enable conservation on agricul-
tural lands*

P.M. Bachman, Bayer Crop Science / Regulatory Science; P. Carroll, F.
Dohleman, S. Ward, The Climate Corporation

Modern agricultural innovations, including the application of digital tools
and data science can help support sustainable and productive agricultural
practices and decision making, and can facilitate the incorporation of
habitats to support biodiversity in agricultural as well as non-crop areas
of the landscape. Digital applications also can help characterize and
maintain functional habitats on public and private lands. Specific to agri-
culture, satellite imagery, data analytics, and vegetation maps can help
farmers identify and elect to set aside patches of habitat alongside crop
fields for the benefit of multiple non-target species including those that
support ecosystem services. Suitable habitat sites could be non-crop areas
in agricultural landscapes, including field borders, conservation strips,
riparian buffers, roadsides, Conservation Reserve Program (CRP) land,
marginal land, wetlands, easements, and utility rights-of-ways. Ensuring
functional habitats for non-target species can appear to be at odds with
a variety of land use objectives: crop and livestock production, urban-
ization, housing, transportation, and industry. To be successful, these
efforts generally require cooperation of multiple stakeholders including
private landowners, government agencies, academia, non-governmental
organizations, and the private sector. This presentation will focus on how cross-sector partnerships and the application of digital tools to promote landscape management decisions that can meet multiple land use objectives, have been developed and utilized to support multi-species habitat efforts and conservation programs.

687 Topeka shiner populations in the context of multiple stressors: a hybrid modeling approach
A. Schmolke, Waterborne Environmental, Inc.; S.M. Bartell, Cardno, Inc.; C. Roy, N.S. Green, D. Perkins, Waterborne Environmental, Inc.; N. Galic, R. Brain, Syngenta Crop Protection, Inc. / Environmental Safety

Threatened or endangered species face challenges to their continued existence from multiple stressors. For example, habitat loss and modification were indicated as substantial threats to the Topeka shiner (Notropis topeka), a small cyprinid fish endemic to the US Midwest, when it was listed under the Endangered Species Act. Topeka shiner habitats are associated with intensive row crop agriculture, overgrazing, urbanization, road construction, and hydrologic alteration. However, assessments of risks to the species are usually limited to individual factors, such as direct effects from potential exposures to pesticides. We developed a hybrid modelling approach to assess Topeka shiner population dynamics and viability within the context of multiple factors including physical habitat characteristics, water quality, and land management practices. Topeka shiner habitat restoration efforts in Iowa are focused on restoring oxbows. Therefore, we simulated physical and chemical characteristics of these oxbow habitats, including their food web structure, as well as aspects of Topeka shiner biology and ecology. Land management was modeled indirectly by characterizing associated alterations of environmental inputs to the modeled oxbow. Land management influences included alterations to oxbow hydrology, temperature, light exposure, and influxes of nutrients, sediments, and pesticides. We analyzed scenarios of realistic ranges of these conditions in Iowa oxbows to assess their implications for long-term population dynamics of the Topeka shiner. With this hybrid modeling approach, we present a methodology for integrated assessments of ecological risks posed by land management and benefits of conservation measures designed to recover listed species. This modelling approach is intended to complement endangered species assessment by informing conservation/stewardship activities in an effort to enhance species viability.

688 Refinement of pesticide exposure estimates through robust incorporation of spatial datasets
M.F. Winchell, H. Rathjens, Stone Environmental Engineering & Science, Inc. / Environmental Systems Modeling

A critical component to advancing pesticide ecological risk assessments is the improvement of pesticide exposure estimates across the landscape. Numerous environmental factors contribute to variability of pesticide exposure potential in both space and time. Traditional screening level approaches to estimating pesticide exposure make generalizations in landscape characteristics that lead to conservative scenarios assumed to apply over broad geographic regions. This generalization of conservative exposure predictions does not allow for the identification of actual locations and conditions that lead to the highest exposure risk, which in turn does not allow for the adoption of conservation measures that result in the greatest ecological benefit. Methods and data sets that allow for spatially explicit predictions of pesticide exposure have been developed over the past decade or longer and are gradually making their way into more routine ecological exposure and risk assessments. Many of these methods rely upon multiple years of high-resolution land use and crop data sets at the national scale to characterize potential pesticide use sites and are coupled with high resolution landscape data sets, such as elevation, slope, and hydrography. Application of these methods allow for prediction of probabilistic pesticide exposure distributes at a spatial scale, such as a water body or small catchment, that can more accurately assess risk to ecological communities or individual species and strategically target effective conservation measures. Examples of these spatially explicit pesticide exposure modeling approaches will be presented along with a discussion on how barriers to their wide implementation in ecological risk assessments might be overcome.

689 Genetically Engineered Crops: An Integral Component to Achieve the Benefits of IPM
S. Levine, Bayer AG - Crop Science Division / Regulatory

Over fifty years ago, an integrated concept combining chemical and biological control became the foundation for all integrated pest management (IPM) programs. Genetically Engineered (GE) crops producing insecticidal Bacillus thuringiensis (Bt) proteins have become an important component of IPM, particularly in cotton. GE crops were planted on over 100 million hectares in 2018 and have been one of the most quickly adopted pest control technologies in part because of the role in IPM. Assessment of environmental safety has been, and continues to be, a key element of research for GE crops. Extensive laboratory and field testing has been conducted to evaluate the potential impacts of Bt crops on multiple species of natural enemies. These studies have shown that commercialized Bt proteins are highly selective. Because of their high specificity for their targets they have become a cornerstone in overall integrated pest management (IPM) that compliment other approaches required for sustainable pest control. This presentation summarizes the impact of GE Bt crops on natural enemies through the perspective of risk assessment and how GE crops have enabled biological control to become a more effective component of IPM.

Citizen Science in Environmental Chemistry and Toxicology

690 A citizen science approach estimating titanium dioxide released from personal care products
E. Wu, Jinan University / School of Environment; M. Seib, Madison Metropolitan Sewerage District; A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering

Titanium dioxide (TiO2) has been widely applied in personal care products (PCP), with up to 36% of TiO2 found in PCPs present at the nanoscale. Due to the high quantity produced and wide application of TiO2, it can enter the wastewater treatment plant (WWTP) and ultimately the environment, along with a great potential for human exposure through various routes. Citizen science is utilized to inform the prevalence and usage of TiO2 containing PCP on a household scale, which generates information as to the quantity of TiO2 entering the WWTP, the portion ultimately discharged to the environment, and the individual exposure concentrations. Citizen science inventories were generated to estimate the quantity of TiO2 entering the WWTP from consumer products and to determine which products had the greatest contribution. The estimated values were compared with water samples from the WWTP which quantified the amount of total titanium present using ICP-AES. In terms of exposure, results suggest sunscreen and body wash are two major contributors for dermal route of TiO2 exposure, while toothpaste has some potential for exposure through the oral route. 0.153 - 3.9 mg/day of TiO2 (0.06 -1.4 µg/day of TiO2 NP) was estimated to be ingested when 10% toothpaste ingestion was assumed. The estimated average daily TiO2 exposure ranges from 2.8 to 21.38 mg TiO2/person-day (an estimated 1 to 7.7 mg TiO2 NP/person-day). These values estimated in present study were at a similar level with previous top-down estimations, suggesting that a citizen science approach is valid to estimate the loading of TiO2, and potentially other emerging contaminants, while at the same time engaging with community stakeholders.
691 Microplastics in the Ottawa River: Utilising citizen science to expand spatial sampling for microplastics in water and sediment samples

S. Forrest, J. Vermaire, Carleton University / Geography and Environmental Studies; L. Holman, Ottawa Riverkeeper

Citizen science methods were developed to engage the public and to quantify microplastics in river water and river sediments throughout an approximate 600 km length of the Ottawa River, Ontario, Canada. An established group of volunteers already sampling water quality through a ‘citizen science’ hub for the Ottawa Riverkeeper, engaged in two citizen science projects to expand spatial coverage for detecting microplastics in water and sediment of the Ottawa River. The first project involved filtering 100 L of river water from the Ottawa River, then the volunteers were asked to obtain a 1 L bulk sample of river sediment in a subsequent project. All but one of the river samples (n = 43) contained microplastics, with the vast majority of microplastics identified as microfibres. Microplastic concentrations ranged from 0.02 to 0.41 microplastic pieces per litre. Utilising citizen scientists, or citizen samplers in microplastic quantification for a freshwater ecosystem provides numerous advantages including actively engaging citizens in the research, ease of recruiting volunteers within the established Ottawa Riverkeeper network, and expanded spatial coverage at minimal additional costs. However, despite these advantages, there are some important considerations while working with volunteers. For example, during the research, a small number of volunteers mislabelled sample sheets (e.g. labelling as control instead of river sample) and for the water sampling project, lower volume samples were prone to microfibre contamination. Recommendations for future citizen science sampling programs for freshwater microplastic research include utilising an established and engaged network, ensuring both field and laboratory control samples are included in the research to obtain estimates of contamination with microplastic fibres, and increasing the amount of water filtered to obtain more reliable estimates of microplastic pollution in our freshwater ecosystems.

692 Using citizen science to increase herbicide monitoring data across the state of Wisconsin

A. White, University of Wisconsin, Madison / Civil and Environmental Engineering

The herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) is used in Wisconsin as a treatment for invasive Eurasian watermilfoil. However, the degradation rate and resulting lifespan of 2,4-D can vary widely, with complete degradation observed to range from 70 to 150 days, potentially increasing risk for off-target effects to fish and aquatic plants due to unintended long exposure times. We investigated the microbial and photochemical degradation of 2,4-D in aquatic environments using a large field campaign to monitor 2,4-D loss following whole-lake herbicide treatments in 8 lakes across the state of Wisconsin. We enlisted the help of homeowners on each lake that was studied to collect daily water samples at multiple locations on the lake to better calculate degradation rates. Stakeholders were actively engaged and involved in additionally weekly regular sampling and were shown how to use field equipment as well as were given an opportunity to provide valuable feedback on their perceptions and values around whole lake herbicide treatments. The involvement of the community created a richer data set than just weekly sampling would have allowed and fostered a connection between the community and scientists for long with the intentions of supporting future collaboration and follow up studies.

693 Proper Disposal of Pharmaceuticals: Targeting Communications to Veterinarians

S. Zuck, Illinois-Indiana Sea Grant / University of Illinois Extension; W. Sander, University of Illinois at Urbana-Champaign / Department of Veterinary Clinical Medicine

Pharmaceutical compounds from medications have been detected in waterways for over two decades throughout the United States and internationally. Veterinarians play a significant role in prescribing, directing, and administering medications to all animal patients ranging from dogs and cats to cattle and swine. Better understanding attitudes and practices of veterinary disposal practices provides an avenue to address environmental concerns through education and outreach, policy discussion, and possible interventions. Illinois-Indiana Sea Grant, in collaboration with the American Veterinary Medical Association, the University of Illinois College of Veterinary Medicine, and other partners, have engaged this audience with outreach and communication efforts since 2011. But while prescribing and disposal practices are well known in human healthcare, much less has been characterized in veterinary healthcare, which leaves a gap in the knowledge of how best to reach this audience. A cross-sectional survey of pharmaceutical disposal practices among veterinarians in the Great Lakes Region (Minnesota, Wisconsin, Illinois, Indiana, Michigan, and Pennsylvania) was administered electronically in the summer of 2019. The survey gathered information on each veterinarian’s disposal practices as well as their instruction to clients and outreach needs. Results of this survey will help inform, target, and refine communication of best management practices. By understanding the role of the veterinarian, we can better reach this audience with necessary outreach and communication and a greater impact can occur on reducing medication entering the waterways and the environment.

694 Organic Micropollutants in Lakes in Upstate New York: Citizen-Science Based Monitoring

S. Wang, T. Zeng, Syracuse University / Civil and Environmental Engineering; M. Perkins, Upstate Freshwater Institute; S. Moran, SUNY-ESF / Department of Environmental Studies

Engaging citizen volunteers offers a promising way to form a transferable and scalable monitoring framework with large spatiotemporal coverage while raising public awareness on environmental issues. Citizen-based water quality programs rarely incorporates concurrent monitoring of organic micropollutants (OMPs). To address this gap, we piloted a citizen-based OMP monitoring study in collaboration with lake associations in Upstate New York. We engaged citizen monitors from 18 lakes within the Citizens Statewide Lake Assessment Program (CSLAP) in water sample collection for OMP analysis during summer 2018. We applied a suspect screening method using liquid chromatography-high-resolution mass spectrometry to screen for over 2000 OMPs contained in an in-house database. We confirmed and quantified a total of 35 OMPs and their transformation products in lake water samples collected by citizen monitors. Overall, the summed concentration of OMPs in 18 CSLAP lakes ranged from 4,000 ng/L to 18,000 ng/L, and the most frequently detected OMPs were atrazine, atrazine-2-hydroxy, metolachlor OA, DEET, and benzothiazole. We divided the confirmed OMPs into three categories by their primary uses: pharmaceuticals, pesticides and transformation products, and household chemicals. Based on concentration similarities of OMPs, 18 lakes were clustered into three groups by cluster analysis. We then applied a non-target screening method to identify common mass spectral features present within each lake group. The purpose of the non-target screening is to identify more OMPs in the samples that are not included in the suspect screening. In total, 108 and 81 unique features were prioritized in lake groups 1 and 2, respectively, for further analysis. Our ongoing work focuses on expanding the OMP monitoring network within the CSLAP program and exploring the relationships between OMP occurrence patterns and general water quality and land use data.

695 Mischief in the Harbour: Experiential learning course designed to bridge the gap between scientists and policy makers

E.M. Leonard, McMaster University

This experiential learning course designed at McMaster University (ON, Canada) was a collaborative initiative between McMaster students, the Bay Area Restoration Council (BARC) and CityLAB Hamilton to support the environmental priority created by Our Future Hamilton’s 25 Year Community Vision. The aim is to provide students with fieldwork experience in a relevant context while helping create a better
community in Hamilton, ON, Canada. Hands-on field experience is difficult to obtain during undergraduate and graduate degrees, however, field work is one of the most sought after skills in many government, consulting and industry jobs in the environmental sectors. The field component of this course gave students a sound foundation of field-work basics, as well as providing context to their efforts and most importantly bridged the gap between scientists and policy makers. These skills will be essential for employability and transition to the workforce. Students also gained a greater understanding of the interdisciplinary nature of issues facing the City and how important it is that we all work cohesively together. We provided the City of Hamilton with preliminary data on whether the implementation of boulders to rehabilitate the shoreline will favour the success of the invasive fish species, the round goby. Our results indicate that after a year of boulder implementation, there is a slight increase in round goby success. Students conceptualized a project to help rectify this issue by adding breeding habitat for the two native fish species (long perch and rock bass) that were found in the area and therefore have the biggest probability of success. We hope that these habitats can be implemented in a follow-up course in the spring. It is evitable with our changing climate that weather events, such as heavy rainfall and high winds, that occurred in the City of Hamilton in 2017 will continue at a greater scale and therefore the use of boulders to provide structure to preserve shorelines will continue to be implemented. Therefore, understanding the effects on shoreline ecosystems is paramount to both the support of native fish habitat as well as deterring the success of the invasive round gobies along these shorelines. Creating more experiential and interdisciplinary courses such as this will create sound foundations of communication between universities, policy makers and the community to share knowledge, increase scientific understanding, and improve the overall impact of research being conducted at institutions.

Integrative Avian Ecotoxicology in a Changing World

696 Emerging contaminants in European raptors: Review and recent developments for analysis of bisphenols and benzophenones

V. Jaspers, Norwegian University of Science and Technology (NTNU) / Department of Biology; S. Gonzalez Rubio, University of Córdoba / Analytical Chemistry Department; B. Oró Nolla, University of Barcelona / Department of Chemical Engineering and Analytical Chemistry; S. Lacorte, IDAEA-CSIC / CSIC; A. Ballesteros Gomez, University of Córdoba / Analytical Chemistry Department; A. Asimakopoulos, Norwegian University of Science and Technology / Chemistry

The European Raptor Biomonitoring Facility (ERBF) COST Action is an open network of researchers and practitioners working towards coordinated Europe-wide monitoring of contaminants in raptors (https://www.cost.eu/actions/CA16224). The overall goal of the ERBF is to support the implementation of EU chemicals regulations and thereby reducing chemical risks to raptors themselves, to the wider environment and to human health. In the framework of the ERBF, we have performed a thorough literature review concerning the presence, concentrations, and (bio-)analytical methods currently available for emerging organic contaminants in raptors (birds of prey and owls) in Europe. We aimed to identify the occurrence and recent trends in emerging contaminants, but also to identify gaps and to provide general guidelines for future raptor biomonitoring initiatives at a pan-European scale. In addition, we have performed analysis on raptor tissues for both bisphenols and benzophenones at the Norwegian University of Science and Technology (NTNU). We searched Web of Science and PubMed for articles related to the analysis of flame retardants (including polybrominated diphenyl ethers - PBDEs), poly- and perfluoroalkyl substances (PFASs) and other emerging contaminants, such as neonicotinoids, parabens, bisphenols, UV-filters (benzophenones) and microplastics in raptors in Europe. Among 44 articles found, 30 included PBDEs, 9 reported on novel flame retardants, 12 on PFASs and only 4 on other emerging contaminants (i.e. neonicotinoids (2), parabens (1) and UV filters (1)). Results indicated that most of the studies were from Western Europe only and that there is still a great lack of published studies on emerging contaminants in raptors. All concentrations reported in these articles were at the ng g⁻¹ level. Screening results at NTNU indicated that the most suitable tissues and species for the determination of bisphenols and benzophenones in raptor tissues were both preen gland and liver from white tailed eagles (Haliaeetus albicilla - WTE) because of higher concentrations and less matrix effects. The highest concentration was found for bisphenol A (BPA) at 805.9 ng g⁻¹ in a preen gland sample. In addition, 38 livers from WTE from Norway were analysed for bisphenols and benzophenones. BPA was found in 55% of the samples (1.08 - 87.31 ng g⁻¹ ), while bisphenol AF, a fluorinated alternative, was found in 84% (1.80 - 11.12 ng g⁻¹) and benzophenone-1 was found in 26 % (2.80 - 14.30 ng g⁻¹).

698 Bioaccumulation of Environmentally Novel Highly Brominated and Methoxylated Contaminants in Great Lakes Herring Gulls and Possible Terrestrial Sources

T.A. Smythe, Carleton University / Chemistry; L.T. Gauthier, R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division

It has become increasingly clear that abiotic and biotic transformation processes can greatly influence contaminant persistence and fate in the environment and accumulation in wildlife and other biota. Herring gulls (HG, Larus argentatus) have been used as a sentinel species for long-term contaminant monitoring in the Laurentian Great Lakes (GL) for over 40 years. In 2011, several novel methoxylated polybrominated diphenoxybenzenes (MeO-PB-DiPhOBzs) were measured in HG eggs, and was the first report of these contaminants in the environment. MeO-PB-DiPhOBzs are believed to be metabolites of photodegradation breakdown-products of the tetradecabromo-1,4-diphenoxybenzene (TeDB-DiPhOBz) flame retardant following dietary accumulation, and are subsequently transferred to their eggs. To date, MeO-PB-DiPhOBzs have only been reported in GLHG eggs and tissues, while any corresponding hydroxy-PB-DiPhOBz metabolites and non-conjugated PB-DiPhOBz by-products have yet to be reported in any environmental medium. It was previously hypothesized that the gulls were exposed to the photolytic PB-DiPhOBz by-products via their aquatic diet component, but previous work did not detect these by-products in fish or sediment samples collected from the GL. Recently, MeO-PB-DiPhOBzs were detected in regurgitant samples collected from the HG nesting colony on Channel-Shelter Island (CS Isl.) within the Saginaw Bay, Lake Huron. This suggests instead that MeO-PB-DiPhOBzs are bioavailable contaminants and HGs are exposed to them directly (via the diet), which then bioaccumulate, and are transferred in ovo to their offspring. To assess potential terrestrial exposure to MeO-PB-DiPhOBzs, the objective of the present study was to adapt existing organic flame retardant (OFR) methods to quantify MeO-PB-DiPhOBzs in soil samples collected from nesting sites on CS Isl. via GC-ECNI-MS. Two of the same (pentabromo) MeO-PB-DiPhOBz congeners previously measured in HG tissues and eggs were measured at low part-per-billion (ppb, wet weight) levels in 7 of the 9 soil sites sampled. Two previously unmeasured penta-brominated congeners were also tentatively identified and confirmed through GC-EI-MS measurement of the corresponding molecular ion clusters centered around m/z 686. Additionally, earthworms collected from CS Isl. were analyzed and found to contain the same MeO-PB-DiPhOBz congeners measured in the soil, and may suggest a possible terrestrial diet source for accumulation in the HGs.
699 Intrinsic and extrinsic drivers of trace element and perfluorinated compound burdens in blood of a coastal avian predator: An integrative approach
A. Carravieri, University of Liverpool; C. De la Vega, University of Liverpool / School of Environmental Sciences; Y. Yonehara, University of Tokyo / Atmosphere and Ocean Research Institute; S. Burton, F. Daunt, M. Newell, Centre for Ecology & Hydrology / Edinburgh; R.F. Shore, Centre for Ecology & Hydrology / Lancaster; R. Jeffreys, University of Liverpool; M. Pereira, Centre for Ecology & Hydrology / Lancaster; J. Green, University of Liverpool / School of Environmental Sciences

Anthropised coastal environments receive a plethora of chemical pollutants from agricultural, industrial and urban sources. Coastal avian species are thus exposed to a complex mixture of contaminants via food ingestion, especially those that feed on the seabed. Yet, few integrative studies have quantified how concurring intrinsic and extrinsic factors determine contaminant exposure in these species. This hampers our ability to use them as bioindicators of coastal pollution, and to understand toxic effects. Here we quantified 11 trace elements and 17 perfluorinated compounds in blood cells and plasma, respectively, of benthic-feeding European shags Phalacrocorax aristotelis breeding in the Firth of Forth, a Scottish estuary with a long history of petro- and agrochemical releases. By using an exceptional long-term dataset, and a novel combination of approaches, our aim was to test the effect of individual traits (sex, age) and trophic ecology on individual variation in contaminant burdens. Shags had high mercury (Hg) burdens (range 0.65-3.21 µg/g wet weight, ww), while selenium (Se) burdens were relatively low (1.59-8.60 µg/g ww), when compared to other seabirds. PFOS, PFOA and PFNA concentrations were exceptionally high (63-396, 3.46-53, and 4.48-44 ng/g ww, respectively), comparable to those found in the congeneric double crested cormorant Phalacrocorax auritus breeding in the highly-polluted North American Great Lakes. In contrast to age, sex-related differences were strong, and were in different directions depending on the contaminant. Males had Hg, PFOA and PFNA concentrations two-fold higher than females, while the opposite was true for Se and PFOS. Biologging data (GPS, time, and depth recorders) revealed unexpectedly strong sexual segregation in foraging sites, despite the small foraging range (~15 km from the colony). Females relied extensively on sandy seabed areas, whereas males targeted rocky seabeds. This sexual segregation was reflected in bulk stable isotopes of carbon and nitrogen (δ15N), and in δ15N values of specific amino-acids in seabeds. This sexual segregation was reflected in bulk stable isotopes of carbon and nitrogen (δ15N), and in δ15N values of specific amino-acids in blood. Isotopic values were strong predictors of Hg, Se and PFOS loads. Collectively, these results suggest that females and males fed on prey from distinct coastal food webs, exposing themselves to different contaminant mixtures. This study stresses the importance of feeding specialisation on contaminant exposure at highly localised scales, and raises toxicological concern for the focal shag population.

700 Comparative effects of three neonicotinoids on food consumption and body mass in common farmland birds
M.L. Eng, University of Saskatchewan / Toxicology; B. Stutchbury, York University; C.A. Morrissey, University of Saskatchewan / Department of Biology

Seed-eating birds that stop to refuel or breed in agricultural areas could be exposed to neonicotinoids through several pathways, including the ingestion of treated seeds. Previous studies in white-crowned sparrows (Zonotrichia leucophrys) found that exposure to sublethal concentrations of imidacloprid significantly reduced body mass and fat stores, and decreased food consumption. We hypothesized that neonicotinoids can reduce body mass by acting as an appetite suppressant. Therefore, we compared the effects of three common neonicotinoids following single oral exposure to sublethal concentrations (0, 10, 20, 30 mg/kg) relative to a food restricted diet (10 or 50% reduction) in a common farmland bird species, red-winged blackbirds (Agelaius phoenicuclus). We found that imidacloprid significantly reduced food consumption (high dose decreased 68%) and body mass (high dose decreased 5%), and birds in the two highest dose groups exhibited significant neurotoxic symptoms. For clothianidin and thiamethoxam, there was no significant effect of dose on body mass over time, and no overt neurotoxicity, confirming their lower relative toxicity to imidacloprid in a songbird species. However, there were dose dependent trends (increasing body mass in clothianidin, decreasing body mass in thiamethoxam, reduced food consumption for both compounds) suggesting potential for fueling effects in situations where exposures are repeated or chronic. When food availability was restricted to approximate the amount of food consumed by imidacloprid exposed birds, mass loss was similar to that of the imidacloprid treatments. We will also present results from analysis of plasma triglycerides (indicates fattening), glyceral and β-hydroxybutyrate (measures of fasting and fat catabolism) to characterize the physiological effects of neonicotinoid exposure compared to fasting. Sublethal effects on fueling and condition in migrating and breeding birds can have subsequent effects on reproduction and survival, providing a mechanism link between neonicotinoid exposure and population-level consequences.

701 Assessment of the transcriptome in tree swallow (Tachycineta bicolor) nestlings from the Great Lakes Maumee River Area of Concern
C. Tseng, Baylor University / Environmental Science; T.W. Custer, C.M. Custer, US Geological Survey / Upper Midwest Environmental Sciences Center; N.K. Karouma-Renier, US Geological Survey / Patuxent Wildlife Research Center; H. Butler, SGS AXYS Analytical Services, Ltd. / Metabolomics; B. Chandramouli, SGS AXYS Analytical Services, Ltd.; J. Cosgrove, Eurofins Eaton Analytical, LLC; C.W. Matson, Baylor University / Environmental Science

Tree swallow (Tachycineta bicolor) have proven uniquely suited for assessing contaminant exposures and biomarker responses in birds from the Great Lakes, in response to Polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), polychlorinated dibenzo-p-dioxins and dibenzo-furans (PCDD/PCDFs), polybrominated diphenyl ethers (PBDEs), and a variety of pesticides and other contaminants of emerging concern (CECs). In 2016, nestlings were collected from six locations on the Maumee River, across different land uses. Transcriptome-wide gene expression projects have been initiated in collaboration with the USGS and funded by The Great Lakes Restoration Initiative. RNA-Seq analysis was carried out on nestlings collected from the Maumee River. We built a tree swallow genome using linked-read technology with scaffold N50 > 15.6 Mbp and a BUSCO score of 88%. The tree swallow genome was further annotated using the transcriptome assembly and avian proteome. We assessed the in situ transcriptomic effects of multiple environmental contaminants exposure to tree swallow (Tachycineta bicolor) nestlings in the Maumee River AOC. Transcriptomic patterns between different sampling sites were correlated with different types of land uses, such as agricultural, industrial, and urban. PBDEs and an organochloride were correlated with transcriptomic variation between sampling sites, which was consistent with the findings of a metabolomics study of the same populations. Associated functional terms and pathways were determined and compared with enriched pathways from metabolomic responses.

702 The effects of weathered MC252 ingestion on red blood cell integrity, aerobic scope, and flying performance in zebra finches (Taeniopygia guttata)
C. Goodchild, Oklahoma State University / Integrative Biology; S. DuRant, University of Arkansas

Crude oil spills that occur at stopover sites for migratory birds are of particular concern due to the potential to delay arrival at summer breeding grounds. In addition to external oiling impairing feather integrity, crude oil ingestion can damage red blood cells (RBCs). However, direct links between RBC damage, metabolic scope for activity, and flying performance have not been established. In this study, we orally dosed zebra finches (Taeniopygia guttata) with 2 or 6 ml kg⁻¹ of artificially weathered MC252 crude oil for 28 days and measured RBC integrity using traditional and novel endpoints, basal and maximal metabolic rates using a ‘hop-flutter’ chamber, and vertical flight speed and take-off acceleration using a high-speed camera. Crude oil ingestion caused
a decrease in packed cell volume (PCV) and an increase in reticuloocytes, indicating regenerative anemia. Furthermore, we also detected an increase in fluorescent heme-degradation products (HDPs), a novel tool for measuring oxidative damage. HDP fluorescence was negatively correlated with maximal aerobic scope, indicating a link between oxidative damage to RBCs and metabolic scope for activity. Interestingly, we found that birds exposed to crude oil increased vertical flight speed. Crude oil ingestion also caused a decrease in fat-score, which may explain why oiled birds increased flight speed. Our results suggest that RBC damage has metabolic consequences, but the metabolic effects do not influence short-range, burst flight.

703 The ins and outs of birds’ feather moult: Effects of methylmercury contamination

C. Bottini, R. Whiley, B. Branfereen, University of Western Ontario / Department of Biology; S.A. MacDougall-Shackleton, University of Western Ontario / Psychology

Although the deleterious effects of methylmercury (MeHg) on wildlife have long been studied, many questions remain unanswered. In particular, how exposure to environmental stressors interacts with MeHg exposure is little studied. In addition to toxicity damage, MeHg may affects birds’ annual cycle transitions, affecting the timing of reproduction, moult and migration. Moult is a particularly challenging period for birds as it is energetically costly and involves reduced flight and escape ability. Because optimal timing is necessary for birds to survive during these transition periods, a delay or advance in seasonal life-stages, such as moult, may increase risks for bird populations. In order to better understand how stressors and MeHg exposure combine to affect seasonal transitions more experimental studies are required. To study this, we exposed song sparrows (Melospiza melodia) to either environmentally relevant doses of MeHg, unpredictable food stress, or both. During a 3-months exposure and further 3-months post-exposure period we measured the birds’ moult as well as two mediators of energy balance: basal metabolic rates and the thyroid hormone T4. Preliminary results indicate that unpredictable food stress decreased males’ basal metabolic rates, while MeHg exposure decreased T4 and increased birds’ basal metabolic rates. Furthermore, moult duration was increased in MeHg exposed birds and was affected by T4 levels. Neither stress nor basal metabolic rate influenced moult duration. The effect of MeHg on moult duration was primarily driven by advancing moult initiation, perhaps to facilitate depuration. Longer moult duration could lead to poorer flight performance and reduce survival and potentially affect bird migration. Although we did not find interactive effects of unpredictable food stress and MeHg, our results highlight that MeHg can affect annual cycle transitions, even after mercury exposure has ended.

Effects of Abiotic Factors and Chemical Additives on the Toxicity of Environmental Contaminants to Aquatic Organisms

704 Risk determinations of chemical mixtures are primitive and unreliable: Accepting complexity and improving site assessments

G.A. Burton, E.C. Cervi, University of Michigan / School for Environment and Sustainability

There have been many efforts by scientists and regulators to develop methods and models to predict chemical mixture toxicity. Some of these efforts were addressed in Pellston Workshops (e.g., Valencia) with a host of international experts. None of these approaches seem reasonable in terms of accurately determining adverse ecological effects or thresholds, given the plethora of possible synergistic, additive, and antagonistic chemical interactions at fluctuating concentrations, in changing environments, to a wide range of species. Indeed, this is beyond the capability exposures derived in the laboratory. Critical exposure knowledge on temporal/spatial variance, degradation rates and metabolites, diurnal flux of fate/effect drivers for the tens of thousands of chemicals (in the presence of inorganic/organic particles) are unknown. If we do not know these real-world exposures - we do not know their risk. This level of complexity makes modeling mixture effects an academic exercise and not useful for effective ecosystem management decisions. We suggest a better approach to chemical mixture risk is to accept this reality and rather focus on in situ toxicity-based endpoints, as lab-based assays cannot replicate important fluctuating site conditions. If the goal of environmental management is protecting and restoring ecosystems, it should be done accurately, moving beyond mandates of using antiquated assessment tools.

705 Incidence of Apoptosis in Larval Red Drum (Sciaenops ocellatus) Co-exposed to Crude Oil and Ultraviolet Radiation

R.R. Leeds, University of North Texas / Biological Sciences & Advanced Environmental Research Institute; J.T. Magnusson, University of California, Riverside / Environmental Sciences; J. Lucero, A. Lund, University of North Texas / Biological Sciences, Advanced Environmental Research Institute; D. Schlenk, University of California, Riverside / Environmental Sciences; R. Chavez, Texas Parks and Wildlife Department / Coastal Fisheries Division; A.P. Roberts, University of North Texas / Biological Sciences, Advanced Environmental Research Institute

Poly cyclic aromatic hydrocarbons (PAHs) are ubiquitous in the environment as a result of both natural and anthropogenic activity. Exposure to ultraviolet (UV) radiation can significantly increase the toxicity of crude oil PAHs to aquatic organisms through a process known as photo-induced toxicity. Photo-induced toxicity of PAHs is well documented in aquatic organisms and can result in increased mortality, reduced fecundity, delayed hatching, impaired development, and increased oxidative stress. Red drum (Sciaenops ocellatus) are an important fishery resource in the Gulf of Mexico and in the southeastern Atlantic Ocean. Co-exposure to UV radiation significantly increases the toxicity of crude oil to red drum larvae, leading to increased mortality. However, less is known about the sub-lethal effects of photo-induced PAH toxicity on early life stage red drum. The present study investigated the incidence of cell apoptosis in early life stage red drum following co-exposure to crude oil and UV radiation. Larval red drum (24 hours post fertilization) were exposed to a sub-lethal concentration of weathered crude oil (0.29-0.30 µg/L ∑PAH50) with and without UV radiation. Larvae were sampled following 24 h and 48 h exposure and apoptosis was quantified using a TUNEL assay. Transcriptomic effects were assessed using RNA sequencing. Apoptotic fluorescence significantly increased in the eyes following 24 h and 48 h exposure to crude oil with and without UV. Apoptotic fluorescence was greatest in the skin following 24 h and 48 h exposure to crude oil with UV, indicating photo-induced toxicity. Consistent with these phenotypic responses, pathways associated with phototransduction, eye development, and dermatological disease were among the top predicted pathways impacted in red drum larvae co-exposed to oil and UV determined through bioinformatic, RNA sequencing analysis. These results suggest that increased apoptosis is one sub-lethal effect of photo-induced PAH toxicity in larval red drum which may impair development and physiological function. This research was supported by the Gulf of Mexico Research Initiative (GoMRI) Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER II).

706 Influence of ultraviolet radiation on transcriptomic effects in larval red drum (Sciaenops ocellatus) following exposure to weathered crude oil

J.T. Magnusson, University of California, Riverside / Environmental Sciences; R.R. Leads, University of North Texas / Biological Sciences & Advanced Environmental Research Institute; A.P. Roberts, University of North Texas / Advanced Environmental Research Institute; D. Schlenk, University of California, Riverside / Environmental Sciences

The Deepwater Horizon (DWH) oil spill released millions of barrels of oil into the Gulf of Mexico, coinciding with peak spawning periods of economically and ecologically important fish species, such as red drum...
The goal of this research is to better understand the underlying mechanisms of toxicity of oil to early life-stage fish, relative to oil exposure alone. Disease associated with heart failure was predicted in larvae co-exposed for 24 hours, relative to 362 DEGs when co-exposed to oil and UV. The alone induced 21 differentially expressed genes (DEGs) in larvae exposed to oil and UV for 48 hours. This data suggests that UV exposure enhances the toxicity of oil to early life-stage fish, relative to oil exposure alone. The goal of this research is to better understand the underlying mechanisms of photo-induced toxicity in early-life stage fish exposed to oil. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER II).

707 Buoyancy Control as a Mechanism of Stressor Avoidance in Pelagic Fish Embryos

C. Pasparakis, Rosenstiel School of Marine Sciences / Marine Biology and Fisheries; R. Faillettaz, RSMAS University of Miami / Marine Biology and Ecology; J.D. Stieglitz, University of Miami / Marine Biology and Ecology; D.D. Benetti, RSMAS University of Miami / Department of Marine Ecosystems and Society; C.B. Paris, University of Miami (RSMAS) / Department of Ocean Science; M. Grosell, University of Miami / Marine Biology and Ecology

Since the Deepwater Horizon (DWH) spill over 9 years ago, more than 50 peer reviewed studies have been published addressing impacts of this environmental disaster on different species of teleost fish. The majority of studies exploring DWH oil toxicity in fish utilize acute exposures (1-2 days), mid-range test temperatures (26-28°C) and otherwise ambient laboratory conditions, leaving a pressing need for more long-term exposures, exposures at the upper and lower levels of environmentally relevant temperatures, and studies investigating combined effects and interactions of oil with other environmental stressors. Stressors occurring in surface waters in the Gulf of Mexico (GoM), such as increased temperature, cardio-toxic oil slicks and ultraviolet radiation (UVR), pose a serious threat to the fitness and survival of the vulnerable early-life stages of pelagic fish. Therefore, a mechanism in which embryos can alter buoyancy and thus control their vertical position in the water column may be indispensable to the sustainability of these fisheries. Co-exposure to crude oil and other environmentally relevant stressors, such as increased temperatures and UVR altered buoyancy in developing mahi-mahi (Coryphaena hippurus) embryos. Further, recovery of normal buoyancy was observed once the exposure period was completed and all the stressors had been terminated, indicating this response is highly dynamic and not solely pathological. To further investigate this mechanism, specific gravity of mahi-mahi embryos exposed to different environmental conditions was measured using density gradient columns and values were subsequently employed to estimate terminal velocity. Loss of buoyancy at earlier time points in exposed embryos resulted in altered vertical distributions in the natural environment, significantly reducing exposure to UVR and other stressors known to be most intense in surface waters. Buoyancy control as a mechanism of UV-avoidance has recently also been characterized in cobia (Rachycentron canadum) embryos, providing evidence that this response is not unique to mahi-mahi. The finding that pelagic embryos regulate buoyancy following exposure to certain stressors may have significant implications for how we perform and interpret future toxicity tests. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).

708 Effects of acute and chronic co-exposures to hypoxia and lead on the cladoceran, Daphnia magna

C.M. Emadi, F. Bonatesta, University of North Texas / Environmental Science; S. Nayek, G. Verbeck, University of North Texas / Department of Chemistry; E. Mager, University of North Texas / Department of Biological Sciences

Hypoxia is a common stressor in many freshwater ecosystems owing to a variety of factors, such as temperature, eutrophication, and water column stratification. Lead (Pb), a non-essential metal and pervasive pollutant, represents another source of stress in many aquatic environments; yet, little is known regarding the potential interactive effects of co-exposure to hypoxia and Pb in aquatic animals. This study focused on the acute and chronic effects of co-exposure to hypoxia and Pb on the water flea, Daphnia magna. A number of known responses are elicited by hypoxia in D. magna, including elevated ventilation and heart rates, a dramatic increase in hemoglobin (Hb) concentration and an increase in Hb oxygen binding affinity. Exposure to Pb, on the other hand, has been shown to decrease Hb production in a variety of animals, including D. magna. The significance of Hb in convective oxygen transport within D. magna presumably changes with development, becoming more important as it grows beyond the critical size limit for purely diffusive oxygen transport (< 1 mm in normoxia). Thus, sensitivity to Pb might be related to oxygen transport effects that likely vary with age-related size differences and oxygen availability. To examine this possibility, acute (48 h) mortality bioassays were performed for different life stages of D. magna (neonates and adults) using Pb exposures in normoxia and hypoxia. Additionally, the effect of prior long-term acclimation to hypoxia was assessed for adults. Chronic (21 d) Pb bioassays were also performed in normoxia and hypoxia to assess various sublethal endpoints, including reproductive output and growth. To gain insight as to the potential role of Pb-induced impairment on convective oxygen transport in contributing to the observed toxicity, Hb concentrations and oxygen consumption rates were measured. Finally, laser ablation ICP-MS was used to localize Pb accumulation and identify the likely target tissues of Pb in adult D. magna. This data should aid in predicting the toxicity of Pb to D. magna in conditions of environmental hypoxia and help clarify the mechanistic underpinnings of such toxicity.

709 Interactive effects of wastewater effluent and hypoxia on the health and metabolic physiology of Atlantic killifish

S. Lau, H. Mehdi, McMaster University / Biology; S. Balshine, McMaster University / Department of Psychology, Neuroscience & Behaviour; G. Scott, McMaster University / Department of Biology

Modern wastewater treatment plants (WWTP) are currently unable to remove some contaminants from the discharged effluent, including pharmaceuticals and personal care products (PPCPs), polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs). Effluent receiving waters can also experience periodic and sometimes severe episodes of oxygen depletion (‘hypoxia’). Our objective was to examine the interaction between these stressors, and determine whether exposure to WWTP effluent disrupts the adaptive responses of fish to hypoxia. We tank exposed adult Atlantic killifish (Fundulus heteroclitus) for 21 days to 100% effluent from a secondary treatment WWTP, to one of two levels of hypoxia (O2 tension of 5 or 2 kPa), or to control conditions in a full factorial design. We then measured standard and maximal metabolic rates, aerobic scope, hypoxia tolerance, and various indices of body condition (body mass, condition factor, hepatosomatic index). Neither wastewater exposure or hypoxia, alone or in combination, altered body condition. Exposure to chronic hypoxia alone led to expected improvements in hypoxia tolerance. However, although wastewater exposure had little effect in normoxia, fish that were concurrently exposed to chronic hypoxia had reduced standard metabolic rates and impaired hypoxia.
tolerance. Therefore, wastewater exposure disrupted the adaptive physiological adjustments of killifish to chronic hypoxia, which would likely constrain their ability to cope in environments where these stressors co-occur. This suggests that the combination of stressors near WWTPs can have significant interactive effects on the physiology and fitness of fish.

710 Combined effects of temperature and pharmaceuticals on freshwater ecosystem processes
H.M. Alhassen, University of Canberra / Institute for Applied Ecology
Freshwater ecosystems are affected concurrently by multiple stressors, and it is hard to predict the consequences of combined stressors based on the knowledge of stressors separately. Global warming marked by elevated temperatures is a significant ecological stressor, and there is an urgent need to understand its effects on freshwater ecosystems in combination with other stressors. Pharmaceuticals are emerging as contaminants of global concern. Despite abundant evidence of the widespread nature of pharmaceutical compounds (PCs) in freshwater ecosystems, empirical evidence for their effects on ecosystem processes such as nutrient cycling remains scarce. The decomposition of leaf litter is a critical ecosystem process in freshwater ecosystems. Using laboratory bioassays, our study reports the combined effects of temperature and a mixture of four common PCs on the decomposition rates of leaf litter. The four pharmaceuticals; caffeine (stimulant), paracetamol (analgesic), sertraline (antidepressant), and amoxicillin (antibiotic) were mixed at a range of concentrations. Leaf decomposition rates were tested in the presence of the mixture at three different temperatures. Experiments were carried out with and without mayfly Atalophlebia sp. to assess any invertebrate-mediated effects on leaf litter processing. We assessed the combined stressors’ effects on extracellular enzymes (ECEs) released from freshwater microbes by measuring their activities fluorometrically, and on leaf litter breakdown overall using weight loss. With Atalophlebia absent leaf decomposition rates were low at high temperature and high PCs’ mixture concentrations. The same observation noticed in the presence of Atalophlebia. The activity of β-glucosidase was highest with Atalophlebia absent, low PC concentrations and high temperatures. For leucine-AP there was a reduction in activity as the temperature increased in PC controls and all PC treatments. No significant effect was observed of either temperature or PC concentrations on phosphatase activity. Phosphatase and leucine-AP activities were significantly reduced at high temperature for both but at low mixture concentration for phosphatase and high PCs mixture concentrations for leucine-AP. This study suggests that there is potential for profound and unexpected ecosystem-wide effects of combined pharmaceuticals and temperature stressors in freshwater ecosystems.

711 Sediment, Surface Water and Porewater PCB Concentrations and Bioaccumulation Before and After Sediment Remediation by In Situ Activated Carbon
M.S. Bowersox, J.W. Roberts, Tetra Tech, Inc. / Laboratory Department; K. Craigie, M. Martin, S. Brenner, Tetra Tech, Inc.; K. Young, E. Ashley, CDM Smith
Historic manufacturing and operational activities at an industrial complex have resulted in elevated levels polychlorinated biphenyls (PCBs) in the sediments of the waterbodies surrounding the site. Due to the concern of potential ecological and human health risk from elevated PCBs entering the aquatic food chain, remediation of the sediment was completed using both sediment removal via dredging and in situ activated carbon amendment. Pre-treatment bioaccumulation, whole sediment, surface water and porewater data were collected for areas targeted for the in situ treatment. Approximately 2,500 tons of AquaGate affixed with 10% powdered activated carbon (PAC) was placed over 13.7 acres to amend the top 6 inches of surface sediments with a targeted 5 percent loading of PAC. Surface water and porewater concentrations were measured using passive polyethylene sheet samplers. Porewater concentrations were also measured using passive samplers in the Lumbriculus variegatus test chambers. The total dissolved PCB concentrations in sediment porewater pre-treatment ranged from 11.2 ng/L to 57.2 ng/L, with an average of 25.6 ng/L. Post-treatment porewater PCB concentration ranged from 0.271 ng/L to 2.29 ng/L, with an average of 0.889 ng/L. This represents an average porewater reduction of 96.5%. Pre-treatment near sediment surface water concentrations ranged from 7.2 to 35.1 ng/L while post-treatment the near sediment surface water total PCB concentrations were reduced to 1.6 to 8.1 ng/L. This represents nearly an 89% reduction in near sediment surface water concentrations. Pre-treatment bioaccumulation tissue PCB concentration ranged from 0.273 to 0.793 µg/g, with an average PCB concentration of 0.429 µg/g wet weight. Post-treatment tissue concentrations ranged from 0.020 to 0.0349 µg/g, with an average of 0.0196 µg/g. This represents an average reduction of 95.4%. Biota sediment accumulation factors were reduced by an average of 84%. The in situ treatment was effective in reducing the sediment porewater and bioaccumulation tissue PCB concentrations. The five year post remediation goals for sediment porewater and invertebrate tissue were an 80% and 70% reduction, respectively. The one-year post remediation results indicated a 96.5% reduction in porewater and a 95.4% reduction in tissue concentration indicating that the five-year goals have been met only one year post remediation.

Fate and Effects of Metals: Regulatory and Risk Assessment

712 Differential selenium uptake by periphyton in boreal lake ecosystems
M.D. Oldach, D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences
Selenium (Se) is an essential trace element with a narrow margin between essentiality and toxicity that is released into aquatic environments by certain industrial practices. Excess Se is rapidly and efficiently assimilated into food webs in a site-specific manner by primary producers and transferred to higher trophic levels through dietary pathways. Most field studies focused on the ecological risk assessment of Se have been conducted in warm-water systems, and more research is needed regarding the effects of increased Se loading in cold freshwater systems and how certain site-specific factors influence the incorporation of Se into food webs by periphyton. The objective of this study was to diminish this uncertainty by quantifying Se uptake at the base of food webs in representative boreal lake ecosystems. This was achieved by investigating if concentration-dependent differences exist in periphyton enrichment functions (EFs) of Se and determining if water chemistry plays a role in Se uptake by periphyton. Periphyton samplers composed of textured glass plates were deployed in five lakes with variable water chemistry at the IISD-ELA (International Institute for Sustainable Development-Experimental Lakes Area) and grown naturally for six to eight weeks. Periphyton plates were then removed and exposed to environmentally relevant concentrations (control [0.1-0.2], 0.5, 1, 2, 4 µg Se/L) of Se as selenite, and allowed to incubate under ambient conditions for eight days. Aqueous and periphyton total Se concentrations, and periphyton community composition were quantified. Significant concentration-dependent differences in EFs were found within the five lakes tested (0.0497< p< 0.0001), with the highest EFs in four of the five lakes occurring in the lowest (0.5 µg Se/L) treatment. Enrichment functions generally decreased with increasing Se concentration, and significant differences in EFs were also found between lakes at the 2 and 4 µg Se/L treatments. The results of this research provide insight on the biodynamics of Se assimilation at the base of boreal lake food webs, which can potentially inform ecological risk assessments in cold freshwater ecosystems in North America.
713 Resolving selenium exposure risk in the San Francisco Estuary using a conservative physical transport model, a benthic bivalve, and a native cyprinid

Estuaries provide critical habitat for migratory birds, shellfish, and juvenile fish and serve as migration corridors for anadromous fish. They are also under constant threat from a range of stressors including climate change, eutrophication, contaminants and invasive species. Estuaries are arguably among the most challenging environments to manage for threats due to layered complexities of physical transport in a tidal environment, biogeochemical gradients, habitat utilization, and competing resource needs from fish and wildlife and those supporting economic development and urbanization. In the San Francisco Bay Estuary (SFE) geological sources of selenium (Se), an essential element and potent teratogen, are concentrated and mobilized through core economical activities including oil refining and agriculture to levels that could threaten fish and wildlife. Ecosystem models for Se evaluate the potential risks of Se in different environments, including the SFE. However, refinement of the factors and processes parameterized in the model is still needed to effectively estimate and regulate for individual and population-level impacts of Se on fish and wildlife. Particular challenges include how to optimally: (1) represent spatial and temporal variation in tissue concentrations and turnover rates of Se in endemic species and (2) link tissue exposures to dietary and ultimately aqueous exposures. Here we present preliminary results for the aqueous transport and distribution of Se loads in the SFE based on a 3D coupled hydrodynamic-water quality model (no biogeochemical reactions). In addition, we assess the consequence of those distributions on Se exposures in a benthic clam (Potamocorbula amurensis) and its predator, a native demersal minnow Sacramento Spleitail (Pogonichthys macrolepidotus). Overall, Se exposures in Spleitail reflected broad regional gradients in Se concentrations in their prey Potamocorbula and in modeled aqueous Se. In contrast, Se concentrations in Potamocorbula, sampled on a monthly timescale, showed a complex relationship with modeled aqueous Se through time (seasonally and inter-annually), highlighting the need to consider other biotic processes including lags for tissue Se uptake rates and factors affecting the biogeochemical cycling of bioavailable Se in determining Se exposures. These results highlight the value of using a conservative physical transport model with tissue exposure data as a first step in identifying processes that should be considered when refining ecosystem models for Se.

714 Effect of Body Size on Mercury Concentration in Shoreline Spiders

M.P. Hannappel, M. Chumchal, R. Drenner, Texas Christian University / Department of Biology; A. Nolan, Texas Christian University

Recently, terrestrial shoreline spiders have been proposed as biosentinels of bioaccumulative aquatic contaminants such as mercury (Hg). Terrestrial shoreline spiders become contaminated with Hg when they feed on Hg-contaminated emergent aquatic insects. Although the effect of body size on contaminant bioaccumulation in other biosentinels, such as fish, has been thoroughly examined, there has been much less research on the effect of body size on concentrations of Hg in shoreline spiders. In this study, we determined the effect of body size on Hg concentrations in six taxa of shoreline spiders belonging to four families (orb-weavers, [Araneidae], long-jawed orb-weavers, [Tetragnathidae: Tetragnatha spp.], jumping spiders [Salticidae] and wolf spiders [Lycosidae: Pardosa spp., Rabidosa spp. and Schizocosa spp.]). We collected 683 spiders during the day using sweep nets or by hand at night on May 14, June 5, 11, 20 and July 6, 2018, from 14 human-made ponds at the Lyndon B. Johnson National Grasslands, Texas, USA. Average total Hg (THg) concentrations (mean ± SE) ranged from 63 ± 4.0 ng/g to 246 ± 20.1 in Schizocosa spp. and Araneidae, respectively, and were significantly different between spider taxa. We measured the length of the tibia + patella of the first leg as a proxy for body size and found that spider THg concentration increased significantly with spider body size for Araneidae, Tetragnatha spp., Salticidae and Pardosa spp. The percent of variation in THg concentration explained by spider body size ranged from 16% to 40% for Pardosa spp. and Salticidae, respectively. This study indicates that concentrations of Hg in shoreline spiders differ between spider taxa and within taxa by spider size. We recommend that future studies of Hg in shoreline spiders assess spider size.

715 Application of the Biotic Ligand Model (BLM): A Case Study in Assessing Metals’ Risk to Vernal Pool Species

S. Thakali, AECOM / DCS Remediation - Risk Assessment; B.J. Reese, AECOM / DHS Remediation; R.G. Stahl, DuPont (retired); T. Stilley, Environmental Remediation

An ecological risk assessment is being performed at a former munitions manufacturing site in Connecticut. The majority of the site is forested upland habitat, with limited or no contaminant migration pathways associated with historical activities; aquatic and ephemeral and permanent wetland habitats are also present, including vernal pools. As such, exposure of vernal pool biota to site-related metals is being addressed as part of the risk assessment. A screening evaluation of existing wetland and vernal pool surface-water data indicated potential for ecological risks associated with copper, lead, and nickel based on exceedance of applicable ecological screening values, including hardness-based Water Quality Criteria for Aquatic Life. However, the initial screening did not account for two site-specific factors in assessing potential risk due to metals in vernal pools and aquatic habitats: site-specific metals bioavailability and site-specific receptors of concern, including the obligate vernal pool invertebrate and amphibian species. To account for site-specific metals bioavailability, sample-specific water quality criteria were calculated based on the application of the Biotic Ligand Model for copper. The Model incorporates site-specific bioavailability-modifying factors such as dissolved organic carbon, pH and alkalinity. For the existing datasets with estimated dissolved organic carbon and alkalinity, exceedances of BLM-based criteria for copper were minor, indicating generally limited aquatic bioavailability of copper at the site. To further account for the site-specific receptors of concern, amphibian-specific No Observed Effect Concentrations (NOECs) were derived based on literature data. Metals exceedances were also generally minor relative to the amphibian-specific NOECs, indicating that potential risks are likely limited to an important group of site-specific receptors. Surface-water samples were collected in May 2018 to represent current site conditions, fill data gaps for a refined evaluation of bioavailability, and capture the most relevant season for aquatic exposure of vernal pool species. Evaluation of the current data includes an initial screening and subsequent refinements using BLM-based water quality criteria for copper and amphibian-specific NOECs. The focus of this presentation will be the results of the BLM-based evaluation of site-specific metals bioavailability and toxicity, and consideration of site-specific receptors of concern for the on-site vernal pools and wetland habitats.
716 Subsistence Fish Consumption in Alaska: Using Regional Monitoring Data to Evaluate Risk and Bioavailability of Dietary Methylmercury

K.N. Bridges, Geosyntec Consultants, Inc. / Epidemiology; C. Furin, State of Alaska Department of Environmental Conservation / Environmental Health; J. McLaughlin, Alaska Division of Public Health / Epidemiology; R. Gerlach, Alaska Department of Environmental Conservation / Environmental Health

US Federal fish consumption guidelines recommend that women and children (10-years of age and older) consume 227-340-grams of fish low in mercury (the majority of which is present as methylmercury; MeHg) per week. This ingestion rate (IR) is thought to maximize the health benefits conferred by fish, while protecting against concerning levels of dietary MeHg exposure. However, subsistence communities in Alaska (AK) often rely on fish (especially salmon) as a primary protein source. As a result, the statewide mean fish IR in AK is 1,043-g/week, which is more than 3 times the maximum weekly Federal consumption recommendations. Growing concerns about dietary MeHg exposure have resulted in declining fish consumption rates in subsistence communities, a trend accompanied by marked increases in diseases of poor nutrition and declines in mental health (this phenomenon has also been documented elsewhere). These trends prompted State health officials to issue less restrictive fish consumption guidelines, citing public health concerns and historically low MeHg concentrations in AK fish. Moreover, Federal fish consumption guidelines do not consider dietary co-exposure to selenium (Se), which reduces MeHg bioavailability when present in molar ratios \( \geq 1 \) (Se:Hg). In order to determine whether the risk posed by increased MeHg exposure outweighs the benefits of traditional subsistence diets in AK, we used data from multiple statewide monitoring programs to perform an integrated evaluation of risk. Our analysis considered [Hg] and [Se] data from the Fish Monitoring Program (AK Division of Environmental Health- Office of the State Veterinarian), regional surveys of subsistence harvests and natural resource use (AK Department of Fish and Game- Division of Subsistence), data from the AK Maternal Hair Mercury Monitoring Program (AK Division of Public Health-Environmental Public Health Program), and disease incidence surveillance reports (AK Division of Public Health-Section of Epidemiology). Results of multiple analyses indicate that the benefits of traditional subsistence diets outweigh the risks associated with increased MeHg exposure in AK, in nearly all scenarios.

717 A regional comparison of long-term responses to stream restoration in mining impacted watersheds

Predicting the period of time required for disturbed communities to recover following the removal of a stressor is one of the key challenges in restoration ecology. However, despite investments exceeding $1 billion (U.S.) per year in stream restoration, our ability to quantify the effectiveness of these projects remains limited. In this study we describe results of a large-scale comparative analysis of 4 western watersheds (Arkansas River, CO; Clark Fork River, MT; Leviathan Creek, CA; Panther Creek, ID) recovering from the long-term impacts of historical mining pollution. Physicochemical data, metal concentrations and benthic macroinvertebrate communities were collected from reference and impacted sites for 20-29 years in each of the 4 watersheds. Because data in each watershed were collected before and after initiation of restoration treatments, this project provided an unprecedented opportunity to compare long-term responses to improvements in water quality across a broad geographic region. The primary objectives of the study are to: a) quantify responses to restoration treatments across broad geographic regions; b) assess differences and similarities in the timing of recovery across regions; c) identify biotic and abiotic factors that determine responses to restoration; and d) identify species trait syndromes that are especially responsive to changes in water quality. Results showed significant reductions in metal concentrations in each watershed following treatment, but the magnitude of these improvements was influenced by seasonal and annual variation in stream discharge. Responses of benthic communities to improvements in water quality and the length of time required to achieve reference conditions also varied among watersheds and among endpoints. For example, measures of abundance and species richness rapidly returned to reference conditions in some watersheds, whereas recovery of metal-sensitive taxa (e.g., grazing mayflies) failed to recover in others. Our results demonstrate the importance of long-term studies for assessing restoration effectiveness in mining-contaminated watersheds within the broader context of regional changes in climate.

718 Validating Predictions of the Freshwater Copper Biotic Ligand Model in an Effluent-Dominated Very Hard Water

Site-specific water quality criteria for copper (Cu) derived using the Biotic Ligand Model (BLM) is under consideration for a power generating station’s discharge to an ephemeral watercourse in the arid Western U.S. The receiving water is usually dry, and only contains water in response to precipitation, or during effluent discharge. Water quality characteristics of both the effluent and the receiving streams consisted of highly elevated concentrations of cations and anions used for BLM inputs. Furthermore, a synthetic metal chelant, Versene 100 (a commercial form of ethylenediamine tetraacetic acid; EDTA) is added to the effluent to eliminate Cu toxicity to the cladoceran Ceriodaphnia dubia. Because of the high ion concentrations and the use of a synthetic form of dissolved organic carbon (DOC), it was unknown whether the BLM would accurately predict toxicity and, hence, derive protective Cu criteria. We conducted toxicity tests with Cu in effluent and two downstream site waters to empirically evaluate the extent to which the BLM accurately predicts Cu toxicity in these waters to C. dubia, along with another sensitive cladoceran, Daphnia magna. Samples were collected when water was present only owing to facility discharge. BLM parameter input concentrations exceeded software validation ranges by 2-5x, and also were higher than previously published examples of BLM prediction accuracy in very hard waters. Observed LC50 values were higher than those predicted by the BLM in all but one case, with the highest difference (4.25x) being observed in water collected from the first downstream location using D. magna. However, other than this value, all the observed/predicted ratios were less than +/- 2x. Therefore, BLM toxicity predictions tended to be conservative, but were within ranges known to adequately predict Cu toxicity in all but one test. These results support the accuracy of the BLM even under conditions of strongly elevated input ion concentrations 2-5x outside the model parameter ranges, and in the presence of a synthetic form of DOC. Therefore, regulatory use of the BLM may still be reasonable and protective under such conditions, reducing the need for additional validation testing or use of empirical alternatives for criteria derivation such as the water-effect ratio.

719 Comparative Performance of Multiple Linear Regression and Biotic Ligand Models for Estimating the Bioavailability of Aluminum and Copper

K. Brex, EcoTox / Marine Biology and Ecology; R.C. Santore, L. Tear, A.J. Edgington, D.K. DeForest, Windward Environmental, LLC

Predicting the bioavailability of metals in aquatic ecosystems is critical to assessing risks posed by elevated metal concentrations and for setting water quality guidelines that are not under- or over-protective. It has been well established that multiple toxicity modifying factors (TMFs) influence metal bioavailability and ultimately toxicity to aquatic organisms. Two general modeling frameworks are currently used to estimate metal bioavailability: mechanistically-based Biotic Ligand Models (BLMs) that predict metal accumulation at a hypothesized site of toxic action and statistically-based Multiple Linear Regression (MLR) models that estimate the effects of TMFs on observed toxicity. Both modeling approaches
Advancing the OMICS into Regulatory Frameworks: Case-Studies and Perspectives - Part 2

720 The re-evaluation of quinone toxicity contribution within particulate matter
H. Peng, K. Yeung, D. Hall, University of Toronto / Chemistry; J.X. Zhao, Queens University

Particulate matter (PM) is a type of air pollution known to increase the risk for respiratory diseases such as asthma and lung cancer. It is an ongoing problem for highly populated cities such as Beijing and Delhi. Quinones are secondary-emission pollutants found in PM and are a major PM toxic component alongside transition metals. Quinones exert toxicity either through reactive oxygen species (ROS) production or through protein alkylation. Traditional toxicological assays for atmospheric pollutants, such as the dithiothreitol (DTT) assay, primarily focus on ROS-mediated toxicity, thereby ignoring the cysteine-mediated pathway. In our study, we tested for the oxidative potential response for both transition metals and quinones with the DTT assay and the Antioxidant Response Element (ARE) assay which measures for cellular oxidative responses via the nuclear factor-like 2 pathway. We determined that the DTT assay overestimates the oxidative potentials of metals and underestimates the oxidative potentials of quinones when compared to the ARE assay results. Our results suggest an overlooked pathway in quinone toxicity which may be cysteine-mediated. We then obtained in vitro cell lysate results using a chemo-proteomics method and several quinones showed strong cysteine reactivity (20 μM or less) including methylquinone and benzoquinone; both of these quinones were underestimated in the DTT assay. Furthermore, using high-resolution quadrupole Orbitrap mass spectrometry, we explored and identified the kinetics and cysteine modification by quinones respectively. Our chemo-proteomics, ARE, and mass spectrometry results were mainly in agreement. In addition, the cysteine-reactivity of quinones using in vivo chemo-proteomics and the identities of several cysteine-affected proteins by quinones using global mass spectrometry proteomic analysis will be discussed. In sum, our study suggests that cysteine-mediated toxicity must be considered in tandem with traditional ROS studies when evaluating the toxicity of quinones in PM thus allowing for better evidence-based regulation and prioritization of atmospheric pollutants.

721 The genomes of the marine copepods Tigriopus japonicus and Paracyclopina nana: expression profiles of 98 cytochrome P450 genes upon cypermethrin
J. Park, J. Lee, Sungkyunkwan University

Copepods are globally distributed in aquatic environments and play important roles in the aquatic ecosystem. The benthic copepod *Tigriopus japonicus* and the pelagic copepod *Paracyclopina nana* are considered suitable model organisms for ecology, evolution, and ecotoxicology. In this study, we assembled and characterized both copepods genome. The total length of the assembled genome of *T. japonicus* was 196.6 Mb and the number of final scaffolds was 358 with an N50 value of 1.69 Mb. A total of 22,505 genes were annotated after manual curation, while the total length of the assembled genome of *P. nana* was 197 expression and hypomethylation of CpG island of HTR4. Finally, in vivo experiments showed that respiratory resistance of wild type mice was 1.5 to 3.5-fold of that of HTR4-null mice (p < 0.01) after 10-days inhalation exposure of FA. Development of lung inflammation and fibrosis were also alleviated in HTR4-null mice. Our study demonstrated the use of CRISPR genomic screen in providing candidate genetic variations to molecular epidemiology through uncovering the link between genes and toxic effects of chemicals.

722 Identification of Critical Role of HTR4 for Susceptibility of Lung to Formaldehyde Using Genome-Wide CRISPR-Cas9 Screening
M. Tian, Nanjing University; X. Zhang, Nanjing University / Environmental Science

Formaldehyde (FA), a common air pollutant, can induce human lung inflammation and fibrosis, which has been linked to chronic obstructive pulmonary disease (COPD). Understanding on interactions between genetic susceptibility of COPD and FA exposure is limited. Here we conducted a CRISPR genomic screen to identify key gene deletions essential for sensitivity of human alveolar epithelial cells (A549) to FA. The results revealed that HTR4, the top under-represented gene, might be involved in susceptibility of human lung to FA exposure. Firstly, deletion of HTR4 could decrease resistance (1.5 to 2-fold) to cytotoxicity induced by FA. Second, HTR4 was required in the molecular mechanism mediated inflammation and fibrosis responses induced by FA in A549 cells. FA up-regulated HTR4 because of suppressed miR-197 expression and hypomethylation of CpG island of HTR4. Finally, in vivo experiments showed that respiratory resistance of wild type mice was 1.5 to 3.5-fold of that of HTR4-null mice (p < 0.01) after 10-days inhalation exposure of FA. Development of lung inflammation and fibrosis were also alleviated in HTR4-null mice. Our study demonstrated the use of CRISPR genomic screen in providing candidate genetic variations to molecular epidemiology through uncovering the link between genes and toxic effects of chemicals.

723 What can gastrointestinal omics contribute to the discussion? - A case study with single-walled carbon nanotube exposures in largemouth bass
A. Warmington, University of Florida / Environmental and Global Health; M. Nouri, University of Florida; S. Robinson, University of Florida / Environmental and Global Health; A. Buerger, University of Florida / Environmental and Global Health; N.D. Denslow, University of Florida / Physiological Sciences; T. Sabo-Attwood, J.H. Bisesi, University of Florida / Environmental and Global Health

Single-walled carbon nanotubes (SWCNTs) are a class of nano-sized molecules utilized in a variety of industrial, medical, and commercial applications. Limited regulation coupled with predicted increases in production and subsequent environmental release of these materials outline the necessity for studies exploring their environmental impact. Previous studies from our team have found that SWCNTs may impact nutrient uptake and growth during dietary exposure. However, our evidence suggests that SWCNTs are not absorbed across the gastrointestinal epithelium, leading to our hypothesis that SWCNTs are interacting...
at the gut-epithelium-luminal interface before excretion to cause these responses. In two separate chronic feeding experiments, we fed adult largemouth bass (Micropterus salmoides) food coated with single-walled carbon nanotubes (SWCNTs, 2.5 mg/kg) for 1.5 months. To explore the potential interactive relationship between the gut and SWCNTs in vivo, we employed a targeted and non-targeted multi-omics approach, including targeted semi-quantitative gene expression analysis, 16S metagenomic sequencing of the fecal microbiome, and non-targeted gut lipidomics. Though we did not see an impact on select genes related to intestinal inflammation, stability, and nutrient metabolism, analysis of both the intestinal microbiome and lipidome revealed significant differences between exposed and control animals. Metagenomic analysis of 16S data revealed numerous impacted KEGG functional pathways related to nutrient homeostasis in the intestinal microbiome, including microbial biosynthesis and metabolism of essential biomolecules. Fish exposed to dietary SWCNTs for 1.5 months had a differentially impacted intestinal lipidome, with an overall reduction across several lipid classes, including numerous bioactive lysophospholipids. The implications of this case study are two-fold: (1) The gastrointestinal system may serve as an early indicator of exposure and effect, and should be considered in regulatory approaches that utilize ‘omics approaches, especially in the case of dietary exposure to chemicals with nonspecific mechanisms of toxicity, such as SWCNTs; (2) These data indicate that while transcriptomics based approaches are most common in discussion in integration of ‘omics into regulatory frameworks, these data alone do not tell the whole story and a multi-omics approach may help to identify new or cryptic adverse outcome pathways.

724 Effects of single and combined low concentrations of neuro-active drugs on Daphnia magna reproduction and transcriptomic responses

I. Fuertes, IDAEA-CSIC; B. Campos, Unilever / Safety and Environmental Assurance Centre SEAC; C. Rivetti, Unilever; B. Piña, Spanish National Research Council - CSIC / Environmental Chemistry / Institute of Envirornmental Assessment and Water Research; C. Barata, IDAEA -CSIC / Department of Environmental Chemistry

Assessing the risks of emerging contaminants such as neuro-active pharmaceuticals in the environment requires an understanding of their joint effects at low concentrations across species. Here, we assessed effects of single and ternary equi-effective mixtures of environmental relevant concentrations of propranolol, diazepam and carbamazepine on the crustacean Daphnia magna. We report enhancing reproductive effects in D. magna adults and global transcriptomic effects on pre-adolescent individuals employing a whole transcriptome cDNA microarray. Joint mixture effects on cumulative reproduction were additive and the same pattern was observed on the global transcriptome. The three compounds affected a total of 3248 genes, which were grouped into four clusters: two of them included 1897 gene transcripts behaving similarly in single and mixture treatments. The third and fourth clusters grouped genes differently transcribes upon exposure to diazepam and propranolol. Functional transcriptomics indicated that the four clusters shared major de-regulated signalling pathways implicated on energy, growth, reproduction and neurological related processes, which may be responsible for the observed reproductive effects. Our study, thus, showed additive effects at the transcriptional and physiological level and is providing a novel approach to the analysis of environmental relevant mixtures of neuro-active compounds.

725 Using a multiomic approach to unravel the mecanisms of acrylamide neurotoxicity

B. Pina, D. Raldua, IDAEA-CSIC / Environmental Chemistry; E. Prats, CID-CSIC; M. Casado, Institute of Environmental Assessment and Water Research IDAEA-CSIC / Department of Environmental Chemistry; M. Faria, Institute of Environmental Assessment and Water Research (IDAEA-CSIC); F. Puig-Castellví, Institute of Environmental Assessment and Water Research (IDAEA), Spanish Research Council (CSIC); Y. Pérez, I. Alfonso, IQAC-CSIC; N. Reyero, US Army Engineer Research and Development Center; M. Arick II, Mississippi State University; A. Admon, T. Ziv, Technion - Israel Institute of Technology; C. Hsu, IGBB-Mississippi State University; S. Ben-Lulu, Technion - Israel Institute of Technology

Acrylamide is a recognized carcinogen that has strong neurotoxic effects in humans and in experimental animals, although the molecular mechanisms underlying these neurotoxic effects are not completely understood. We studied acrylamide neurotoxicity in the brain of adult zebrafish using an integrated approach that included biochemical, transcriptomic (RNAseq), proteomic (MALDI-TOF mass spectrometry) and metabolomic (proton-NMR)d ata. We detected the formation of acrylamide adducts with thiol groups in the brain metabolome, and the accumulation of acrylamide conjugates and propionamide adducts in Cys residues of proteins. These combined effects resulted in a quasi-complete depletion of glutathione and to the inactivation of different components of the thioredoxin system. Multi-omic functional analyses identified microtubules, thioredoxin-related proteins, transmembrane transport, redox metabolism and catalytic activity, as the cellular functions significantly altered by acrylamide in the fish brain. We propose that the combined loss-of-function of both redox metabolism-related systems configure a perfect storm that explains most, if not all, observed acrylamide neurotoxic effects.We derived an Adverse Outcome Pathway for acrylamide neurotoxicity at different levels of organization, from molecular interactions to behavioral changes. We think our mechanistic approach may be applied to other neurotoxicants that may share its toxic mode of action.

726 Systems toxicology assessment of chemical induced development cardiotoxicity in zebrafish larvae

R. Li, Philip Morris International / Environmental Toxicology; C.M. vom Berg, Eawag Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; M. Talikka, J. Szostak, Philip Morris International; S. Madan, J. Doerpinghaus, Fraunhofer Institute for Algorithms and Scientific Computing; F. Martin, M.C. Peitsch, J. Hoeng, Philip Morris International; A. Zupanic, Eawag Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology

One of the main challenges that needs to be addressed before OMICS technologies receive regulatory acceptance in chemical risk assessment is a specific and quantitative connection to adverse outcome of regulatory concern. We present a multidisciplinary pipeline that can be used to develop causal biological networks that describe the current knowledge on adverse outcomes of interest and evaluate the perturbation of the network, based on measured transcriptomics datasets. The pipeline includes semiautomatic literature curation and annotation based on the BEL language, causal network development and integration of transcriptomics data for the purpose of network scoring. To demonstrate the utility of our approach for zebrafish cardiotoxicity, we developed a zebrafish cardiotoxicity network, which includes approximately 400 nodes (including mRNA abundance, protein activity, biological process activation, etc) and >500 connections. We then screened 20 different chemicals environmentally relevant chemicals for cardiotoxicity using the fish embryo toxicity test and additional measurements of cardiotoxic outcomes (eg cardiac edema, bradycardia) and took samples for RNA-Seq after 120 h of chemical exposure. The RNA-Seq datasets were to score the perturbation of the cardiotoxicity network and the results of our screening approach will be presented at the conference.
727 Environmental in vivo NMR metabolomics study of small aquatic living organisms
M. Tabatabaei Anaraki, University of Toronto, Scarborough; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences; A.J. Simpson, University of Toronto Scarborough / Department of Physical and Environmental Sciences

Metabolomics, the final downstream product of gene transcription and the closest to the phenotype of biological systems, is one of the omics that with other omics will prove beneficial to allocate capturing the entire view of a complex biological system in response to stressors. Metabolomics is highly time-dependent and monitoring metabolites’ fluctuation in a real time by implementing in vivo metabolomics allows clearer metabolite pattern and hence better reflection of responses to stressors. Nuclear magnetic resonance (NMR) spectroscopy is the most common technique for metabolomics, and, so far, the only non-destructive and non-invasive analytical tool that meets this demand and allows to study alive organisms, in vivo. Moreover, the water flea Daphnia is a very common test model organism in regulatory toxicology and freshwater ecology. The current study indicates how the in vivo NMR metabolomics technique can be applied to the small aquatic living organism, Daphnia magna. Also, to demonstrate the application of the technique, D. magna are monitored over time and their metabolic trajectories are compared in two control and exposed conditions.

Structural Fires and Wildfires: Environmental Hazards and Firefighter Health

728 Ambient Air Quality Assessment around Olusosun Dumpsite: Hazards and Firefighter Health
S. Ishola, A.L. Ogundaybi, University of Lagos, Akoka / Department of Cell Biology and Genetics; O. Adenekan, University of Lagos, Akoka / Department of Chemistry; K.O. Omogatowo, University of Lagos, Akoka / Cell Biology and Genetics (Environmental Biology)

Olusosun dumpsite is one of the largest waste repositories in sub-Saharan Africa and also an economic hub for the low-income class in Lagos. Olusosun dumpsite has gradually experienced a massive expansion towards residential and commercial areas perhaps due to rapid urbanization, population growth and injudicious use of the dumpsite and on the 14th March 2018, it witnessed a serious fire outbreak that destroyed many properties, causing a displacement of people and lasted for about 12 weeks - attributed to the build-up of methane from the anaerobic decomposition of piled-up waste. Hinged on this concern, this study assessed the air quality around Olusosun dumpsite during and after the incident for health risk assessment. Ten ambient air quality parameters which include temperature, wind speed, carbon monoxide (CO), volatile organic compounds (VOCs), hydrogen sulphide (H2S), nitrogen dioxide, sulphur dioxide, nitrogen monoxide, and particulate matter (PM2.5 and PM10) were jointly monitored by the Lagos State Environmental Protection Agency (LASEPA) monitoring team at ten different sampling points around Olusosun dumpsite using standard air quality monitors with readings taken as mean values (μgm-3) and compared with WHO and LASEPA permissible limits. During the fire outbreak, CO ranged from 1.20±0.13 to 8.95±3.52 (exceeded the limit of 5.00 ppm); VOC ranged from 0.05±0.03 to 1.87±0.81 (exceeded the limit of 0.008 ppm). PM2.5 ranged from 377.16±60.34 to 815.40±80.04 (exceeded the limit of 25 μgm-3); PM2.5 and PM10 during and after the fire outbreak exceeded both LASEPA and WHO permissible limits. PM2.5 positively correlates with wind speed at 0.05 significant levels. Based on the findings in this study, it could be adjudged that people living or working around Olusosun dumpsite are likely to be exposed to high levels of CO, VOC, PM2.5 and PM10 which could cause respiratory disorders and other health havoc. Hence, periodic monitoring for air quality and compliance in this area should be done. Nonetheless, there is a critical need for government and relevant stakeholders to stimulate genuine concern for environmental sustainability via implementation of integrated waste management and public sensitization on health risks associated with injudicious use of dumpsites; otherwise it would be a disservice to humanity.

729 Investigating the Fate of Polycyclic Aromatic Hydrocarbons in Fort McMurray Wildfire Ash
L. Chan, University of Alberta / Department of Chemistry; Y. Zhang, University of Alberta / Department of Laboratory Medicine and Pathology; S. Styler, University of Alberta / Department of Chemistry

The 2016 wildfire in Fort McMurray, Canada was a major environmental disaster that released significant amounts of toxic pollutants into the atmosphere, causing severe and widespread negative impacts on both local air quality as well as that of distant regions. Polycyclic aromatic hydrocarbons (PAHs), which are one of the major toxic pollutant classes produced by the wildfire, decay in the environment primarily through heterogeneous oxidation mechanisms on environmental surfaces. Previous studies on other surfaces (e.g. soot and silica) have shown that PAH reactivity is highly substrate dependent, but thus far no studies have been conducted on fire ash, which limits our ability to predict PAH lifetimes on this substrate. In this study, we subjected Fort McMurray wildfire ash to photochemical and oxidative transformations in a simulated atmospheric chamber, and thereby determined the kinetics of PAH decay in situ. These kinetic parameters are valuable because they can be used to predict the lifetime and long-term environmental contamination potential of wildfire PAHs and may help determine when safe PAH thresholds are reached to direct post-fire remediation efforts and inform public health guidelines.

730 Assessing wildfire influence on indoor/outdoor chemical concentrations and diffusive flux between soil and air of PAHs in the Western United States
C.C. Ghetu, Oregon State University / Environmental and Molecular Toxicology; D. Rohlman, Oregon State University; K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology

This study focused on the development and testing of a proof of concept, community engagement approach to understanding the fate of polycyclic aromatic hydrocarbons (PAHs) from wildfires, and their potential for human exposure. Passive sampling devices were deployed in air at 13 sites, and co-deployed at the air and soil pore air interface at 5 sites across Washington, Idaho, California and Oregon from September to October of 2018. At each of these sites, volunteers placed samplers in a room inside their home and outside their home during the wildfire season, for about three weeks. These passive samplers were extracted and analyzed by gas chromatography mass spectrometry for parent and alkylated PAHs, parent and alkylated PAH compounds specific to forensic source determination and a quantitative screen of 1530 organic chemicals. Air Quality Index data and NASA satellite imaging was also collected for the corresponding locations during their sampling period. PAHs were detected at all sites sampled, with PAHs including mainly 2-4 ring. Forensic source identification indicate that all samples were pyrogenic in nature. Additional PAH ratio information were used to examine the influence of wildfires on the PAH signatures of all samples. Results also indicate that PAH concentrations in the air are higher indoors than outdoors, even in locations where the home was not a primary residence. This is the first study to compare concentrations indoors and outdoors during wildfire season. Repeat measures collected in summer of 2019 at the same locations are compared. We report air and pore air concentrations and the bulk movement of vapor phase contaminants between the soil and air, which is referred to as diffusive flux. The diffusive flux between air and soil during wildfire season will be demonstrated for the first time with low density polyethylene passive samplers in this study. The diffusive flux vaporization from soil and/or deposition from air at each site during wildfire season will be presented. We will also present on the results of a 1530 organic chemicals analysis for previously unmonitored contaminants.
731 Thoughtful Stakeholder Engagement Through Solutions-Driven Research Approaches to Better Understand Human and Ecological Impacts from Wildfire

While devastation in communities burned in recent wildland fires is readily visible, adverse human health effects of smoke exposure are less visible, and yet substantial in communities near and far from fires. The USEPA Office of Research and Development (ORD), supports a breadth of research and outreach designed to help federal, state, local, and tribal organizations prepare and respond to impacts from wildland fire. This work is designed to fill gaps in scientific information in air quality, public health, toxicology, emissions measurement and modeling, and social science. This information is used to develop tools to prevent and reduce impacts of wildland fire smoke, and support translation of research and tools into action that reduces the public health burden of smoke. This presentation highlights projects designed around wildland fire smoke and health: Wildland Fire Framework: Developed to state ORD’s vision of wildland fire research, indicate where EPA’s role is in wildland fire research, and outline and coordinate research priorities through problem statements and research questions related to air quality, public health, water quality and aquatic resources, chemicals, and preparing for and building resilience to wildland fires. Smoke Sense: A crowdsourcing, citizen science research project with > 25,000 participants that aims to better understand public awareness of and responses to exposures to smoke from wildland fires, and the subclinical impacts of exposure to wildland fire smoke. The Smoke Sense projects are working to increase issue awareness and engagement in health protective behaviors related to smoke. Preliminary findings from two years of data will be shared along with future plans. Cardiac Care and Air Pollution: This study draws upon insights from cardiac patients, physicians, and non-physician health care providers to inform how air quality information could be integrated into cardiac rehabilitation, where individuals who are at risk to exposure to air pollution receive regular healthcare provider attention after an acute cardiac event. Findings will inform health risk communication research and outreach. We will also share critical stakeholder engagement activities that shaped these research products to meet needs of partners. Disclaimer: The views expressed in this report are those of the authors and do not reflect the views or policies of the USEPA.

732 Exposure Risks in Today’s Fire Service

G. Horn, University of Illinois Fire Se / Fire Service Institute

Risk facing today’s fire service are constantly evolving as fires progress more rapidly and produce more toxic smoke than ever before. Not only are the fuels changing in the structures during emergency response, the training ground is undergoing rapid changes as it evolves to improve the training firefighters receive to prepare for these threats. Cancer is a primary chronic health concern associated with firefighting. Sudden cardiac events are the leading cause of line-of-duty deaths in the Fire Service and a primary acute health concern. In an on-going series of project between IFSI Research, UL FSRI and NIOSH, we have developed a deeper understanding of the exposure risks associated with firefighting activities. This presentation will provide a brief overview the critical results from those efforts with a focus on implications from this study as well as straightforward means to reduce exposures to these risks while operating on today’s fireground and training ground.

733 Military-Style Silicone Dog Tags Examine Occupational Firefighter Chemical Exposures

C. Poutasse, Oregon State University / Environmental and Molecular Toxicology; W.C. Poston, S. Jahnke, C.K. Haddock, National Development and Research Institutes, Inc. / Center for Fire, Rescue, and EMS Health Research; L. Tidwell, P. Hoffman, K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology

Firefighters are charged with protecting the citizens and property in the communities they serve, but occupational hazards specific to the fire service are hypothesized to play a role in the increased risk of cancers. These hazards include exposures to recognized or probable carcinogens, such as polycyclic aromatic hydrocarbons (PAHs). However, exposure classification for fire service studies is often rudimentary and based on inexact surrogates, resulting in tremendous variability between and within departments with respect to exposures to environmental carcinogens. Passive sampling devices, such as silicone wristbands, have previously provided personal exposure assessments and often partner with demographic data assessed by questionnaires to infer lifestyle and behaviors associated with chemical concentrations. This study presents the military-style dog tag as a new necklace configuration of the silicone passive sampling device. Firefighters (n=56) recruited from two different stations wore the dog tag for 30 shifts to capture accurate measurements of bioavailable occupational chemical exposures. Firefighters served as their own controls (on-shift vs. off-shift) at each station (high volume vs. low volume). This research is the first to provide comprehensive characterization of firefighter chemical exposures with the analysis of over 1500 analytes using gas chromatography mass spectrometry, an analytical method which includes PAHs, polychlorinated biphenyls, flame retardants, pesticides, and personal care products.

734 Cardiovascular Health Response to Biomass Smoke Particulate Matter Exposure Among Wildland Firefighters

J. Nelson, University of Alabama, Birmingham / Environmental Health Science; M. Chalbot, College of New Rochelle / Environmental Health Sciences; I. Kavouras, CUNY Graduate School of Public Health and Health Studies / Department of Environmental, Occupational, and Geospatial Health Sciences

The characterization of smoke exposures and the biological (or clinical) monitoring among wildland firefighters is limited due to the inherent hazards of interfering with firefighting tasks during “active” wildfire environments. Wildland firefighters are the largest group of public safety employees exposed to biomass smoke on a regular basis. Cardiovascular diseases are the leading cause of mortality and morbidity, accounting for more than half of work-related deaths. Even though occupational smoke inhalation during active fire events has been identified as the primary risk factor for disease development, respiratory protection is rarely practiced by wildland firefighters due to the cumbersome weight and limited air capacity of most currently available respirators. The purpose of this study was to utilize the strengths of situ occupational exposure monitoring and cardiovascular health assessments to determine the effects of biomass smoke’s particles on acute cardiovascular function among wildland firefighters during active fire events. Personal exposures to particle composition and size distribution (total, course, fine) were assessed by lightweight continuous particle counting monitors attached to the shoulder-pads of each firefighter. These monitors were worn throughout the duration of each burn event and collected measures in one-minute intervals. Changes in cardiovascular function were measured by cross-shift blood pressure monitors and ambulatory heart monitors. The ability of the arteries to dilate was quantified by measuring blood pressure using desktop and ambulatory sphygmomanometers. Changes in cross-shift peripheral blood pressure (pBP), augmentation index for arterial stiffness, and pulse rate variability were obtained by utilizing a desktop supra-systolic oscillometric blood pressure monitor. Activity during periods of exposure were determined utilizing the ambulatory heart rate monitors. During this study, firefighters were exposed to PM ranging from 0.1 to 10.2 mg/m³ over
735 Firefighters’ exposures to polycyclic aromatic hydrocarbons and other environmental mutagens during emergency fire suppression

J. Keir, U.S. Akhtar, University of Ottawa / Department of Biology; D. Matschke, Ottawa Fire Service; P.A. White, Health Canada; T.L. Kirkham, University of Toronto / Occupational & Environmental Health Division; H.M. Chan, J.M. Blais, University of Ottawa / Biology

Firefighters experience above average risks of cancer and other serious illness. Their exposures to combustion emissions, including polycyclic aromatic hydrocarbons (PAHs), metals, and other products of combustion are a concern. Few studies have examined firefighters’ exposures to combustion emissions during on-shift, emergency fire situations. To assess firefighters’ occupational exposures to combustion emissions during emergency fire suppression, we measured exposures to PAHs, antimony, cadmium, and lead using (1) personal air samplers worn by firefighters during emergency fire suppression; (2) wipe samples of skin, personal clothing, and personal protective equipment (PPE) collected before and after emergency firefighting; and (3) urine samples collected before and after emergency firefighting. We examined chemical exposures by measuring PAHs and metals in air and surface wipe samples of skin, clothing, and PPE. We determined urinary PAH metabolite concentrations and urinary mutagenicity using the Salmonella mutagenicity assay (Ames test). Urinary Clara Cell 16 (CC16) and 15-isoprostane F2t (8-isopGF2α) concentrations were used to assess lung injury and oxidative stress, respectively. Air concentrations exceeded occupational exposure limits at two fire events for lead and nine for PAHs. After fire suppression, PAH concentrations were significantly higher on skin and PPE (p < 0.001), antimony on skin, clothing, and PPE (p < 0.001, 0.01, and 0.05, respectively), and lead on skin and PPE (p < 0.001). Post-event concentrations of urinary PAH metabolites were, on average, 2.9-to 5.3-fold higher than pre-event values, depending on the PAH metabolite (p < 0.0001). Average post-event urinary mutagenicity showed a significant 4.3-fold increase (p < 0.0001). Urinary CC16 and 8-isopGF2α did not increase. PAH concentrations in personal air and on skin accounted for 54% of the variation in fold changes of urinary PAH metabolites (p < 0.002). The results indicate that emergency, on-shift fire suppression is associated with significantly elevated exposures to combustion emissions. Future studies are required to determine effective ways to reduce such exposures to ultimately reduce disease and illness in firefighters.

736 Derek Muir’s adventures on the AMAP trail

C. de Wit, Stockholm University / Environmental Science and Analytical Chemistry

Derek Muir’s Arctic science trajectory began in 1988, with his first publications on organochlorines in Arctic biota. In 1994, he was appointed one of two co-leads of the Persistent Organic Pollutants (POPs) Expert Group within the Arctic Monitoring and Assessment Programme (AMAP). At that time, Canada and Sweden were the international leaders in driving policy and regulation of hazardous chemicals, thus Canada’s interest in filling one of the co-lead positions of this expert group. In this capacity, he was strongly involved in the planning, writing, and editing of AMAP’s four major scientific assessments of POPs and chemicals of emerging concern in the Arctic. These assessments as well as his work with Canadian Northern Contaminants Program assessments played crucial roles in the development of chemicals policy in Canada, the creation of the Persistent Organic Pollutants (POPs) Protocol of the Convention on Long Range Transport of Atmospheric Pollutants in 1997 and the UN Stockholm Convention on POPs in 2001. He has also been deeply involved in planning and writing parts of assessments on temporal trends in Arctic biotic and abiotic media, which have supported the Stockholm Convention Global Monitoring Plan. These have included his own research such as his long-term studies of contaminants in ringed seals and Arctic char. In his AMAP work, he has attended and co-led numerous workshops of international POPs experts in the preparation of assessment reports, taken part in various AMAP Working Group meetings to discuss results of assessments with policymakers, presented results of the assessments at AMAP conferences and at special sessions at international conferences. He has also been engaged in helping to update the AMAP Monitoring Programme and AMAP’s assessment strategies. This presentation will highlight Derek’s work within AMAP in more detail, his scientific work in identifying new potential POPs and the important role he has played as an expert in the development of international chemicals regulation.

737 A Muir legacy: Understanding contaminant dynamics in arctic food webs

A. Fisk, University of Windsor / Great Lakes Institute for Environmental Research; K. Børgå, University of Oslo / Department of Biosciences; G.T. Tomy, The University of Manitoba / Department of Chemistry

Contamination of the Arctic by industrial and agricultural chemicals was first recognized almost 50 years ago. Although a vast majority of these contaminants originate from temperate regions, concentrations of chlorinated compounds in arctic marine top predators are among the highest of any animals on earth, and Inuit, through their diet rich in marine mammals, face the highest exposure levels of any humans. Bioaccumulation and trophic transfer of organochlorine contaminants, such as DDT and PCBs, were known to contribute to elevated levels in higher trophic level organisms, but the extreme levels in Arctic marine apex predators were initially difficult to explain. Detailed and well-planned studies across the entire Arctic, most led, including or inspired by Derek Muir, demonstrated that the long life, high lipid content, varying biotransformation capacity of Arctic marine animals and the persistent nature of these compounds contributed to efficient trophic transfer of organochlorine contaminants in polar food webs. These factors were later used to explain the biomagnification of other types of contaminants, including brominated and fluorinated compounds, in Arctic food webs, with Muir again spearheading many of these studies. Documenting the presence and the potential for bioaccumulation of these contaminants in the Arctic was a central part in global agreements to reduce their use and emissions, and to develop effective consumption guidelines for wild Arctic foods. This talk will review and celebrate the expansive research of Derek Muir on the bioaccumulation and biomagnification of contaminants in Arctic food webs, and its important impact on global policies.
between the species. PCBs and PBDEs were highest in the limpets and sea urchins. HCB and pp-DDE were the most prevalent OCPs, followed by HCHs, heptachlor and oxychlordane. OCP concentrations generally did not differ among species. Limpets contained POPs with higher logKow and logKoa, related to their grazing behaviour on biofilms and potential limited exchange with the water due to their shell. Sea squirts and cucumbers contained POPs with relatively high water solubility, which indicates a water-borne exposure. The sea star and sea urchin were somewhat in the middle ground between the mentioned groups. Tissue concentrations and patterns will be related to the dissolved and particulate concentrations. Temporal changes will be presented and accumulation kinetics in the particulate matter will be related to seasonal algae blooms and uptake patterns in the animals. Drivers of seasonal accumulation will be derived and examined in contrast with the Arctic, for which much more data and knowledge already exists. Thereupon, overarching patterns of environmental partitioning and accumulation of POPs in both polar regions will be discussed, placing the immense impact of Derek Muir on Arctic research in an even wider perspective.

739 Contrasting temporal trajectories of legacy and current use flame retardants in Herring Gull (Larus argentatus) eggs in the Laurentian Great Lakes
S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; G. Lu, Hong Kong University of Science and Technology / Shenzhen Research Institute / Marine Environmental Laboratory; G. Su, Nanjing University of Science and Technology / School of Environmental Science and Engineering; D.J. McGoldrick, Environment and Climate Change Canada / Water Quality Monitoring and Surveillance Division; P.A. Martin, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate

Following the discovery of widespread adverse reproductive and developmental impairment in fish-eating colonial waterbirds nesting in the Canadian Great Lakes, Environment and Climate Change Canada started monitoring contaminants in the Herring Gull (Larus argentatus) eggs in 1974. Here we contrast the spatial and temporal trends of both legacy contaminants, some of which are flame retardant chemicals, such as Polychlorinated Biphenyls (PCBs) and Polychlorinated Naphthalenes (PCNs), with flame retardants currently in production, such as organophosphate esters (OPEs) and Dechlorane Plus (DDC-CO) isomers. In general, the temporal trajectories of legacy compounds in gull eggs were consistent with first order exponential declines. An exception were PCNs in gull eggs from colonies immediately downstream of the Detroit River, in which concentrations peaked again in the early 2000s. PCN concentrations appeared to have a temporary resurgence following dredging of sediment for remediation of contaminated within the Detroit River, the effect of which was detectable at least as far downstream as eastern Lake Ontario. Compared to legacy contaminants, concentrations of DDC-CO have increased over time, whereas temporal trends of OPEs were inconsistent. Spatial trends of all persistent contaminants (e.g. PCBs, PCNs and DCC-COs) appear to be associated primarily with industrial activity or nearby centers of human population. Conversely, OPE temporal trends in gull eggs were only weakly related to the trends seen in sediment, and body burdens appeared to be driven not by municipal density but instead are heavily influenced by metabolism in the maternal birds or by embryos.

740 Photodegradation of naphthenic acids and other organic classes in oil sands process-affected water extracts
J.K. Challis, University of Saskatchewan / Toxicology Centre; A. Parajy, J. Anderson, University of Winnipeg / Department of Chemistry; E.K. Asiedu, University of Alberta / AET Division; J.W. Martin, Stockholm University / Department of Environmental Science and Analytical Chemistry; ACES and Science for Life Laboratory; C.S. Wong, Southern California Coastal Water Research Project Authority / Chemistry; M. Ross, MacEwan University / Physical Sciences

Naphthenic acids (NAs) are persistent and toxic natural constituents of bitumen that are solubilized and concentrated in oil sands process-affected water (OSPW) during oil sands extraction. Few studies have investigated environmentally-relevant photochemical transformation of NAs. We hypothesized that NA-like compounds are susceptible to phototransformation, and this process may be a significant removal pathway. To examine direct photolysis via wavelengths in solar radiation (i.e., >290 nm), changes in NA profiles (i.e., C and z numbers) were characterized following bench-top scale studies using OSPW, and acid- (AF) and base-extracted fractions (BF). Intensities were measured by HPLC and ultra-high resolution mass spectrometry in negative (-) and positive (+) modes. Photolysis reduced all constituent groups in OSPW-, OSPW+, AF-, and BF+, over the course of the 18-day irradiation period. Total NAs in OSPW were reduced by 99% and by 87% in AF-. Highly photolabile species included O2-, O3-, O4-, O4S-, O4S-, and O5S- containing structures, which were degraded by 93% to 100% after 5 days and by 94% to 100% after 18 days. Following photolysis, there was a noticeable shift towards smaller species with less cyclicity, double bonds, or aromaticity. On Day 18, mean carbon number and z-values in OSPW- shifted to 12 and -4, respectively, from 15 and -8 on Day 0. First-order kinetic models were used to investigate removal trends. Half-lives of heteroatomic classes ranged from 2.7 (O4S-) to 14.9 (O3-) days for OSPW-, and from 3.9 (O3S+) to 20.9 (O5+) days in OSPW+, indicating differences across structures, but overall efficient NA removal via photolysis.

741 Muir & Mabury: 24 Years of Collaborative Discovery & Impact with OrganoFluorine
S. Mabury, University of Toronto / Chemistry

Starting with the smalled perfluorinated alkylcarboxylic acid TFA, the collaboration between Muir and Mabury has produced 52 joint publications that averaged over 96 citations/paper and a resulting H-factor of 34; sixteen of these papers have over 100 citations. Funded through two NSERC Strategic grants, a TSRI, and a number of smaller grants, this collaboration has involved mentoring and training of at least 27 students, many of whom were joint formal supervisions of M&M. Significant discoveries and advances in our understanding of the role Fluorine plays in the fate, disposition and persistence of organofluorine compounds have been made possible by this collaboration. They include a number of newly identified pollutants such as the long-chain perfluorinated acids and volatile precursors; the extent of Arctic contamination and temporal response; and physical properties (BCF/BAF) of fluorinated chain length; these and others will be used to highlight why this collaboration was so productive.

742 Advances in environmental chemistry over 40 years and a look forward
D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

The last 40 years has seen many advances in measurement of persistent organic pollutants in environmental media, in understanding fate and distribution, and regulating them at the national and global level. SETAC has been a major forum for this research with advances in measurements, bioaccumulation, biodegradation, ecotoxicity and modelling often reported for the first time at these conferences since 1979. Highlights for me, have been the confirmation of the importance biomagnification both in the field and on a fundamental level using fugacity, modelling of global long range transport, the expansion of measurements from semi-volatiles

744 Site-specific and standard toxicity tests for ecological risk assessments of oil spills

P.V. Hodson, J. Adams, Queens University / School of Environmental Studies; R.S. Brown, Queens University / Department of Chemistry

Ecological risk assessments (ERAs) of oil spills rely on laboratory tests of the toxicity of crude and refined oils to aquatic organisms. The more that test conditions reflect site-specific conditions such as temperature, salinity, and test species, the more useful and reliable the test data will be. However, ERAs also include reviews of published toxicity data for species and test conditions that are not specific to a spill site. Differences among studies in estimated toxicities will add uncertainty to risk estimates if the underlying causes of those differences are not understood. These uncertainties can be reduced through experimental design, specifically the inclusion of appropriate controls and standard tests that provide perspective on why toxicity varies among studies. We will review factors that affect the outcome of oil toxicity tests, including the storage and handling of test oils, the methods chosen for mixing oil and water, the characterization of test solutions that may be highly dynamic, the species and developmental stages of test organisms, and details of test conditions such as the materials of test tanks. When site-specific toxicity tests are matched by tests conducted under standard conditions and supported by detailed chemical characterization of test solutions, experimental characteristics that affect oil toxicity and the extent to which they change toxicity, can be identified. This more complete detailed understanding of how methods affect oil toxicity will support a better interpretation of toxicity data and more reliable ERAs.

Oil Toxicity Testing: Current Experimental and Analytical Methods, Exposure Metrics and Risk Interpretation

743 A Path Forward for Improving Aquatic Toxicity Testing of Hydrocarbon Substances

A.C. Bejarano, Shell Health - Americas / Shell Health Risk Science Team; G. Coelho, Sponsor Group, Inc.; C.L. Mitchellmore, UMCES / Chesapeake Biological Laboratory; D. Wetzel, Mote Marine Laboratory / ELF

Petroleum substances are complex mixtures of many chemical constituents with different physicochemical properties that determine their partitioning into the aqueous exposure media, and therefore their bioavailability to exposed organisms. Because of these complexities, assessing their hazard to aquatic resources relies on the use of established standard toxicity testing protocols that include detailed chemical and physical characterization of the exposure media. For nearly four decades, members of the scientific community have strongly encouraged the use of standardized toxicity testing protocols, for example, Chemical Response to Oil Spills Ecological Effects Research Forum, and modified versions developed during the Deepwater Horizon oil spill. Despite these efforts, the continued use of dissimilar testing and exposure media preparation methods has generated irreproducible toxicity test results that are inappropriate or inadequate for inclusion in hazard assessments. Consequently, there is a continued need to employ toxicity testing methods that are supported by current scientific knowledge and that can be applied to likely real-world exposure regimes. Studies must, at a minimum, follow rigorous protocols that ensure reproducibility across laboratories, have well defined and accepted statistical criteria for result validation and interpretation, and include chemical and physical characterization of exposure media to determine the constituents contributing to toxicity. Generating reliable test results is imperative as these data are essential to generate comprehensive toxicity models and decision-making tools used for supporting spill response, and to support environmental assessments. The purpose of this presentation is to highlight key challenges associated with current practices, but more importantly, to present suggestions for a path forward aimed at generating test results that are easily interpreted by environmental decision-makers. Specific discussions will be focused on rigorous established approaches that include: experimental design, test media preparation with/without dispersants, the role of mixing energy and presence of oil droplets, the influence of chemical characterization methods, minimum and ideal chemistry requirements, and the potential role of passive sampling methods. The primary objective of this presentation is to encourage multi-disciplinary collaboration for generating meaningful data with practical real-world applications.

The Chemical Aquatic Fate and Effects (CAFE) database is a tool that facilitates assessments of accidental chemical and oil releases into aquatic environments. CAFE contains aquatic toxicity data summarized in the form of species sensitivity distributions (SSDs) with associated 5th percentile hazard concentrations (HC5s). Since its initial release in 2015, CAFE has been used in hundreds of chemical and oil spills. However, for many chemicals and oil gaps, in species diversity and toxicity data limited the development of SSDs. In CAFE’s upcoming web version, some of these data gaps were addressed with Interspecies Correlation Estimation (ICE) models. The incorporation of ICE predicted values into CAFE allowed the development of >800 new SSDs and increased diversity in SSDs by an average of 34 species. Multiple analyses showed that SSDs supplemented with ICE-predicted values generally produced HC5 estimates that were within a 3-fold difference of estimates from measured SSDs (58%-82% of comparisons), but that were often more conservative (63%-76% of comparisons) and had lower uncertainty (90% of comparisons). ICE SSDs did not substantially underpredict toxicity (<10% of comparisons) when compared to estimates from measured SSD. With the addition of ICE models into CAFE’s upcoming web version, more SSDs are generated, increasing CAFE’s capacity to respond to chemical and oil spills.
746 From Models to Beakers: A Comprehensive Evaluation of Oil Toxicity

B.S. Echols, Environmental Toxicology Associates, LLC; W.A. Stubblefield, Oregon State University / Environmental and Molecular Toxicology

The complex chemical composition of oil, comprised of soluble and insoluble constituents, contributes to the difficulty in both the laboratory assessment of potential toxicity to aquatic organisms, as well as the interpretation of test results. Additionally, the presence of microdroplets in test material and poorly characterized exposure concentrations are also factors contributing to the difficulty in reliably assessing crude oil toxicity and extrapolating that information to real-world scenarios to evaluate oil spill risk to aquatic receptors. Oil solubility and toxicity models enhance our ability to understand exposure and toxicity by predicting the bioavailable fraction of oil in exposure media and the toxicity potential of that fraction across a range of experimental methods, oil types and species. The current study aims at comparing model predicted toxicity in terms of total oil exposure to a robust empirical dataset. These data include acute and chronic toxicity test data for fresh and field-collected Macondo oil with and without chemical dispersant (Corexit 9500). By comparing model-predicted estimates to empirically determined lethal concentrations generated from laboratory tests, we will not only be able to provide further validation of model estimates but also provide a more comprehensive understanding of species sensitivity to various stages of oil weathering.

747 An antibody-based biosensor method for the rapid assessment of polycyclic aromatic hydrocarbons in porewater to predict sediment toxicity

M.A. Unger, G.G. Vadas, M. Vogelbein, K. Prossner, Virginia Institute of Marine Science / Aquatic Health Sciences; C. Prosser, ExxonMobil Biomedical Sciences, Inc.; L.T. Yonkos, University of Maryland / Environmental Science and Technology

A biosensor that quantifies 3-5 ring polycyclic aromatic hydrocarbons (PAH) to sub-pb concentrations in small volume (1-5 mL) aqueous samples was developed that allows analysis in minutes at spatial and temporal scales not possible by GC-MS methods. Biosensor measurements in porewater were highly correlated to benthic amphipod toxicity at field sites and in PAH-spiked sediment samples. Porewater measurements were much better at predicting toxicity than whole sediment concentrations due to sediment properties altering the partitioning and bioavailability of the contaminants. Porewater measurements are difficult to obtain by standard analytical methods so our biosensor analysis is being evaluated as a potential tool for near real-time evaluation of sediment toxicity. Sediment porewater from field collected creosote contaminated sediments and oil-spiked sediment samples were analyzed for total PAH by biosensor and/ or solid phase micro extraction followed by gas chromatography (SPME/GC) and evaluated for toxicity to the benthic amphipod (Leptochirus plumulosus) in 10-day survival tests. Both SPME/GC and biosensor measurements were strongly correlated to amphipod toxicity. When total 3-5 ring PAH concentrations in sediment porewater exceeded 10-20 μg/L amphipod toxicity increased dramatically. Survival curves were very steep and typical of PAH with a narrow range where toxicity spanned from 0-100%. Differences in results between oil-contaminated and creosote-contaminated sediments may result from differences in the complex mixtures not measured by the rapid analytical methods. However, the narrow concentration range where toxicity occurs shows that these analyses can be valuable tools for toxicity assessment. Combined with the ease of collecting data in the field, near real-time assessment of sediment toxicity is feasible at PAH contaminated sites during oil spills, flood events or to guide remediation.

748 Variability in toxicological response of Atlantic cod (Gadus morhua) larvae exposed to petroleum hydrocarbons

B.P. de Jourdan, Huntsman Marine Science Centre / Environmental and Molecular Toxicology; R.J. Eldridge, L.E. Burridge, Huntsman Marine Science Centre

Oil and gas exploration and production activities have existed for decades within the productive environment offshore of Newfoundland & Labrador and Nova Scotia. These activities are expected to continue expanding to new areas of Canadian frontier lands offshore. These same areas overlap with historical highly productive oceanic feeding and spawning habitat for complex marine species assemblages, including Atlantic cod (Gadus morhua). A series of bioassays were performed with larval Atlantic cod from 16 crosses with contributions from 10 female and 8 male adult cod. Fin clips were taken from each adult cod and sent for genotyping to estimate the relatedness of individuals based on six microsatellite markers. The bioassay involves a 24-hour exposure to a series of 8 concentrations of physically and chemically dispersed crude oil. The treatments were chosen to match the microdroplet size profile and distribution results from wave tank dispersion trials (SL Ross, Ottawa, ON), which served as a proxy for the environmental conditions observed offshore Newfoundland & Labrador, Canada. At the initiation of each exposure, 10 reference organisms were collected from each test population and had morphometric measurements taken. The larval cod ranged in age from 162 to 242 degree days. Percent mortalities were obtained at the conclusion of the test and concentration-response curves were estimated by fitting log-logistic functions (drc package, in R). Median lethal effect concentration (LC50) estimates accounted for control condition, and were used to generate a distribution curve for the species based on the responses of each cross. Statistically significant differences were observed between the LC50 values of several cod crosses. The LC50 for mortality observed in cod larvae ranged from 8.6 to 44.7 mg TPH/L. The variability observed in the cod results could not be explained by age (as degree days) at time of exposure (p = 0.22), and there was no significant relationship between any of the reference organism measurements and the LC50 values. From the sensitivity distribution the HC5 was calculated as 14.2 mg TPH/L (10.3, 19.1; 95% CI) and used to determine predicted no effect concentrations which would be protective of the population. The causes and consequences of the observed experimental and natural variability will be discussed with specific implications for risk assessment.

749 A Physiologically Based Oiling Model (PBOM) to Predict Thermoregulatory Response in Oiled Birds

P. Stuhr, P. Mazzocco, M. Stephenson, Stantec Consulting, Ltd. / Environmental Services; L. Knopper, Stantec Consulting, Ltd.

When birds are exposed to oil their ability to thermoregulate is impaired as a result of damage to the insulative properties of their feathers. If an oiled bird is unable to maintain thermal homeostasis, hypothermia and death can follow rapidly. Physiological responses to oiling depend on several variables including environmental conditions (e.g., cold vs. temperate climates; air and water temperatures), life history of bird species (e.g., habitat selection and body size), and foraging strategies (e.g., divers, surface feeders and shorebirds). The most widely used approach to assess the effects of spilled oil on birds is the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) Type A Natural Resource Damage Assessment Model for Coastal and Marine Environments. While the CERCLA model minimally addresses body size and time spent in a hypothetical slick, it lacks the flexibility to assess other variables related to physiological response. Building on benchtop “proof-of-concept” experiments with model “birds,” we developed a dynamic physiologically based oiling model (PBOM) for birds. The PBOM has been validated against empirical data from a dose-response study in which common eiders (Somateria mollissima) were exposed to Statfjord A crude oil. At this time, PBOM is being used to predict thermoregulatory responses of five representative bird species: common eider, spotted sandpiper, great blue heron, dovekie and American white pelican. The model can predict time to hypothermia
for birds of differing body size and habitat preference, in warm or cold environments. Here we present: 1) a conceptual model of quantifiable variables (e.g., life history of bird species, environmental conditions and foraging strategies) that can influence thermoregulatory responses to oiling; 2) the approach used to validate PBOM; and 3) examples of thermoregulatory responses predicted using PBOM.

750 Antibody-based biosensor technology as a tool for near real-time measurement of PAH contamination in bivalves

K. Prossner, College of William & Mary / Aquatic Health Sciences; M.A. Unger, G.G. Vadas, Virginia Institute of Marine Science / Aquatic Health Sciences; C. Prosser, ExxonMobil Biomedical Sciences, Inc.; T. Parkerton, ExxonMobil Biomedical Sciences Inc. / Toxicology & Environmental Science

Sessile filter feeders such as bivalves are susceptible to accumulation of hydrophobic contaminants such as polycyclic aromatic hydrocarbons (PAH) due to limited metabolic capacity. During spills or flood events, quick assessment of seafood safety is crucial for stakeholders and resource managers to determine potential risk to consumers. Established quick response methods such as sensory analysis (i.e. sniff testing) are non-quantitative and met with distrust by the public. More reliable PAH quantification methods such as conventional GC-MS analyses take several weeks and are expensive. A new, highly sensitive, antibody-based biosensor method has been developed to rapidly measure total 3-5 ring PAH concentrations in individual bivalves using small volume (1-2 mL) aqueous samples. Application of the biosensor method to measure PAH concentrations in individual animals relies on fundamental partitioning of hydrophobic chemicals in a system at dynamic equilibrium. At equilibrium, an unknown concentration of PAH in one phase can be calculated from another based on the partition coefficient for the two phases. PAH concentrations in oyster mantle fluid (i.e. aqueous phase) analyzed by biosensor correlate well with PAH concentrations in field-collected oysters analyzed by GC-MS suggesting internal equilibrium within individual oysters may allow whole animal concentrations to be predicted rapidly and reliably. In a laboratory study, adult C. virginica were exposed to the water-accommodated fraction of crude oil for 3-days followed by a 14-day depuration period. Animals were sampled to compare the ability of the biosensor method to track changes in PAH concentrations over time to that of conventional body burden analysis by GC-MS. Results from this study will be discussed. Biosensor technology could serve as an important tool for rapid evaluation of potential PAH-contaminated seafood in time-sensitive situations such as oil spill response. This technique is significantly cheaper than conventional methods on a per sample basis. Further applications include assessing other bivalve species as well as rapid, economical mapping of background PAH levels for contingency planning.

Emerging Environmental Contaminants: Human Exposure and Associated Risks - Part 2

751 Re-thinking chemical fate and exposure indoors

M.L. Diamond, University of Toronto / Department of Earth Sciences; A. Anderson, University of Toronto / Department of Computer Science; L. Melymuk, J. Kalina, Masaryk University, Faculty of Science, Research Centre for Toxic Compounds in the Environment (RECETOX); C. Yang, University of Toronto / Department Earth Science; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; J. Kvasnicka, University of Toronto / Environmental Health Sciences; S.A. Harris, Cancer Care Ontario & University of Toronto / Population Health and Prevention & Occupational Cancer Research Centre & Dalla Lana School of Public Health

When we first considered the SVOC fate indoors, we brought our paradigm from the outdoor environment that fate processes were dominated by the physics of transport processes and we largely neglected the role of human occupants. However, ample evidence shows that neglecting human occupants can give a simplified and unrealistic assessment of indoor chemical dynamics. What if people’s “everyday” activities directly influence the transport and distribution of chemicals indoors which, in turn, influence exposure? We illustrate the role of human activities, and hand contact in particular, using a dataset from 51 homes and their residents in Ontario, Canada. The concentrations of 23 organophosphate esters (OPEs), 14 polybrominated diphenyl ether (PBDEs) congeners, 10 non-PBDE halogenated flame retardants (HFRs) and 6 phthalate esters were measured in air, floor dust, and wipes of surfaces of electronic devices and participants’ hands. Here we use data for 5-8 OPEs, 3 PBDEs, 2 non-PBDE HFRs and all 6 phthalates for which detection frequencies were >80%. Although we expected to find dominant flame retardants and/or plasticizers in the surface wipes of specific devices, a cluster analysis showed similar chemical profiles on most surfaces (e.g., electronic surfaces, hand backs and palms). Network analysis of chemical profiles showed the centrality or “connectedness” of hands to all other surfaces, followed by air and dust. Next, we probed the similarity among surfaces by analyzing their Euclidean distances obtained from the cluster analysis. We found a surprising similarity of chemical profiles on hands of 51 “random” participants, which we believe comes from hands contacting and transferring chemicals. The concept of hands as agents of transport is well known in terms of disease transmission. We hypothesize that our hands transport chemicals from surface-to-surface, leading to similar chemical profiles on indoor surfaces, and that hands are a reflection of our exposure to this mixture of chemicals in our indoor environments.

752 Association of emerging contaminants with biomarkers of placental disease and development during mid-gestation of pregnancy

J. Varshavsky, University of California, San Francisco / Program on Reproductive Health and the Environment; J. Robinson, University of California, San Francisco / Department of Obstetrics Gynecology & Reproductive Sciences; Y. Zhou, K. Williams, E. Kwan, S. Buarpung, R. Aburajab, S. Gaw, University of California, San Francisco; S. Sen, University of Tennessee Health Science Center; J. Park, California EPA / California Department of Toxic Substances Control; S. Crispo Smith, California Environmental Protection Agency / Department of Toxic Substances Control; S. Fisher, University of California, San Francisco; T. Woodruff, University of California San Francisco / Program on Reproductive Health and the Environment

Perfluorinated alkyl substances (PFAS) and organophosphate flame retardants (OPFRs) are emerging chemicals of concern that may be associated with placent-mediated pregnancy and maternal health complications. However, few studies have evaluated these environmental chemicals during mid-gestation or in relation to biomarkers of placental disease and development. Thus, we performed a descriptive analysis and epidemiologic study evaluating PFAS and OPFR exposure with several molecular and morphological biomarkers of placental disease and development among N=62 pregnant women during mid-gestation. Molecular biomarkers included trophoblast invasion-promoting adhesion molecules, integrin alpha-1 (ITGA-1) and vascular endothelial-cadherin (VE-cadherin), as well as an extracellular matrix-degrading enzyme, metalloproteinase-1 (MMP-1). Morphological endpoints included leukocyte and fibrinoid deposition (potential indicators of placental stress) as well as the extent of spiral artery remodeling during placentation. We found an inverse association with ITGA-1 immunoreactivity and a positive association with morphological indicators of placental stress in multiple regions of the basal plate during mid-gestation. However, our study was limited by sample size. Further research with a larger sample size and/or expanded panel of molecular and morphological biomarkers is warranted.
753 Risk assessment of air pollutants arising from burning of tyres on exposed children

I. Dike, University of Nigeria; C. Onwurah, University of Nigeria / Educational Foundation; E.N. Onwurah, University of Nigeria / Biochemistry

Occasional burning of used tyres during a festive period may not be seen to produce significant air pollutants. However, it has become everyday practice in its use in roasting of slaughtered cows, goats and sheep/rams in many abattoirs in Nigeria and this has been viewed to have an economic advantage in terms of cost and “recycling of used or worn-out tyres.” In spite of the above, it has become obvious that this practice releases particulate matter, volatile organic compounds (VOCs) and hazardous air pollutants (HAPs) especially polycyclic aromatic hydrocarbons (PAHs) into the environment. Research has shown that these PAHs could trigger some health problems ranging from respiratory irritation, cough, dermatitis, depressed immune system and a decrease in lung function. This study was aimed at evaluating the risk of exposure of school children whose schools are located in close proximity to these abattoirs. The study sought to determine the concentrations of some selected Environmental Protection Agency (EPA) priority PAHs, particulate matter in ambient air in and around the studied school environment, concentrations of some PAH metabolites and some heavy metals in post-shift urine of selected primary school children and control subjects. Lung function, cytogenetic evaluation of DNA damage in buccal exfoliates and urinary phenol of exposed children were undertaken. Some of the results show that the concentrations of 1-Hydroxypyrene (1-OHPyr) (µg/molCret), a PAH metabolite, in the post-shift urine samples of the 75% of the children were 0.68±0.06µg/molCret vs 0.32±0.05µg/molCret while urinary phenol concentrations were 18.45±0.39 mg/l vs. 7.89±1.52 mg/l respectively in exposed children and the control (children in a primary school 8-10 km away from the abattoir). The buccal epithelial exfoliates showed that karyorrhexis and condensed chromatin bodies were significantly higher in the exposed children than in the control. The above result gives an insight of possible future complex health problems which can be prevented through integrated policy and interventions that will simultaneously and holistically address the release of these pollutants from the abattoir.

754 Screening for Novel Halogenated Compounds in the Great Lakes fish using Two-dimensional Gas Chromatography with High-Resolution Mass Spectrometry

A. Renaguli, Clarkson University / Institute for a Sustainable Environment; S. Fernando, Clarkson University / Center for Air Resources Engineering & Science; B. Crimmins, Clarkson University / Civil and Environmental Engineering; P. Hopke, Clarkson University / Institute for a Sustainable Environment; T.M. Holsen, Clarkson University / Civil and Environmental Engineering

The Great Lakes are impacted by emissions of chemical contaminants from industries, agriculture and urban centers in the region. Monitoring these chemical stressors in Great Lakes wildlife can be challenging, but vital to assessing the overall health of the system. Traditional analytical methods target select compounds or compound classes in the biota; however, these may represent only a fraction of the contaminant burden. Due to complexity of the biological matrix, classical analytical techniques are not suitable for understanding the complete halogenated fingerprint in the biota. In this study, a non-targeted screening approach was developed and applied to the Great Lakes fish using a two-dimensional gas chromatograph coupled to a high-resolution time of flight mass spectrometer (GCxGC-HR-ToF MS). More than 60 novel halogenated species were identified in whole fish lake trout from all Great Lakes and the most abundant chemical class detected was halomethoxyphenols (MeOPs). Halo-MeOPs were present at higher concentrations than PCBs, but little is known about their potential origin. To assess the risks that these contaminants may pose to human consumers, fish fillets were also analyzed. A discussion of the tissue distribution of the halogenated chemical signature will be presented with insight to possible sources of detected novel halogenated chemicals.

755 The Sorption of Pharmaceutical and Personal Care Products on High-density Polyethylene and Polypropylene Microplastics

D. Rubave, University of Maryland, College Park / Chemistry and Biochemistry; A. Sanchez, University of Maryland, College Park / Civil and Environmental Engineering/Marine-Estuarine Environmental Sciences; L.T. Yonkos, University of Maryland / Environmental Science and Technology; K. Bailey, Micromeritics; A. Torrens, University of Maryland / Civil and Environmental Engineering

Wastewater treatment plants are a major transport pathway for microplastics; however, they are also a significant source of organic pollutants, especially pharmaceutical and personal care products (PPCPs). It is well known that microplastics are capable of sorbing organic pollutants to concentrations magnitudes higher than the surrounding water; however, it is unknown if microplastics may act as vectors for PPCPs from wastewater to the environment. One of the major knowledge gaps is the relatively little information known about the sorption behavior of PPCPs and microplastics. To better understand the role of microplastics as vectors for PPCPs, their sorption equilibrium should be quantified. Additionally, compounds of differing solubility (i.e., the octanol-water partition coefficient, Kow) must be tested to begin to understand the relative risk of different PPCPs. Therefore, this study will examine the sorption of (in order of decreasing Kow) venlafaxine, diphenhydramine, DEET, and caffeine with high-density polyethylene and polypropylene microplastic particles of different diameter (i.e., surface area). Results will be presented that will show the differences in sorption between particles of different surface area and polymer type. Studying the toxicity of microplastics in the environment will require an understanding of what organic pollutants, such as PPCPs, are likely to be present. This work will provide such data and will be used to create a simple model for the sorption of microplastics based on Kow for PPCPs found in wastewater.

756 Occurrence & Fate of Emerging Organic Contaminants in Water in Chennai, India

T. Anumol, Agilent Technologies, Inc.; A. Vijayanandan, Indian Institute of Technology, Delhi / Civil Engineering; L. Philip, Indian Institute of Technology, Madras / Department of Civil Engineering; S. Snyder, Nanyang Technological University / NEWRI

The presence of pharmaceuticals, hormones, pesticides, perfluorinated compounds and industrial contaminants in wastewater has been well-documented in the USA, Europe, and many developed regions in the world over the last two decades. However, information on occurrence and fate is still lacking from many parts in India which is the second most populous country in the world. The goal of this study was to detect for the presence and concentration of twenty two emerging organic contaminants (EOCs) at 3 different wastewater treatment plants in Chennai which is one of the most densely populated regions in South India. The treatment plants selected were different in size and treatment capacity to mimic more urban and domestic settings. Three different sampling campaigns at different seasons were conducted at different locations in the wastewater treatment plants including the influent, primary, secondary and final effluent. The wastewater data indicated 11 EOCs were detected in every sample from every location at all sites, while only 5 EOCs were detected consistently in effluent samples. The effluent composition of the 22 EOCs were similar within the three WWTPs but quite different to those seen in the US, indicating the importance of region-specific monitoring. Diurnal trends indicated that variability is compound specific but trended within certain classes of compounds (artificial sweeteners, and pharmaceuticals). We also studied the treatment efficacy of the wastewater treatment plants for these emerging contaminants. Finally, 22 surface water sites upstream and downstream of the WWTPs were evaluated for presence of these EOCs to determine their fate and exposure to the population in the area.
757 Occurrence and distribution of antibiotics and antibiotic-resis- 
tant bacteria in the Suquia River (Córdoba, Argentina)
M.E. Valdés, National University of Córdoba-CONICET / CIBICI-
ICYTAC Fac. Cs. Quimicas; S.E. Ruiz, National University of 
Córdoba-CONICET / CIBICI-Fac. Cs. Quimicas; L.H. Santos, Catalan

C. Solá, H.A. Saka, National University of Córdoba-CONICET / CIBICI-
Fac. Cs. Quimicas; S. Rodriguez-Mozaz, Catalan Institute for Water
Research (ICRA) / Water Quality; M.F. Amé, National University of
Córdoba-CONICET / CIBICI-Fac. Cs. Quimicas

Antibiotics (AB) are a particular group of emerging contaminants that 
have gained a lot of attention because of their high consumption in human and 
veterinary medicine, worldwide distribution in the environment, in 
addition to association with the proliferation of antibiotic resistance bac-
teria (ARB), bearing clinically relevant antibiotic resistance genes (ARG). 
The aim of this study was evaluating the presence and environmental dis-
tribution of both AB and ARB in the urban area of Suquía River (Córdoba 
city-1,330,023 inhabitants, Argentina). Samples of water, sediment and 
natural river biofilms were collected at 5 sampling points: S1- control 
(upstream Córdoba city and the intake of water supply), S2 (dump area), S3 
(downstream a city ring way), S4 and S5 (6 and 10 km downstream the 
river and flood protect the area, over 1 million cubic metres of soil will be 
infilled with heterogenous fill placed on top of the existing peat, 

cyanotoxins exceeding human consumption limits will require advice on 
safe consumption and irrigation regimes.

758 Quantifying Potential Human Exposure to Cyanotoxins from 
Crops Grown with Contaminated Water
A. Bartos, Utah State University / Watershed Sciences; D. Drost, Utah 
State University; J. Brahney, Utah State University / Watershed Sciences

The prevalence of harmful algae blooms and their associated cyanotoxins 
in lakes near urban centers is an increasing global issue that poses an 
environmental and human health hazard. Exposure to cyanotoxins via 
consumption can result in acute and chronic neuro- and hepatic effects. 
Microcystin, Nodularin, and B-methylamino-L-alanine are common 
cyanotoxins that pose a threat to humans who use contaminated water 
for crop and garden irrigation. Experimental data is lacking on the fate of 
these toxins in the environment and for their capacity to bioaccumula-
tion in food crops. To fill these knowledge gaps, we will first quantify the 
 mobility of cyanotoxins in typical agricultural soils that vary in organic 
material content, pH, and cation exchange capacity (CEC) to determine relationships between soil characteristics and cyanotoxin mobility. Initial 
results show a positive trend of Microcystin-LR availability to plants in 
soils with decreasing CEC. An illicite clay (CEC= 33.6 mEq per 100 
grams) adsorbed 93% of Microcystin-LR in solution whereas a silt loam 
(CEC = 17.3 mEq per 100 grams) adsorbed none. The ability for soil to 
remove cyanotoxins from a soil-plant system can reduce risk for human 
exposure. Second, we will quantify uptake in lettuce crops irrigated with 
contaminated water. Three environmentally relevant concentra-
tions of cyanotoxins will be applied to lettuce grown in a random block 
design in a greenhouse. Cyanotoxin concentrations in roots and shoots of 
lettuce and the accommodating soil medium will be quantified using an 
enzyme-linked immunosorbent analysis kit. Lettuce bioaccumulation of 
cyanotoxins exceeding human consumption limits will require advice on 

759 River Valley Constructability, Design Evolution and 
Harmonization
D. Forbes, Waterfront Toronto / Project Delivery

Port Lands Flood Protection & Enabling Infrastructure Project is led 
by Waterfront Toronto with the support of the Toronto and Region 
Conservation Authority and is funded by the City of Toronto, Province of Ontario and Government of Canada This S1.25B project will protect 
approximately 250 hectares of urbanized land from flooding during a 
regional storm event. This project will transform 30 hectares of indust-
trial brownfields in Toronto’s Port Lands into a naturalized, multi-outlet 
river valley system with critical supporting infrastructure. Completion of 
this project will unlock billions of dollars of redevelopment potential. 
Once the largest wetland in the Great Lakes the mouth of the Don River 
was infilled with heterogenous fill placed on top of the existing peat, 
organic sediments and sand deposits. This resulted in extremely poor 
and highly variable geotechnical conditions in the area. Additionally, 
the Port Lands are subject to a water table that is very near surface and 
directly connected to Lake Ontario. These highly challenging geotechni-
cal and hydrogeological conditions make construction in the Port Lands 
very challenging. Over the course of the project the structural design of 
the river valley system and other flood protection features has evolved 
as the subsurface investigations have been advanced and the manner by 
which all features can be constructed determined. Integrating the design 
of the flood protection features with the river finishes, parks, roads and 
utilities has required significant coordination between multiple design 
and construction teams. This presentation will provide an overview of the 
evolution of the river valley system design, the critical factors that have 
influenced that design and will describe how this has been integrated 
with all other aspects of the Port Lands Flood Protection and Enabling 
Infrastructure Project.

760 Validity of Field Data, Bench Scale and Treatability Testing for 
Full Scale Land Use Controls
M. Janes, Waterfront Toronto / Projects

Formerly one of the largest natural wetlands in North America, the area 
was infilled in the early 1900s to make more land available to serve 
Toronto’s growing industrial sector and for shipping. While still used for 
industrial and port purposes today, these brownfield lands are generally 
underutilized, contaminated, lack adequate municipal services neces-
sary for other uses and also fall within the flood plain of the Don River. 
Plans are underway to flood protect and revitalize this valuable part 
of the city by building a new river outlet to Lake Ontario. Addressing 
metal impacts, petroleum hydrocarbons and non-aqueous phase liquid 
in redevelopment areas is challenging. Traditional practices of measure-
ment can be supplemented by advanced and specialized techniques that 
are now used to fully understand the in situ contaminant. To build the 
river and flood protect the area, over 1 million cubic metres of soil will be
excavated. A portion of the soil will be reused to construct flood protection walls. Poor environmental and geotechnical conditions complicate the soil removal and creation of a new river valley. Waterfront Toronto initiated a process in 2016 to test innovative but proven technologies in the following categories: 1. In situ remediation and/or stabilization of Non-aqueous Phase Liquid (NAPL). 2. In situ Soil Stabilization to Improve Geotechnical Conditions. 3. Ex situ soil remediation, amendment and dewatering technologies. A key component of the project is also to prevent any NAPL migration to the future river valley, reduce over-excavation for channel design slopes, and treat excavated and dredged soil to levels that would allow its reuse within the project area. It is anticipated that most of the excavated and dredged material will have to be dewatered, sorted, and remediated to reduce contaminant concentrations and/or amended to improve its geotechnical conditions. Investigation tools have used laser induced fluorescence, NAPL mobility coring and sorption isotherms. Over 300 investigation points in land and water with approximately 10,000 sediment, soil and groundwater samples were used in a 10,000 record database to model the spatial extent of the site conditions. Treatability studies were completed using sorption, thermal treatment, surfactant flushing and immobilization methods. The tested technologies include: - In situ remediation (STAR - in situ smoldering; - Electro-thermal treatment, SEPR-S-ISCO - surfactant enhanced removal with chemical oxidation); - Ex situ remediation (enhanced bioremediation, soil washing and STARs); - Risk management (block and adsorb and stabilization); and - Geotechnical improvement (urea-based soil stabilization). The decision process in selecting the final remedy will be discussed. The risk management strategy that has been developed includes a combination of barrier layers with low permeability, reactive and sorbent materials.

761 The Use of Numerical Models to Assess and Inform the Design of Environmental River Valley Risk Management Measures

The design of environmental risk management measures (RMMs) is a key component to providing long-term environmental protection of surface water, future visitors, workers, and ecosystem components within the proposed Port Lands Flood Protection and Enabling Infrastructure Project (PLFPEI) river channel. The proposed river channel RMMs consist of a concrete vertical cutoff wall, clay berm, and horizontal barrier, comprised of a geosynthetic clay liner, a geomembrane, and a granular/powdered activated carbon treatment layer. The river channel RMM design process incorporated the use of a 3-dimensional groundwater flow model and a combination of two industry standard horizontal barrier numerical chemical transport models to evaluate changing subsurface conditions over the design life of the RMMs. These models were used to evaluate the predicted future RMM performance, estimate current, interim, and post construction groundwater site conditions, and develop environmental goals that serve as the basis of design for the river channel. In this presentation we will provide an overview of how the models were constructed and discuss how the model outputs successfully supported the overall river channel RMM design in accordance with the project environmental goals while identifying the most cost-effective methods for implementation.

762 Construction of Integrated Reactive and Low Permeability Barriers for Future Sediment and Surface Water Protection in the New River

D.M. Thorson, Geosyntec Consultants, Inc.; M. Janes, Waterfront Toronto / Projects

The City of Toronto, the Province of Ontario, and the Government of Canada are undertaking a massive design and redevelopment of the Port Lands as part of the Waterfront Toronto Port Lands Flood Protection and Enabling Infrastructure (PLFPEI) Project. The Port Lands are a 1,000-acre area on the shore of Lake Ontario, immediately east of downtown Toronto. The area was man-made through decades of infilling of historic wetlands and has historically been used for heavy industry. Contaminants of concern primarily include petroleum hydrocarbons and metals. Much of the area is within the flood plain of the Don River and therefore flood protection must be created before the area can be fully developed. This includes the design and construction of a new River Valley that will connect the existing Don River to Lake Ontario. This presentation will provide an overview of the risk management measures being constructed to prevent the migration of contaminants into the new River Valley. These measures will include structural and non-structural concrete secant pile walls, concrete slurry walls, clay berms, a geosynthetic clay liner, a geomembrane, and a reactive (activated carbon) layer.

763 Isotherm and Non-aqueous Phase Liquid Treatability Tests in Support of a Horizontal Barrier System Design for the Port Lands Flood Protection Project

K.M. Bechard, H. Groenevelt, D.M. Thorson, D. Meric, D. Bertrand, Geosyntec Consultants, Inc.; M. Janes, Waterfront Toronto / Projects; M. Healey, K. Ashworth, SiREM

The design of the Port Lands Flood Protection and Enabling Infrastructure (PLFPEI) project includes a horizontal barrier system which will incorporate an engineered barrier (i.e. sediment cap) to mitigate the transfer of dissolved phase petroleum hydrocarbons (PHCs) as well as non-aqueous phase liquid (NAPL), where necessary, from the sediments to the waterway. Amendments such as activated carbon (AC) which have been demonstrated to be effective at reducing concentrations of hydrophobic compounds in the aqueous phase, and oleophilic clay (OC) media, which have been demonstrated to sequester free or mobile NAPL, are among those being considered for inclusion in the sediment cap. A treatability study was designed to obtain site-specific sorption isotherm parameters and NAPL sequestration rates to replace conservative literature values which were previously used in the horizontal barrier system design. This presentation will describe the treatability study design, challenges, and results in the contexts of amendment performance and the applicability of the data for use in modeling of the sediment cap.

764 Port Lands Flood Protection and Enabling Infrastructure Project: Design of Aquatic and Terrestrial Habitat

H. Sweeney, Michael Van Valkenburgh Associates, Inc. / Projects; M. Janes, Waterfront Toronto / Projects

As indicated earlier, the Port Lands Flood Protection and Enabling Infrastructure (PLF) Project is a $1.25B project led by Waterfront Toronto, the City of Toronto, Toronto and Region Conservation Authority (TRCA) and CreateTO, and with the support and involvement of Ports Toronto, and funding from the three levels of government. In addition to providing flood protection to approximately 250ha of flood vulnerable lands, this project will transform ~30 hectares of industrial brownfields into a naturalized, multi-outlet river valley system with associated channel spanning infrastructure, while unlocking the area for revitalization and facilitate billions of dollars in investment. PLFP will improve quality of life, bring nature back to an underused industrial site and better protect our neighbourhoods from extreme weather conditions. Built and established over a number of years PLFP will transform the new Don River corridor into a functioning aquatic and terrestrial system. The design does not attempt to duplicate pre-settlement historic conditions in the Don River Mouth area as the sediment transport regime, hydrology, and soil structure have changed dramatically in the past 150 years and cannot be restored. The Don River mouth restoration, therefore, is a new naturalized system based on regional river mouth areas that share similar urban watershed characteristics. The primary ecological goal is to establish a river channel and riparian vegetation framework that supports diverse native plant, fish and wildlife communities within the constraints of the Don River land use, hydrology and constructed valley form. The type and location of habitat features to be introduced by the project have been influenced by several specific objectives. First and foremost is the desire to establish ecological and geomorphic function within an immobile river channel. Toward this end, the design will include habitat forms and features that are resilient to site hydrology, in particular the predicted
variations in water levels throughout the project area. Another goal is to increase riverine, inner harbor shoreline, and wetland habitat quantity, diversity, and complexity for native fish over a range of flows and lake levels. The project will create wetland habitat that mimics the form and characteristics of off-channel and deltaic wetlands that historically were created naturally, including wetlands that provide a diversity of habitat types for multiple species. Habitat created by the project will include suitable nesting areas, basking and overwintering habitats for reptiles and amphibians, including turtles, in strategic locations. There will also be suitable areas for refuge, perching, and foraging habitats for wild mammal and bird species. These areas will be largely be located away from human activity to maximize the habitat value for wildlife.

765 Great Lakes Water Quality Improvement and Environmental Monitoring

M. Janes, Waterfront Toronto / Projects; V. Francella, Toronto and Region Conservation Authority

Toronto is Canada’s largest city, located on the north shore of Lake Ontario. In 1985 the International Joint Commission listed Toronto and Region as one of 42 Areas of Concern (AOC) on the Great Lakes where water quality and ecosystem functions were badly impaired due to industrialization and urbanization. Impacts to the public use of the waterfront included poor water quality and nutrients, contaminated sediments, contaminants in fish, loss of fish and wildlife habitat and populations and beach closings due to high bacteria. Since that time Implementation of the Toronto and Region Remedial Action Plan and restoration action have resulted in 4 of the 11 original beneficial uses being designated as “not impaired,” including bird or animal deformities or reproductive problems, degradation of benthos, fish tumors or other deformities, and restrictions on dredging activities. Implementation of the Toronto Waterfront Aquatic Habitat Strategy has created and restored habitats increasing the diversity of fish and wildlife species in the Toronto AOC. Levels of contaminants in fish continue to decline and there are no longer restrictions on consumption for many resident fish. Eight of Toronto’s 11 waterfront beaches are now Blue Flag beaches due to substantial reductions in E. coli loadings and beach closings. The aesthetics of Toronto watercourses and the waterfront are primarily considered excellent or good. Two pivotal projects to delist Toronto as an AOC are currently underway, the $2.8 billion Don River and Central Waterfront Combined Sewer Overflow (CSO) Project which is critical wet weather flow infrastructure to address phosphorus and E. coli, and the $1.25 billion Port Lands Flood Protection and Don River Mouth Naturalization Project. The Don River Mouth project will create 29 hectares of naturalized area in a new river valley, which includes 14 hectares of aquatic habitat and wetlands to improve biodiversity and water quality and reduce flooding and erosion.

Pharmaceuticals in the Environment - Science Innovation and Current Regulatory Developments

766 Antidepressants in Surface Waters: Fluoxetine Influences Mosquitofish Anxiety-Related Behavior at Environmentally Relevant Levels

J.M. Martin, M.G. Bertram, M. Saaristo, J. Fursdon, S. Hannington, Monash University / School of Biological Sciences; B.W. Brooks, S.R. Burket, R. Mole, Baylor University / Department of Environmental Science; N. Deal, B.B. Wong, Monash University / School of Biological Sciences

Pharmaceutical pollution is a serious, global issue. Indeed, the rise in production and diversification of pharmaceuticals--and synthetic chemicals more generally--is equal to, or exceeds, most other recognised drivers of global change. Of particular concern are pharmaceutical pollutants with evolutionarily conserved drug targets and the ability to alter biological function at minute concentrations. The antidepressant fluoxetine is one such pollutant, which has the potential to disrupt behavioural pathways through impacts on the central nervous system and neuroendocrine system. Despite this, it remains unclear whether environmentally relevant fluoxetine exposure can adversely impact behavioural processes in wildlife. To address this knowledge gap, we investigated effects of two field-realistic concentrations of fluoxetine (x: 60.5 and 351.9 ng/L) on sociability and anxiety-related behaviours in male and female eastern mosquitofish (Gambusia holbrooki). Sociability and anxiety-related behaviours are known to regulate important inter- and intraspecific interactions and, if disrupted, have the potential to impact the fitness of exposed wildlife. Additionally, we measured whole-body tissue concentrations of fluoxetine and norfluoxetine (fluoxetine’s primary metabolite). We found that fluoxetine exposure altered anxiety-related behaviour, whereas no significant effect of exposure on sociability was observed. What is more, observed impacts of fluoxetine on anxiety-related behavioeur were sex-specific, with females showing reduced anxiety-related behaviour at the lower dosage, while males showed an increase at the higher dosage. Fluoxetine and norfluoxetine were present in the tissue of male and female fish in both the low (x: 5.5 and 10.1 ng/g, respectively) and high dosages (x: 10.3 and 26.8 ng/g, respectively). Further, the bioconcentration of fluoxetine and norfluoxetine was size-dependent, with smaller fish showing higher relative tissue concentrations of fluoxetine and norfluoxetine. In combination, these findings provide evidence that fluoxetine at field-detected levels can alter the behaviour of fish, but also suggest that the magnitude and direction of these effects are dependent on sex and dosage. Moreover, our results provide insights into the apparent disparity of previously reported behavioural effects resulting from fluoxetine exposures.

676 How to tackle the environmental risk of mixtures? A new Adverse Outcome Pathway-informed model approach for drug mixtures in fish

P. Marmion, Brunel University London / College of Life Sciences; S. Owen, AstraZeneca / Safety Health Environment; L. Margiotta-Casaluci, Brunel University London / Institute of Environment, Health and Societies

The presence of low concentrations of non-steroidal anti-inflammatory drugs (NSAIDs) in the aquatic environment has raised the concern that chronic exposure to these compounds may cause adverse effects in wild fish populations. This potential scenario has led to the inclusion of diclofenac in the European Union Watch List of emerging pollutants; however, there are currently over 20 NSAIDs on the market suggesting that mixture effects may occur. Here we present an integrated pharmacology-informed framework that enables the prediction of potential adverse effects in fish exposed to a mixture of NSAIDs. This framework combines two mechanistic visions: network-centred and target-centred. Initially we generated an in vitro bioactivity network for a mixture of nine NSAIDs. This network, including over 140 nodes, was filtered using drug uptake and pharmacokinetic parameters to generate a more simple network displaying the biological activity expected at environmentally relevant levels of exposure. This was subsequently used to generate multi-organ target-phenotype anchoring predictions, specific for zebrafish, to identify the most likely phenotypic effects that might occur under the considered exposure scenario. This network-based approach was successfully combined with a more traditional target-centred approach based on the pharmacological hypothesis that the sustained inhibition of NSAIDs primary targets; cyclooxygenase (COX) 1 and 2 in healthy tissues is the key driver of toxicity. We developed a quantitative Adverse Outcome Pathway-informed model that incorporates both pharmacokinetic and pharmacodynamic aspects of NSAIDs toxicity. This dynamic visual model enables a rapid assessment of the risk posed by environmental levels of NSAIDs, and their potential to trigger multi-scale adverse effects. Although total COX inhibition activity in the plasma of wild fish may be sufficient to trigger COX ICS5s, the mean effect concentrations for all 9 phenotypic endpoints are above predicted environmental levels. Only 9% of the effect concentration data points were within predicted environmental levels, residing within endpoints for reproduction, immunomodulation, male testosterone, and plasma prostaglandin. We anticipate that the integration of these mechanistic approaches will provide a useful predictive tool to support
the implementation of effective NSAIDs ecopharmacovigilance strategies; facilitating the regulatory interpretation of past and future toxicity data.

768 Revisiting the fish plasma model - experimental evidence for the underlying hypotheses
A. Coore, ECT Oekotoxikologie GmbH; R. Brown, University of Exeter; R. Länge, Bayer Ag / Pharmaceutical Devision; S. Owen, AstraZeneca / Safety Health Environment; J. Ryan, GlaxoSmithKline / EHS&S; C. Tyler, University of Exeter / Biosciences College of Life and Environmental Sciences; M. Weil, ECT Oekotoxikologie GmbH / ECT Oekotoxikologie

The fish plasma model (FPM) combines the prediction of blood plasma concentrations of pharmaceuticals in exposed fish with extrapolation of the potency of pharmaceuticals from humans to fish. Within the research project iPIE (Intelligence-led Assessment of Pharmaceuticals in the Environment), extensive experimental and theoretical work was carried out with the purpose of widening the applicability of the FPM and validating it as a prioritization tool for environmental risk assessment of human pharmaceuticals. The various underlying hypotheses of the FPM will be revisited in this presentation, namely the predictability of fish plasma concentrations using lipophilicity as a descriptor, the evolutionary conservation of pharmacological targets mediating specific effects in fish, and the expectation that no adverse toxic effects occur in fish at plasma concentrations below human therapeutic plasma concentrations. Experimental data, made available through iPIE from both standard and non-standard studies with fish, were applied to test the hypotheses of the FPM and identify remaining uncertainties and limitations. The overarching finding is that fish plasma concentrations can be predicted from external water concentrations also for ionized pharmaceuticals, yet with remaining uncertainty. For some (but not all) selected pharmaceuticals, sub-lethal non-standard endpoints such as heart beat and enzyme activity indicated that effects in fish were indeed mediated by the pharmacological target. Effects on apical standard endpoints as obtained in a fish early life stage test according to OECD 210 appeared mostly unlikely to occur below human therapeutic plasma concentrations, providing some further support for this key hypothesis of the FPM. This work has received support from the EU/EFPIA Innovative Medicines Initiative Joint Undertaking (iPIE grant no 115735).

769 Ecological implications of the exposure of marine mussels to sulfamethoxazole antibiotic. Bioconcentration, metabolic alteration and antibiotic resistance
S. Rodríguez-Mozaz, A. Serra-Compte, D. Alvarez-Muñoz, Catalan Institute for Water Research ICRA; M. Solé, ICM-CSIC; N. Caceres, Catalan Institute for Water Research ICRA / Water Quality; A. Sanchez-Melsio, J. Balcazar, Catalan Institute for Water Research ICRA; D. Barcelo, ICRA / Department of Environmental Chemistry

Antibiotics are contaminants of emerging concern found in aquatic environments worldwide. They may alter the normal functioning of exposed organisms and microorganisms and also contribute to antibiotic resistance in the environment. The main objective of this work was to study the effects of antibiotic pollution into marine organisms through the comprehensive assessment of several ecotoxicological endpoints. Mussel specimens (Mytilus galloprovincialis) were exposed to water with 10 µg/L of the antibiotic sulfamethoxazole (SMX) and SMX occurrence in mussel’s haemolymph was monitored during the experiment. Haemolymph was also analyzed for metabolomics profiling using a non-targeted approach based on High Resolution Mass Spectrometry (HRMS). Data was further analyzed by chemometrics to evaluate the contribution of each potential marker to the distinction between the control and exposed groups. Results showed low bioaccumulation of SMX, up to 4 µg/L in mussel’s haemolymph after 96h exposure. Exposed mussels did not show any significant alteration in the enzymatic activities related to the xenobiotic metabolism and oxidative stress. However, the metabolomics approach allowed the identification of endogenous metabolites significantly altered due to SMX exposure including amino acids, nucleosides, etc. involved in different biological functions. In a second experiment, marine mussels were exposed to SMX subinhibitory concentrations (100 µg/L) to investigate the spread of antibiotic resistance. The presence of genes conferring resistance to sulfonamides (sul1 and sul2) and the class 1 integron-integrase gene (intI1) and the bacterial community composition associated with the gastrointestinal tract were investigated. Results showed that all analyzed antibiotic resistance genes (ARGs) were present in mussels, even in those used as controls. Moreover, exposure to SMX caused a significant increase in the absolute copy number of sul in mussels. Overall, our findings provided further understanding on the ecotoxicological implications of antibiotic pollution to exposed organisms. No risk for consumers derived from mussel ingestion is expected due to the low bioconcentration capacity of SMX and fast depuration. However, the presence of ARGs in these organisms, as well as the contribution of anthropogenic pollution to spread of ARGs, highlights the importance of monitoring antibiotic pollution in the aquatic media.

770 The Movement of Antibiotics in Urban Streams: Do Different Classes Influence Transport?
A.D. Gray, A.E. Hershey, University of North Carolina at Greensboro / Department of Biology

Antibiotics have been detected in various aquatic habitats (river, lakes, streams, estuaries, open ocean). Due to their widespread presence in aquatic habitats, extensive research has investigated their distribution and concentration. Several studies have tracked antibiotic concentrations over kilometer (km) scale reaches. However, monitoring data do not provide insight into controls on antibiotic transport within a reach. Reach scale uptake studies across antibiotic types are needed to understand the role of sediment processes in regulating downstream antibiotic transport and, accordingly, controls on observed larger scale patterns of antibiotic distribution. In this study, we conducted field experiments in a second order stream in Peabody Park, an urban stream that runs through the University of North Carolina at Greensboro campus. We applied solute spiraling concepts to assess Snet (net uptake rate), Vfnet (uptake velocity), and unet (uptake rate) of sulfamethoxazole, sulfameralazine, danofloxacine, erythromycin, and ciprofloxacin following introduction into a stream reach. Studies were conducted in the spring of 2019. We found that Snet of SMX, SMR, DAN, ETM, and CIP was 15.7, 16.9, 14.5, 19.8, and 158.7m respectively. Vfnet for the previously mentioned antibiotics was 1.97E-06, 6.63E-06, 2.14E-06, 1.56E-06, and 1.95E-07 m s-1, respectively. Unet was 1.58E-05, 5.62E-05, 3.31E-06, 1.31E-06, and 1.09E-08 µg m-2 s-1, respectively. These findings demonstrate that antibiotics are not transported conservatively in streams and that reach-scale retention occurs in low order streams. This study also highlights that transport and retention dynamics vary widely among antibiotics, which could enlighten understanding of patterns of antibiotic distribution among environmental compartments.

771 Predicting the reduction in total estrogenicity and fish intersex in response to wastewater treatment plant upgrades
M.J. Arloz, Eawag - Swiss federal Institute of Aquatic Science and Technology / Biology/Civil and Environmental Engineering; W.J. Parker, University of Waterloo / Department of Civil and Environmental Engineering; J. Bicudo, P. Law, Region of Waterloo: K. Hicks, Alberta Environment and Parks / Biology; M. Fuzeen, McMaster University / Biology; S. Andrews, University of Toronto; M.R. Servos, University of Waterloo / Biology

Endocrine-active compounds (EACs) have been associated with reproductive health effects in fish (e.g. intersex) exposed to poorly treated municipal wastewater treatment plants (MWWTP) effluents. Although many chemicals can alter endocrine function, natural hormones (17β-estradiol [E2] and estrone [E1]) and the active ingredient in birth control pills (ethinylestradiol [EE2]) have been shown to be the primary contributors to the estrogenic activity in effluents. Unfortunately, with the current analytical methods, it is difficult to detect estrogens at low concentrations in surface waters. In this study, we first employed
a consumption-based model based on population demographics and estrogen excretion rates to determine the concentrations of target EACs in major WWTP effluents in the Grand River watershed in southern Ontario (Waterloo & Kitchener). Then, the results of this model were fed onto a fate and transport model that estimated the temporal and spatial variability of the concentrations of estrogens along ~80 km river stretch. The predicted concentrations were then compared with the observed interspecies difference measured in rainbow darter (Etheostoma caeruleum) over the period when some of the treatment upgrades were made to the Kitchener MWWTP (2007-2015). The total estrogenicity (considering E1, E2, and EE2 only) during normal low flow (11m^3/s) was 0.45 ± 0.1 ng/L and 3.4 ± 0.9 ng/L E2 equivalents downstream of Waterloo and Kitchener WWTPs respectively. After the Kitchener WWTP upgrades, the total estrogenicity dropped to an average of 0.7 ng/L E2 equivalents (similar flow conditions) and is likely associated with Waterloo WWTP (located upstream) which was not upgraded at the time of our study. Furthermore, when the relationship between predicted total estrogenicity and observed interspecies difference was characterized via a concentration-response curve (four-parameter Hill equation), an effects concentration that is 10% of the maximal response (EC10) for estrogenicity was estimated to be ~0.1 ng/L E2 equivalence. This value suggests that low levels of intersex will be associated with many effluents until upgrades such as those at the Kitchener MWWTP are implemented. However, the relatively steep dose-response curve also suggests that improved treatment can dramatically reduce the intersex occurrence and severity in watersheds. The model may be used to test scenarios related to the potential effectiveness of treatment, impacts of population growth, or changes in hydrology (e.g., related to climate change).

772 The first global study of pharmaceutical contamination in riverine environments: Perspectives on drivers and risk from over 70 countries

J. Wilkinson, A. Boxall, University of York / Environment and Geography Department

Knowledge gaps exist regarding the occurrence and drivers of active pharmaceutical ingredients (APIs) in the environment, particularly in low to middle-income countries. Where data are available, use of a multitude of analytical methods hamper the ability to make robust associations with ecotoxicity risk and specific socioeconomic, health or physical drivers. Here we present the largest global API monitoring study and identify key drivers of pharmaceutical contamination and ecotoxicity risk in rivers worldwide. The study was composed of 92 sampling campaigns (n=711 sampling locations) performed across 72 countries (20 never studied before) at the time of writing. Analysis occurred for 61 APIs (19 therapeutic classes) using one interlaboratory-validated method. At least one API was detected in all of the countries analysed and as many as 35 were found in a single river (Kai Tak River, Hong Kong). Highest total API concentrations were in rivers suspected to receive discharge from API manufacturing facilities (eg, Delhi, India and Lagos, Nigeria), limited sewage treatment or unregulated waste discharge (eg, Lahore, Pakistan and Nairobi, Kenya) as well as regions of political instability (eg, Palestinian West Bank). Spatial analysis indicates while highest total API concentrations were observed in African and Asian rivers, those in Europe and N America typically exhibited a higher diversity of APIs but at lower concentrations. API contamination was positively associated with World Health Organisation disability adjusted life years. This was generally driven by specific disease pressures and the concomitant use of respective therapeutic classes of medicines. Multivariate statistics revealed associations between API contamination and socioeconomic drivers. Lowest levels of API contamination were observed in World Bank-defined ‘low’ income countries which dramatically increased in the ‘low-to-middle’ bracket before again dramatically decreasing in the ‘upper-middle’ and ‘high’ income countries. Clear geographical trends were observed in the global distribution of APIs, elucidating hotspots for potential ecotoxicity endpoints. Risk quotients for the selection of resistance to antimicrobials exceeded minimum selection concentrations by as much as 300 times (eg, Bangladesh). Our results show that API contamination is a global problem, linked to socioeconomic and health drivers for the first time, and may affect biological endpoints on a regional basis.

773 Ecopharmacovigilance of human medicinal products: Assessing and managing the real world risks resulting from patient use

Ecopharmacovigilance (EPV) is a developing science concerned with the detection, evaluation, understanding and prevention of adverse effects of active pharmaceutical ingredients (APIs) in the environment. In Europe and North America, a new regulatory submission or a line extension is normally accompanied by an Environmental Risk Assessment (ERA), but there is no regulatory requirement to monitor the environmental risks of medicines post-launch. However pharmaceutical residues in the environment and ecotoxicological studies on effects of pharmaceuticals are continuously published. To understand the significance of these emerging data and ensure that any potential risks are identified and managed appropriately, we have developed a process for EPV. This presentation will describe our EPV processes, how it works in practice and present a semi-probabilistic and spatially explicit environmental risk assessment for the patient use of several cardio-vascular and oncology APIs detected in the environmental surface waters. The EPV process includes: (i) routine literature monitoring for emerging data on APIs we have a commercial interest in, (ii) quarterly review of the data and appropriate risk management, (iii) transparency of product-specific ERA, and (iv) update of ERA where emerging data challenge the original assumptions. Over 23,000 instances of selected APIs have been reported; most are recorded on GIS maps to understand hot spots. Less than 2% of the data required more detailed investigation and most relate to a small number of well-studied compounds such as β-blockers (propranolol, atenolol and metoprolol) and some generic compounds used in AZ combination products (mostly naproxen, hydrochlorothiazide and metformin). Semi-probabilistic assessments of environmental risk have also been conducted for each API. EPV is the environmental equivalent of pharmacovigilance and allows the environmental impact of ongoing patient use to be managed through (i) routine literature monitoring for emerging data, (ii) the update of an ERA where emerging data challenge the original assumptions, and (iii) highlighting when APIs are detected in the environment at levels above published PNEC. EPV to date indicates that these instances represent < 2% of the total reported concentrations indicating site specific rather than generic risks that can be attributed to low flow, low dilution or poor wastewater treatment.

Tangible Ways to Integrate One Health into Risk Assessments

774 One Health concept is not applicable to modern chemicals management

A. Fairbrother, Exponent / EcoSciences

One Health is a seductive concept. People are no different from other species in our dependence on a functional ecosystem to maintain life and thus, keeping the planet healthy is the same goal for environmental managers and public health practitioners. Indeed, pets and livestock that live in close proximity to humans are known to share diseases and accidental poisonings to common drugs and household chemicals, so closer interactions between physicians and veterinarians would be beneficial. However, direct extension of One Health to environmental chemicals management has proven to be elusive. The “canary in a mine” analogy works for surprisingly few substances as it is dependent upon a species with a sensitivity to a chemical that is greater than that of people or that
has a shorter exposure-to-effect time. Enlightened methods of chemical risk review and management reduce the probability of an environmental surprise, such as occurred in mercury-poised cats in Minamata, Japan in 1956 or DDT-poisoned birds in the 1960s, and we now have more accurate personal dosimeters to monitor human exposures to known hazards in the workplace. A study by the U.S. National Academy of Sciences in 1991 found very little evidence of animals acting as good sentinels for chemical risks to humans, either based on cancer registries or environmental exposures. Perhaps newer information 25 years on may have a different outcome but if so, it’s not obvious. Given that various ecosystem services (clean water, clean soil, fishable rivers, etc.) are standard endpoints in ecological risk assessments, it is difficult to envision what additional advantage derives from the application of the One Health concept to modern chemicals management.

775 Ways that One Health has been integrated into contaminant risk assessments and other ideas for its future integration

M.W. Kierski, Exponent / Ecological and Biological Services Practice
One Health is defined as “the collaborative effort of multiple disciplines-working locally, nationally, and globally–to attain optimal health for people, animals, and our environment.” The practice of chemical risk assessment first developed by USEPA fosters the collaborative efforts embodied in the One Health approach in that the practice of risk assessment, both human or ecological is very multidisciplinary, and integrates both risk information about people and the myriad of other animals exposed to chemicals in the environment. However, USEPA created separate guidance for human and ecological risk assessment, with little to no guidance written to integrate the two disciplines together, which is not in the spirit or consistent with One Health. Most risk assessors do not think consciously about using a One Health approach when they do their risk assessments, however, in practice most risk assessors have integrated human health and ecological risks together which is in the spirit of One Health. This is seen most keenly in the development of the complex conceptual site models we create that help us to illustrate the potential linkages between pathways of chemical exposure and the human and other animal receptors potentially exposed and at risk. With the increasing consideration of ecosystem services in contaminant risk assessments, the linkage among all organisms becomes even more clear. This talk will explore how the integration of human health and ecological risk assessments is typically achieved when performing contaminated risk assessments and offer ideas how we can further use a One Health approach as we conduct contaminant risk assessments.

776 Problem formulation for integrated human and ecological risk assessment

G.W. Suter, US Environmental Protection Agency / ORD/NHEERL
Achieving the advantages of integrated health and ecological risk assessment depends on consistent problem formulations. Problem formulation is the process of determining the content of a risk assessment. It first appeared in the U.S. Environmental Protection Agency’s (EPA) 1992 framework for ecological risk assessment and was adopted by the EPA’s health risk assessors in 2016. However, health and ecological problem formulations are still not consistently integrated. Potential advantages of integration include efficiency due to reduced duplication of effort, more complete information as results are shared, and compatible risk assessments results due to more consistent input. Integration could be facilitated by increased formality of problem formulation so that everyone would know what is needed. For example, the recently proposed dimensions of water quality criteria can serve as a problem formulation checklist for setting criteria to protect aquatic life. If a chemical is found to be bioaccumulative, that could trigger inclusion of a dietary pathway for humans and other piscivorous species. Formalization of problem formulation would also include greater transparency of the methods. For example, problem formulations involve literature reviews and increasingly those are systematic reviews. Also, the weighing of evidence to determine the appropriate endpoints and assumptions concerning exposure should be more transparent and should follow an explicit method. The institutional silos and traditional processes are still impediments to integration, but jointly formulating the problem formulation could begin to clear those impediments.

777 The Critical Role of Environmental Quality in a One Health Framework: An NIEHS Perspective

H.F. Henry, National Institute of Environmental Health Sciences / Department of Extramural Research and Training; K. Thigpen Tart, (NIEHS) National Institute of Environmental Health Sciences / Office of Policy, Planning, and Evaluation; N. Sipes, Division of National Toxicology Program/NIEHS / NTP; D. Carlin, National Institute of Environmental Health Sciences / DERT; M. Heacock, B. Trottier, W. Suk, NIEHS / DERT
One Health is a concept that recognizes the interdependence of people, animals, plants, and our environment for achieving optimal health. Given its broad scope, a One Health framework requires coordination among human biomedical, veterinary, ecotoxicology, and environmental expertise to address complex health problems. Excellent headway has been made on identifying integrative solutions for waterborne/vector-borne disease transmission and anti-microbial resistance using a One Health approach. However, despite the critical role environmental contamination plays in ecosystem function, disease resilience (both animal and human), and general well-being, there has been less emphasis on the use of environmental health science in One Health approaches to risk assessment and disease prevention. Organizations, including the National Institute of Environmental Health Sciences (NIEMS), are recognizing the need and opportunity to identify tangible lines of evidence that will better delineate and quantify the role of environmental health in One Health. NIEHS supports several transdisciplinary research programs and initiatives that employ the One Health approach. For example, chemical pollution’s impact on the immune system may increase susceptibility to infection and, therefore, the incidence of waterborne/vector-borne disease transmission. NIEHS explores new approach methodologies that have potential to expand the use of non-traditional animal and in vitro models to identify common mechanisms of action that may inform risks assessment or potential interventions. The NIEHS Superfund Research Program has been identifying environmental solutions, such technologies that can reduce the bioavailability of contaminants in food, thus preventing their transfer up the food chain and protecting human health and the environment. NIEHS also is engaged in national and global health studies using a One Health approach to understand the role of environmental exposures in exacerbating poor health outcomes in agricultural communities, in areas of high Zika transmission, in mining communities, and in times of disasters such as oil spills, wildfires, and flooding. Collectively, these ongoing activities support the development of scientifically sound human health risk assessment and ecological risk assessment tools, and demonstrate the importance of integrating the consideration of environmental exposures into the One Health framework.

778 Ecological Risk Classification: A One-Health Approach for Prioritizing Organic Chemicals for Further Risk Assessment in Canada

M.A. Bonnell, Environment and Climate Change Canada / Ecological Assessment Division
In 2016 Environment and Climate Change Canada (ECCC) published the Ecological Risk Classification (ERC) approach to re-prioritize 640 organic chemicals on Canada’s Domestic Substances List (DSL) originally prioritized in 2006 as persistent (P) or bioaccumulative (B) and inherently toxic (IT). ERC was used to re-think organic chemical priorities for further risk assessment for the third phase of Canada’s Chemicals Management Plan (CMP3). ERC classifies the risk potential of organic chemicals using multiple descriptors contained in hazard and exposure profiles and is a large departure from the traditional hazard criteria approach (e.g., PBT or vPvB). ERC provides weight of evidence for risk classification by integrating data from new approach methods (NAMs)
with traditional data from human and ecological toxicology. ERC employs novel exposure descriptors that assesses exposure potential to human and ecological receptors at various spatial and temporal scales. The second version of the ERC (ERC2) is under development by ECCC for the prioritization of approximately 12200 organic chemicals on the DSL not prioritized in 2006 as P or B and it chemicals. Details of ERC2 are presented. Like ERC1, ERC2 remains a rule-based prioritization system, but expands on the one-health concept by increasing the toxicological and exposures space from ERC1. ERC2 seeks consensus within and among in vitro, in silico, in chemico, exposures space. ERC2 will provide ECCC with one mechanism for determining chemicals of most concern for post 2020 chemical's management work planning by responding to various regulatory questions such as identification of potential endocrine active substances, regrettable alternatives, high hazard or exposure concerns, potential research and monitoring priorities, etc.). A case study showing the results of a comparison of approximately 100 high priority substances identified in 2016 using ERC with the original 2006 classifications will also be presented.

779 Integrating the “One Health” approach in the design of sustainable compounds for military use

M.S. Johnson, US Army Public Health Center / Toxicology

Sustainable use of testing and training ranges within the U.S. Department of Defense is a critical goal in maintaining a ready force capable of meeting future security requirements. Large land areas are required for these purposes, many of which support valuable resources to local communities in terms of maintaining ecosystem services, preserving rare species, and providing for the general health of civilians and their families. Although there are regulations that require that environmental and occupational health aspects be considered, specific data requirements coincident with new chemical and weapon system design have not been elucidated. Working with research, testing and development entities, the Army has demonstrated a phased approach to environmental and occupational health data acquisition that is commensurate with the relative development of material research, design, testing and evaluation. This process using new and innovative approaches to initially provide relative comparisons provides a technical foundation from which to make decisions and focus toxicity testing designs that include human health and ecotoxicity. Examples will be provided.

780 Towards an Integrated Understanding of Environment and Health Risks from Inland Harmful Algal Blooms

B.W. Brooks, Baylor University / Department of Environmental Science

Though we have known for decades that nutrient enrichment of surface waters can lead to excessive algal growth, including the development of harmful algal blooms (HABs), the causes and consequences of toxins produced by these blooms has recently received heightened attention from environmental public health practitioners. Nutrient enrichment, primarily from phosphorus (P) and nitrogen (N), increases the frequency and magnitude of blooms along the freshwater to marine continuum. Climate change can affect incidents of HABs and salinity, which can be altered by both changes in precipitation and sea level rise. Whereas ecological studies and monitoring activities have previously examined “toxicity,” these efforts are routinely limited by absence of robust analytical quantitation of diverse toxins produced by specific HAB species and comparative toxicity exerted through multiple mechanisms of action including major alterations in water quality conditions resulting in differential risks to human health and ecosystems. This represents a critical consideration for management of water resources and protection of human health and ecosystems because algal growth does not necessarily predict toxins production, yet routine monitoring and surveillance activities, an essential environmental public health service, when these efforts do exist, use microscopic methods for cyanobacteria and thus do not quantify the presence of toxins. If toxins analysis occurs, it most commonly uses ELISA techniques to check for presence of microcystin. Further, commonly used water quality models lack inputs for toxins production, which inherently limits predictive capacity of HAB events. Some species of cyanobacteria have evolved unique adaptations to promote their growth under N-deficient conditions, but it remains unknown whether or not these traits actively exist simultaneously with toxins production. Developing predictive growth, toxins production and comparative toxicity models for cyanobacteria that commonly dominate toxic HAB events across relevant environmental gradients is thus imperative for forecasting, diagnosing and preventing human health and ecological risks presented by algal toxins, which appear to represent a transformative threat to water resources assessment and management. Our ongoing research is examining inland HABs and known toxins along the freshwater to marine continuum, which supports development of water quality modeling capacity for environment and health risks.

781 The Old Lead Belt in Missouri: A One Health Approach

K. Knott, Missouri Department of Conservation / Environmental Health Unit; J. Baker, P. Blanchard, Missouri Department of Conservation; C. Kennedy, Missouri Department of Conservation / Department of Biological Sciences; J. Isabelle, Missouri Department of Conservation; L. Lawson, J. Wenzel, Missouri Department of Health and Senior Services

Lead (Pb) and zinc mining in Southeast Missouri began in 1740 with the greatest production occurring during the early 20th century. Many areas continue to be contaminated with elevated concentrations of heavy metals that are of concern to the health of both humans and the environment. The Old Lead Belt includes the Big River watershed (BRW) which was designated as a Superfund site in 1992 due to elevated concentrations of Pb in water, sediments, and fish tissues. Tissues from sportfish and hunter-harvested turkeys from the BRW were collected during 2018 to examine the concentrations of Pb and inform consumption advisories for anglers and hunters. These data will improve our knowledge of the sub-lethal effects of Pb in aquatic and terrestrial species, guide ecological risk assessments, and protect recreational activities in Missouri. The Department of Health and Senior Services advises to not consume Sunfish, Carp, and Redhorse species from the Big River due to elevated concentrations of Pb. Current results indicated that sportfish from the Big River also had a reduced organ: body mass ratio for hepatopancreas and spleen. Organ: body mass ratios will be compared to metal concentrations in fillets of fish sampled during 2018 and organ histopathology to determine whether elevated Pb concentration is associated with cellular injury. Concentrations of Pb in turkeys decreased as bone > feathers > kidney > liver > muscle. Pb concentrations in muscles from the turkey harvested from the BRW were 2.4 times higher than reference birds, but Pb concentrations were below 100 ng/g ww and considered safe for human consumption. Concentrations of Pb in liver and kidney in the BRW turkey, however, exceeded reference concentrations by over 50-fold. Pb in liver and kidney of the BRW turkey and kidneys from 2 reference turkeys exceeded human health thresholds. Fish, wildlife, and humans that share a contaminated landscape also share similar health risks. A One Health perspective on these risks is necessary to protect anglers and hunters that consume fish and wildlife to improve food security and recreational value. An evaluation of Pb concentrations in fish and wildlife from the Big River watershed will identify the spatial extent of contaminated soils in the Old Lead Belt, and support remediation and restoration of contaminated habitats.
Effective Science Communication in a Science Unfriendly World

782 International Science Communication: Starting Points For And By Environmental Scientists

L.M. Langan, Baylor University / Biological and Marine Sciences; A.D. Hunka, RISE Research Institutes of Sweden / RISE Viktoria ICT

SETAC as a society could arguably be considered a very large social network which is actively teaching, and engaging people who are already interested in and understand the importance of science. However, there is increasing pressure and an expectation that both scientific institutions (viz. companies, universities, governmental bodies) and the scientists within them should communicate their research to a wider audience. Importantly, this is without any appreciable training but is duty-bound in order to improve perceived quality and credibility of the institutions and the science. Despite a high degree of interest in improving communication between the public and various disciplines including academic journals, it is still difficult for faculties and scientists to integrate social networks into their daily routines at an appreciable level. In a polarized world, environmental sciences pose many personal value-laden and ethical questions. This necessitates the identification and use of specific strategies or guidelines which encourage two-way communication and enables trust in both experts and the scientific results. Furthermore, as scientists who collaborate and work internationally, it is also important to recognize the different drivers of effective communication strategies have a cultural element. In this presentation, tools for effective science communication are outlined based on sound scientific advice that does not require further specialization in communication studies and with respect to country and cultural differences. Some examples based on SETAC regions will be outlined.

783 Nano-Titanium Dioxide in Food: What Can We Learn From France?

S.P. Toquica-Diaz, Globalomics Enterprises, Inc.

Food-grade Titanium Dioxide containing nanoparticles (nanoTiO₂) is used as a whitening, brightening and anti-caking agent by the food industry in various products (i.e. chewing gums, candies, cake icing, sauces, etc.). In Europe this food additive is registered as E171. Safety concerns are rising on nanoTiO₂. NanoTiO₂ can move across the intestine membranes and has been absorbed in blood in studies with patients suffering from ulcerative colitis. NanoTiO₂ has been found in organs such as liver, kidney, lung, brain and spleen in oral exposed rodents. Also, research in mice indicates precancerous lesions. Furthermore, children have the highest exposure and are the most susceptible receptors. For example, the food products that have higher nanoTiO₂ representation for young children are confectionery (chewing gums, chocolate and sweets) and baked goods (biscuits). France exemplifies risk management that includes NGOs and research institutes, among others to ban E171. Greenpeace, Foodwatch and the Alliance for Health and the Environment ethically that included the decision to ban E171 by 2020 and the French government followed with a ban as of January 1st, 2020. There is mounting evidence backed by Science of the harmful effects of nanoTiO₂ in food albeit uncertainty. However, how can scientists present their findings more effectively to effect change in North American policies? Especially, when the health risks seem high and when children are the most vulnerable, susceptible and exposed segment of the population. What lessons can we learn from France? Could the Precautionary Principle and examples of novel “nano” regulation be relevant for North America policy makers?

784 Possible solutions to controversy over scientific data generated for regulated products: What does industry have to offer

A. Alix, Corteva Agrisciences / Risk Management

Distrust, questioning and rejection of scientific data is an even more generalized issue when dealing with industry data that are generated for regulated chemistries. The basis for this probably lies in the lack of visibility on the purpose of these data, the data requirements that dossiers must comply with, the quality standards of the studies to be generated to address those data requirements, on the content of the studies themselves, and on the review process that is in place in all geographies to evaluated the scientific quality and reliability of regulatory data. In addition, there is little visibility on the inherent relation between regulatory data and academic science: testing guidelines, risk assessment guidance documents and additional studies used for in situ risk assessments are all based on academic research in the first place. Finally, research and development processes are covered by industrial property and secrecy, which makes difficult to communicate and illustrate how science does drive the discovery of a new mode of action, what a molecule can and cannot do, and on the selection process of a molecule that meets both efficacy and safety purposes. This presentation proposes to illustrate the initiatives in place within industry, taking the example of the pesticide industry, to address the visibility issues over the content of regulatory dossier, which match the expectations of the upcoming General Food Law in Europe. The presentation will discuss industry data into the context of regulations, i.e. for the characterization of potential risks to human health and the environment and define the conditions of use that represent negligible risks, as a basis to address the controversy issues that may be resolved by contextualization. Finally, some proposals to further increase visibility, exchange of data and communication will be presented to feed into the discussion.

785 Grassroots Organizing Strategies for Effective Science Communication in Environmental Justice Communities

M.E. Guvader, Earthjustice / Community Steering Committee Representative

Transactional engagement with the public undermines traditional methods of science outreach, particularly when working with communities directly impacted by environmental racism. Insights from grassroots organizations offer an alternative model for science communication centered upon intentional relationships and trust building. This presentation will introduce basic principles of grassroots organizing and racial justice theory, while proposing strategies for science communicators to break out of the “white savior model.” Audience members will be challenged to articulate their self-interest in science communication. Funding challenges for environmental justice research will also be discussed.

786 Challenges of communicating scientific methods to lay and technical audiences: Use of the Risk Challenge Program

R.G. Stahl, DuPont (retired); A. Liu, The Chemours Company; D. Lander, The Chemours Company / Fluoroproducts; Z. Yin, DuPont Company

We have been involved with communicating scientific methods to lay and technical groups in the U.S. and elsewhere for multiple years. Our main focal areas have been in toxicology, exposure science, and risk assessment for humans and ecological receptors. Over time, we have had to adapt the communication approach to recognize the rapid changes in communication technologies, and how members of our audience are expecting to receive new, relevant information. In our presentation we will illustrate four aspects of communicating that required us to change: 1. Our thought process and methods for assessing risks; 2. Level of detail we convey; 3. Time involved with the exercise; and, 4. Speed and ease of obtaining feedback from audiences. Our case example is built upon our Risk
Thursday Platform Abstracts

Challenge Program that we use to illustrate the approach for assessing risks to humans and ecological receptors, both for new/existing chemicals, and for a remediation site. Our discussion will draw upon recent experience gained through conduct of the Program in the U.S., mainland China, Taiwan, and South Korea.

787 Profile-building, research sharing, and data proliferation using social media tools for scientists
A.J. Williams, US Environmental Protection Agency / National Center for Computational Toxicology

Many of us invest significant amounts of time sharing our activities with friends and family via social networking tools such as Facebook, Twitter or other related websites. However, despite the availability of many platforms for scientists to connect and share with their peers in the scientific community, most do not use these tools to impact and influence their professional careers. Scientists are already being indexed and exposed on the internet via our publications, presentations and data and new “AltMetric scores” are being assigned to scientific publications as measures of popularity and, supposedly, of impact. We now have more options to contribute to science, to annotate and curate data, to “publish” in new ways, and many of these activities are part of a growing crowdsourcing network. With so many web-based platforms to share publications, presentations, data and activities, how does a scientist shortcut their way to understanding what is available and the benefits of use? Participating online, whether it be simply for career advancement or for wider exposure of your research, there are now a series of web applications that can provide a great opportunity to develop a scientific profile within the community. This presentation will provide an overview of what is available and the potential benefits of investing a small amount of time in developing an online profile and communicating your science to a networked audience, especially as an increasing number of potential employers and collaborators utilize the web to research scientists. This abstract does not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

788 How to effectively communicate science to a larger audience using blogging
M.L. Rodgers, University of Southern Mississippi / Division of Coastal Sciences

As the internet continues to shape our world, scientists are faced with communicating research online to non-science groups such as shareholders, friends and family, and the general public. If you’re like me, you understand that effective science communication (scicomm) can open the door to exciting career opportunities, but you may find it difficult to showcase your science communication skills using your own research. What’s a potential solution so that you can sharpen your scicomm skills without awkwardly gushing about the importance of your own science? Getting involved in talking about OTHER people’s science, especially the foundational works and the latest and greatest advances! This talk will focus on ways for scientists to hone in their science communication skills through blogging. The wonderful thing about blogging is that it’s free and you have the ability reach a large, global audience! However, starting your own blog as an individual can make it difficult to “get the word out” and have a large viewership, especially when your posts may be infrequent due to work and other responsibilities. So what’s a toxicologist to do? One way to increase frequency and visibility of posts is to work with a team to build a blog featuring free, simple, and digestible science content to readers. As a founding member, editor, and writer for the scicomm blog project Immunobites, I’d like to share my trials and triumphs of getting a scicomm blog up and running (by working with an editorial board, setting up a website, recruiting quality writers, coming up with rules for formatting and writing posts, and ensuring quality editing). I hope that this talk with inspire the early career professionals of SETAC so that we can gather as many willing toxicologists as possible to found a toxicology-based blog to promote basic concepts in toxicology and current toxicology research to readers. A large endeavor such as this can gather toxicologists from all backgrounds, skills, and areas of interests to maintain a blog that not only benefits its readers, but also benefits its contributors by helping them gain experience in editing, writing, scientific illustration, and more!

789 Effectively Engaging the Public About Your Research: Tips to translating Your Science to Everyday People
A.D. Gray, University of North Carolina, Greensboro / Biology

Science communication is a skill that is not heavily practiced in graduate school. Many researchers never really delve into the world of science communication because in most cases their work is presented to an audience of their peers at scientific conferences/meetings. In an era where the disconnect between the scientist and the public is evident, engaging to those outside of our respective field is an important way to ensure we as scientist can help bridge the gap between the scientist and the public. The world we live in now is fast pace and is driven heavily by social media. There are countless ways we as scientist can use this to our advantage to help us translate our research. Science communication is not just for those that are social media savvy, but also those that are effective at communicating to the general public. The work we do as scientist always has a broader impact, however, if the people we serve do not understand the work we do, it make appreciation of it very difficult. Through the past few years I have practiced effective science communication with my research at a local, regional, and national level. The better we are at communicating, the better we are able to close the gap between the public and scientist. The success we have in communicating can translate to policy decisions and educating individuals that previously, may not have had much insight into our respective fields.

Oil Sands Monitoring Program: Synthesis of Results and Progress Towards Cumulative Effects Monitoring

790 History, overview and governance of the Oil Sands Monitoring program
M. Dube, Alberta Environment and Parks / Environmental Monitoring and Science Division; K. Cash, Environment and Climate Change Canada; F.J. Wrona, Alberta Environment and Parks / Environmental Monitoring and Science Division; N. Hamzawi, Environment and Climate Change Canada; Y. Ilesanmi, Government of Alberta / Environmental Monitoring and Science Division; J. Dawson, Environment and Climate Change Canada; R. Hazewinkel, Alberta Environment and Parks / Environmental Monitoring and Science Division

The current Oil Sands Monitoring (OSM) Program has developed through a series of independent reviews commissioned by the Federal and Provincial governments and by the Royal Society of Canada. In 2011, Federal and Provincial governments committed to a new environmental monitoring system designed to report on changes in environmental condition associated with oil sands development. OSM initially reflected a three-year commitment to implement a program designed by environmental experts including external monitoring partners, organizations, and academic institutions to assess environmental change associated primarily with the mineable segment of the oil sands industry. The comprehensive design includes monitoring across environmental media and a commitment to a cumulative effects approach funded by industry through regulation up to $50M per year. Over $350M has been invested in the OSM program to date. Following the three-year implementation phase, a mandated review process in 2016 identified the need for more specific scientific goals, improved integration across components, more comprehensive analysis and interpretation, and greater transparency. To this end, in 2017 the governments of Canada and Alberta committed to a renewed Memorandum of Understanding. Also in 2017, OSM undertook to develop a more inclusive approach to program design, management, and implementation, with the intent to involve Indigenous communities in all aspects of the program and explicitly to incorporate Indigenous...
Knowledge in a system of knowledge co-creation. The commitment of OSM to meaningful engagement with Indigenous communities is set out in the 2018 Operational Framework Agreement, which establishes a multi-stakeholder participatory governance structure for the program. Extensive engagement with Indigenous communities and the oil sands industry, and a commitment to honouring their concerns, perspectives, expertise, and ways of knowing, has begun to rebuild trust in the scientific credibility of environmental monitoring in the Canadian oil sands.

791 Oil Sands Industry - What Development Looks Like Today and Into the Future
C. Edwards, O. Mkrlas, Canada’s Oil Sands Innovation Alliance (COSIA) / Monitoring

Canada has the third largest proven oil reserves in the world, 97% of which are located in the oil sands deposits of northern Alberta. Commercial production from the oil sands has been occurring for over 50 years with significant changes and advances in technology over that time. For example, while early development focused on surface mining, most present-day development is comprised of in situ extraction methods. In 2018, surface mines occupied only 1,039 km2 of the ~142,000 km2 oil sands deposit area (0.7%), while in situ extraction undergoes phased development throughout the area. Despite the longevity operations, uncertainty and disagreement persists with respect to the environmental impact of the various industrial aspects of oil sands development.

The Canadian oil sands are a strategic natural resource and a key driver of economic development. However, rapid expansion of this valuable resource intensifies the need for an integrated comprehensive understanding of potential cumulative environmental impacts. With annual industry funding, the Oil Sands Monitoring (OSM) Program was launched in 2012 by the Governments of Canada and Alberta to improve, consolidate and integrate previous monitoring efforts within the region. Since this time, OSM has made significant progress in the establishment of a more scientifically robust, transparent, holistic, and adaptive monitoring approach, led in partnership by government and knowledge holders, to detect and report cumulative effects of oil sands development. In this session, we present an overview of what development looks like today, the different extraction processes, and the types of infrastructure currently in place. We also discuss key environmental issues facing the industry today and how research and innovation are helping improve the industry’s environmental performance.

793 Temporal and spatial variation of snow chemistry in winter air deposition in the Athabasca Oil Sands Region
Y. Gopalapillai, Environment and Climate Change Canada / Department of Earth & Atmospheric Sciences; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C. Cooke, Alberta Environment and Parks / Environmental Monitoring and Science Division; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Atmospheric deposition of pollutants (e.g., polycyclic aromatic compounds, metals) in snowpacks and their release into freshwaters during spring snowmelt has been a concern in the Athabasca Oil Sands Region of Alberta. The chemistry of the snow that will impact the bioavailability of these pollutants has not been as well studied in terms of temporal and spatial patterns. The present study was designed to evaluate the concentrations, loadings, and distribution of snow chemistry parameters (pH, major cations, anions, organic matter) in springtime snowpack and how they vary spatially and over time. Temporal data spanning several years (2008-2017) of data collected through a rigorous monitoring program, the Joint Oil Sands Monitoring (JOSM) program, are examined. Snowpack samples were collected in late winters at varying distances from the main developments. Temporal trends were divided into sites less than 8 km, 8-50 km, and 50-100 km from the major industrial site (AR6), and compared to reference sites collected from the Peace Athabasca Delta (PAD). Spatial distribution from site AR6 versus from the closest industrial site will be compared. Closest industrial site will be calculated using industrial facilities operational in the wintertime. Results of this study will help understand the impact of oil sands activity on snow chemistry, and how that may impact the bioavailability of pollutants.

794 Surface Water Quality Monitoring under the Oil Sands Monitoring Program: key findings and ongoing study design recommendations
N. Glozier, ECC / Water Science & Technology; C. Cooke, Alberta Environment and Parks / Environmental Monitoring and Science Division; K. Pippy, Environment and Climate Change Canada / Water Science & Technology Directorate; L. Levesque, Environment and Climate Change Canada / Water Science & Technology

Study design updates and results from the water quality (WQ) monitoring program outlined initially by Joint Canada/Alberta Implementation Plan (JOSM) in 2012 and now continued as the Oil Sand Monitoring (OSM) will be presented. Well over 30 WQ monitoring sites have been reported through JOSM, of which, only 5 had pre-existing water quality monitoring programs. Routine water quality sampling approaches were reviewed, streamlined, and standardized, resulting in data from well over 5000 samples, for > 270 parameters (nutrients, major ions, total and dissolved metals, total and methyl mercury and organics); resulting in at least a 5-fold increase in sampling effort. Several non-standard monitoring approaches were evaluated including detailed cross-sectional sampling, auto-monitoring deployments, and semipermeable membrane devices (SPMDs) for the collection of time integrated low level organics. Status and trend results are reported for Athabasca, Peace and Slave rivers as well as multiple tributaries and interconnecting channels of the Peace Athabasca Delta. Concentration in the larger rivers showed more similarity when compared to the smaller, tributaries. Evaluation of the cross-sectional sampling found high cross sectional variability (>50%), however, no significant difference in loading estimates were determined from the range of sampling approaches tested. Total metals as well as other parameters with high correlations with suspended sediments commonly (50-90%) showed values higher than published guidelines particularly during periods of high discharge. Long term trends on the Athabasca River near Wood Buffalo National Park showed that most trends remained consistent, however, upward trends in total phosphorus have been curtailed and dissolved phosphorus concentration has exhibited declines over the last 15 years. After these results were summarized, a workshop was held in late 2016 with the purpose of reviewing, rationalizing and optimizing water quality monitoring conducted under the JOSM Program, and an approach was developed that could be used in an ongoing manner to evaluate and make recommendations for the ongoing OSM water quality monitoring program. Key outcomes of the workshop included: a new decision framework to guide water quality monitoring site selection and sampling frequency; a review of current water quality monitoring locations based upon the decision framework as well as recommendations on water quality methodologies.

795 Current status and assessment of change in two environmental performance metrics in the Athabasca oil sands region
M.L. Olsgard, G. Goss, University of Alberta / Biological Sciences; M. Dube, Alberta Environment and Parks / Environmental Monitoring and Science Division

The mandate of the OSM Program is to assess if changes in environmental indicators are occurring relative to baseline condition in the oil sands region of Alberta. For several reasons, an integrated assessment of environmental change has not occurred to date. This information and supporting methodology is essential to understanding; environmental changes that are currently occurring, level of risk, suitability of current limits of change, uncertainties and the existing accumulated state that can be used to inform models for future scenario assessments. The research presented here focuses on analytics for allowing an integrated assessment of changes in environmental condition relative to thresholds of change. The development of an integrated data analytics platform and preliminary results of Environmental Performance Metrics (EPMs) for i) air quality
and ii) pipeline releases in habitats designated as sensitive or protected by provincial and federal government will be discussed. The presented EPMs were assessed through statistical analysis of spatial and temporal changes using available JOSM/ OSM data sets and by comparison to thresholds of change. Thresholds for assessing change were identified from various sources, including: provincial and federal guidelines/ objectives/ criteria, local Indigenous community’s health-based criteria, and toxicological effects data. Results indicate that key risk drivers for air quality and sensitive habitats with respect to pipeline releases can be identified and used to guide risk-based decisions and adaptive management of the OSM program going forward. By leveraging current EPM status and predicting future changes based on the integrated data both net environmental and economic benefits can be achieved.

796 Community-based Monitoring in the Oil Sands Monitoring Program: Synthesis and Review

D. Beausoleil, Government of Alberta / Environmental Monitoring and Science Division; M. Dube, Alberta Environment and Parks / Environmental Monitoring and Science Division

Indigenous people living in the Canadian Oil Sands Region (OSR) have been practicing their traditional rights and culture since time immemorial. Through years of lived experience on the land, Traditional Knowledge (TK) holders have gained the ability to recognize change, drawing on the inextricable link between traditional practices and environmental health. The Operational Framework Agreement of the Oil Sands Monitoring Program (OSM) provides opportunities for Indigenous participation in the design and implementation of environmental monitoring, building capacity within communities to examine indicators directly relevant to them. Community-Based Monitoring (CBM) in the OSR, such as the Berry Focus Group in Fort McKay, have filled research gaps through braiding of Western Science (WS) and Indigenous knowledge (IK). The integration of these knowledge systems enhances the relevance of OSM by examining the relationship between chemical stressors and culturally relevant indicators. We conducted a review of CBM in OSM between 2009 and 2018, across theme areas of vegetation, water quantity, water quality, fish and wildlife contamination and health, and air quality. As community driven programs, most CBM initiatives have focused their energies on community-focused reporting and engagement, rather than publications or publicly accessible reports. As such, CBM is a valuable tool to address community concerns about environmental health, cultural health, and food security. An integrated approach to environmental monitoring would pair WS and CBM to provide context to cumulative effects monitoring strategies over time and space in locations or on issues that may be understudied, and potentially inform monitoring design. Where integration supports monitoring priorities and where it meets community interests, it requires meaningful communication between collaborators, sufficient training, resources and opportunities for knowledge sharing and Elder-Youth knowledge exchange. CBM is fundamentally about empowering community members to make decisions about environmental safety and partner in environmental management decisions. This presentation will summarize the CBM activities occurring in the OSR and demonstrate how these activities build capacity, with minimal external support, and help drive sustainable, long-term projects that achieve OSM’s multi-stakeholder objectives.

797 Synthesizing a decade of environmental monitoring and research in the Canadian Oil Sands

M. Dube, Alberta Environment and Parks / Environmental Monitoring and Science Division; K. Cash, Environment and Climate Change Canada; F.J. Wrona, Alberta Environment and Parks / Environmental Monitoring and Science Division; T. Arciszewski, D. Beausoleil, E. Horb, A. Mahafey, Government of Alberta / Environmental Monitoring and Science Division; R. Hazewinkel, Alberta Environment and Parks / Environmental Monitoring and Science Division; D. Sayanda, D. Roberts, F. Wyatt, Government of Alberta / Environmental Monitoring and Science Division

The Oil Sands Monitoring (OSM) Program is jointly led by the Governments of Canada and Alberta, in collaboration with local Indigenous communities and industry. In 2019, OSM conducted a review of >300 peer-reviewed papers, published between 2009 and 2018, investigating the environmental effects of oil sands development. This review provides an integrated assessment of environmental condition using a cumulative effects approach, with a focus on five key theme areas: air, surface water, groundwater, terrestrial biology, and geospatial methods, as well as community based monitoring conducted across theme areas. OSM represents knowledge of stressor-response linkages in the oil sands via conceptual models–simplified system diagrams visualising key environmental pathways. This conceptual model framework promotes integration across theme areas by linking distinct study components using common environmental pathways. The integration of Western Science and Indigenous knowledge systems to these pathways enhances the relevance of the monitoring program by identifying and characterizing endpoints that have both environmental and cultural or spiritual significance. Our review identified stressor-based change related to atmospheric deposition of PAHs, heavy metals, nutrients, and acidifying emissions in the immediate vicinity of oil sands mines. There is limited evidence for an ecological response to these stressors, although forest ecosystems may be responding to elevated nutrient loads and sentinel species to dietary and atmospheric exposure in areas adjacent to emission sources. Response to habitat related stress varies among mammals and birds depending on their habitat preferences, resulting in complex responses at the community level. Differentiating among anthropogenic and natural contaminant sources and effects related to natural and anthropogenic exposure remains a major challenge. We also present our vision for accumulated state reporting based on geospatial analysis and mechanistic modelling to assess the environmental condition at multiple scales using a spatial-temporally explicit approach. Implementation of this approach requires integration of knowledge and data systems, and represents the next phase for the OSM program.

Invasive and Vertebrate Pest Species Control: Hazard and Risk to Non-Target Species and Innovations on the Horizon

798 Anticoagulant rodenticides: Background, exposure and toxicity in birds of prey

J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch Ecotoxicology and Wildlife Health Division; B.A. Rattner, US Geological Survey / Patuxent Wildlife Research Center; S. Hindmarch, Fraser Valley Conservancy; V. Silverthorn, Revelstoke, BC; S. Lee, Environment and Climate Change Canada / Science Technology; V. Boves, BC Ministry of Agriculture and Lands; F. Maisonneuve, Environment Canada

There is a global demand for rodent control to reduce risks to human health, and loss and damage of food stores and property. Anticoagulant rodenticides (ARs) dominate the global market for rodent control. Here we focus mainly on second-generation anticoagulants (SGARs) which in regulatory terms are PBT, persistent, bioaccumulative and toxic chemicals. Surveys of SGAR concentrations in many jurisdictions reveal
their widespread contamination of terrestrial predators and scavengers, particularly raptorial birds. We present largely new data on hepatic concentrations of anticoagulants and autopsy results for 700+ raptorial birds found dead or presented for rehabilitation, 1988-2016 in British Columbia. Larger generalist owls, e.g. barred owl (Strix varia) and great-horned owl (Bubo virginianus), had the greatest incidence of exposure; smaller owls e.g. barn owl (Tyto alba) had lower incidence, as did hawks, e.g. red-tailed hawk (Buteo jamaicensis) and Cooper’s Hawk. Bird eating merlins (Falco columbarius) had lowest incidence of exposure among diurnal raptors. We based our assessments of toxicological implications of exposure on diagnosis at necropsy, and on application of threshold guidelines, derived from modeling necropsy findings and liver residue concentrations. Recently, we have enhanced that assessment with evidence showing that a proportion of free-living raptors appear to be suffering from sub-lethal coagulopathy, which almost certainly aggravates the effects of trauma. We will further examine those relationships in the talk and a corresponding poster.

799 Rodenticide use and risk to non-target wildlife
R. Poche, D. Poche, G. Franckowiak, T. Clark, Genesis Laboratories, Inc. / Wildlife Toxicology
A number of rodent species in the United States transmit diseases to humans and pose significant public health issues when populations are left unchecked. Rodenticides have been developed over the past 80 years for control of invasive rodent species such as Norway rats, roof rats, and house mice. Certain rodenticides were eventually for use against field rodents such as voles, ground squirrels, and pocket gophers. The use of differing chemistry over the years has evolved to minimize non-target domestic and wildlife exposure. All chemicals, when used incorrectly, may pose problems to non-target animals. The key to reduced risk is defining the dose of any product, the time of usage, and adhering to label instructions stipulated by the US Environmental Protection Agency. The initial series of rodenticides made public had no antidotes. However, in the early 1950’s warfarin was developed and revolutionized rodent control having an antidote to reverse the effects of toxicosis. We present data from numerous laboratory studies conducted using acute and anticoagulant products against wildlife such as European ferrets, magpies, bobwhite quail, mallard ducks, and American alligators. Results of this research show those potential adverse effects. Acute toxicants have their drawbacks since none are species-specific, they lack antidotes, and some are not humane. A review of rodenticide development is presented along with recent laboratory and field data to show the potential effects of various products.

801 Towards a new generation of ecofriendly anticoagulant rodenticides
V. Lattard, USC1233 INRA-VetAgro Sup - Veterinary campus; I. Fourel, S. Lejebvre, USC1233 INRA-VetAgro Sup; H. Caruel, Liphatech France; E. Benoit, USC1233 INRA-VetAgro Sup
Second generation anticoagulant rodenticides (SGAR) are 4-hydroxy-coumarin-derived delayed acting molecules with a powerful and easily available antidote and are for most of them highly efficient to control rodent populations even those with resistant VkorC1 mutations. However, this benefit is associated with a major disadvantage: SGAR have very long tissue persistence and are thus often responsible for secondary poisoning of wildlife by ingestion of contaminated rodents. Here is a way to overcome this major issue. Because of the presence of two stereogenic centers in all SGAR, commercial baits containing one SGAR contain systematically a mixture of the four stereoisomers (i.e., (1R,3R), (1S,3S), (1R,3S) and (1S,3R)-isomers) of this same SGAR in proportion controlled by the authorities. For all the SGAR, the four stereoisomers have systematically different pharmacokinetic properties. Therefore, all the stereoisomers are not involved in secondary poisonings of wildlife because they are quickly eliminated first by rodent, then by wildlife if exposed. By modifying the proportion between stereoisomers, it is possible to obtain a new generation of anticoagulants efficient, ecofriendly and safe.

802 Population models as a tool for guiding development and application of new management tools: Applications to Asian carp
R.A. Erickson, US Geological Survey / Leetown Science Center
Management of invasive species often requires the integration of multiple techniques or tools. These tools can be used to limit their spread and/or decrease their population. The use of population models can extremely useful to inform managers on potential impacts of their management actions. These same population models can be used to evaluate feasibility of new control strategies and tools (e.g., under what scenarios would the proposed tool be effective?). We used this approach to evaluate potential synthetic biology applications to control Asian carp. Using population models in this way we can then prioritize the development of synthetic biology techniques to insure efficient use of resources for the greatest effects. We will present on the use of population models to evaluate the use of modified males to skew sex ratios and RNA interference as a lethal control.

803 Using population models to assess risks of chemicals and invasive vertebrates to species of conservation concern: A case study of trout
V. Forbes, C. Accolla, University of Minnesota / Ecology, Evolution, and Behavior
The greenback cutthroat trout (GCT), Oncorhynchus clarkii stomias, is classified as threatened under the U.S. Endangered Species Act and is currently believed to persist in a very few areas. One of the threats to the species is believed to be competition with introduced trout such as the brown trout (BT), Salmo trutta. Whereas BT may be highly valued by anglers, they are also considered an invasive species because they often disrupt the systems to which they are introduced. In this case study, we applied a well-established individual-based model, InSTREAM, to assess the risks of the human-derived estrogen (17-alpha ethinyl estradiol, EE2) and the presence of BT for GCT populations. We found that the two species were differentially affected by EE2, with GCT showing more sensitivity. Thus, BT and EE2 had a synergistic negative effect on GCT populations. However, we showed that removal of BT by anglers could enhance persistence of GCT and offset some of the negative effects of EE2. This case study demonstrates how mechanistic models can be used to link impacts of multiple stressors on individual survival, growth, and reproduction to consequences for populations and ecosystem service delivery. When coupled with ecosystem service valuation, the approach facilitates interpretation of traditional toxicity data in the context of realistic ecosystem conditions and provides quantitative information on risks to various - and sometimes competing - ecosystem services that people care about.

804 Risk analyses and risk management for invasive rodent eradication on islands using anticoagulants
K. Campbell, P. Castaño, Island Conservation; P. Fisher, Independent; G.R. Howald, Island Conservation
Invasive rodents on islands are a primary driver of extinctions. To prevent extinctions and restore island ecosystems more than 600 island-wide invasive rodent eradication have been conducted. Current methods for eradicating rodents from islands larger than a few football fields requires applications of anticoagulant rodenticide into every potential rodent home-range. These applications may impact individuals and populations of non-target species, including endemic species threatened with extinction. On inhabited islands, there is potential for people, domestic animals, and wild-harvested foods to be exposed to rodenticide as the result of bait application for rodent eradication. We have adopted a priori informed consent process that combines scientific, a priori ecological risk assessments and community engagement. The approach aims to assist island communities and the project in assessing risks against the benefits, identify needs for non-target mitigation and understand implicit uncertainty. Floreana Island in the Galapagos is one such case. Process components include food web analyses, assessing whether island taxa are evolutionarily significant units, categorizing primary and secondary risk of poisoning.
mortality, defining approximate population impacts and certainty of these. Where population level impacts may represent risks for a species or an evolutionarily significant unit, population viability assessments have been conducted to evaluate the impacts of combined potential risks and benefits. For decision making regarding wildlife, a workshop format has been adopted where wildlife managers, researchers, eradication practitioners and community members together assess potential impacts to each taxa and reach consensus on whether it is acceptable or not. Unacceptable risk to a taxa initiates assessment of mitigation options to effectively manage risk to an acceptable level. Risks to livestock, pets and people, through rodenticide bait, agricultural produce or wild-harvested foods are transparently communicated in one-on-one meetings or with families, concerns are noted and all the options to manage risk are identified. The preferred risk management option is then decided upon by the potentially affected parties in coordination with eradication practitioners. This process on Floreana Island has taken multiple years and is ongoing, and may be useful for other island restoration projects where the support of an island community is essential for success.

805 From Risk Assessment to Post-marketing monitoring. New developments in Europe with special focus on rodenticides

P. Berny, VETAGRO-SUP / Toxicology; O. Cardoso, ONCFS (National Game & Hunting Institute) / USF; M. Cœurdassier, University of Franche-Comté / UMR ChronoEnvironment; J. Chollet, ONCFS (National Game & Hunting Institute) / USF; A. Decors, ONCFS / SAGIR Network; M. Kammerer, ONIRIS / CAPAE-ouest

Plant Protection Products (PPPs) and Biocidal Products (BPs - including rodenticides for commensal rodent control) are currently marketed with an EU Marketing Authorization Dossier. As part of the registration requirements, any information regarding non-target poisoning should be made available (see for instance, SANCO-2012 Guidance Document for Birds and Mammal Risk Evaluation). Currently, RA covers human RA (workers, residents, by-standers), crop residues, environmental RA (soil surface and ground water, ecotoxicology). Safety factors are applied to cover for uncertainty and lab to field extrapolation. With respect to environmental risk assessment, more comprehensive evaluation on non-target arthropods and toxicokinetic/toxicodynamic models for aquatic organisms are being considered. In terrestrial RA, current revision of the Bird and Mammal SANCO guidance document is underway and should consider more realistic exposure models. Recent scientific opinion published by EFSA also suggest broadening the scope of this document to cover species not well protected by the current guidelines, such as amphibians, reptiles or bats. Furthermore, large scale landscape / systemic assessment of pesticide safety has not been considered and is still in its infancy but there is evidence that it could be used with great benefit to develop even more realistic exposure/effect models. ECHA evaluation of BPs follows very similar guidelines. Differences will be pointed out in the presentation. In 2014, France voted a new law to develop the “phytopharmacovigilance” or toxicovigilance of Plant Protection Products. This original program is intended to monitor non-target incidents occurring during the course of the field use of a PPP/BP and to include these data in the re-registration process as part of the risk/benefit ratio evaluation. In this process, risk mitigation measures (RMMs) may also be considered and retrospective and/or prospective analysis of monitoring data may help identify effective measures to reduce the frequency and/or severity of non-target incidents. Examples with rodenticides will be used to highlight the current RA procedure and potential changes.
Addressing Existing Challenges in Immunotoxicology: From Tool Development to Risk Assessment

**MP001 Optimization and validation of respiratory burst and phagocytic cell activity assays in the fathead minnow, an emerging immunotoxicity model**

L. Thornton Hampton, University of North Texas / Biology; B.J. Venables, University of North Texas / Biological Sciences; M.K. Sellin Jeffries, Texas Christian University / Department of Biology

Respiratory burst (RB) and phagocytic cell activity (PCA) assays are utilized to evaluate the immunotoxic effects of environmental contaminants on cellular immune function in a variety of teleost species. Though several methods are available for assessing RB and PCA, plate-based assays may be preferred, as they do not require highly-specialized equipment. As such, the goal of this study was to adapt, optimize and validate a colorimetric plate-based RB assay and a fluorometric plate-based PCA assay for use in kidney cells from fathead minnows (Pimephales promelas), an emerging immunotoxicity model. To optimize the RB assay, the following experimental parameters were explored: stimulant (phorbol 12-myristate 13-acetate, PMA) concentration, incubation time, erythrocyte lysis and presence of superoxide dismutase (SOD). The performance of the RB assay was maximized when a PMA concentration of 0.5 µg/mL and an incubation time of one hour was used. Erythrocyte lysis and SOD did not enhance the performance of the RB assay. For PCA, incubation time and erythrocyte lysis were evaluated. The inclusion of multiple timepoints improved assay performance, and samples in which erythrocytes were lysed increased phagocytosis. It is recommended that measurements be made at multiple timepoints to evaluate PCA rate. Erythrocyte lysis will enhance PCA, but cell yield will be decreased and may cause other limitations. Overall, these results contribute to the standardization of cell-based assays for immunotoxicity assessments.

**MP002 A 15 year evaluation of toxicity monitoring for irrigated agriculture: how data linked to management practices has improved water quality**

M.J. McElroy, S.L. Clark, Pacific EcoRisk; C. Linneman, J. McGahan, Summers Engineering

Beginning in 2004, the Central Valley Regional Water Quality Control Board (California, USA) required the Westside San Joaquin River Watershed Coalition (Coalition) to begin monitoring of runoff from agricultural lands during both the irrigation and stormwater seasons. The Coalition has been required to perform monthly monitoring at up to 20 sites for aquatic toxicity, as well as supporting analytical chemistry (e.g., pesticides). Toxicity tests included the 96-hr chronic Pseudokirchneriella subcapitata (formerly S. capricornutum), acute Ceriodaphnia dubia, and Pimephales promelas tests. Follow-up triggers based on the initial toxicity tests included dilution series testing if complete mortality was observed in the invertebrate or fish test, and Phase I Toxicity Identification Evaluations (TIEs) if a >=50% reduction in response was observed for any organisms compared to the associated laboratory control treatment. Early in the program, toxicity observations were relatively common, and more frequently observed for the P. subcapitata and C. dubia tests than for the P. promelas test. Non-polar organics were typically identified through TIEs as the class of contaminants most likely responsible for toxicity. Based on the outcome of toxicity testing and supporting chemical analyses, pesticides were identified as most likely responsible for the toxicity based on a concentration that exceeded effect thresholds in the literature. Pesticide use evaluation reports were then obtained from the Agriculture Commissioner and/or CA Department of Pesticide Evaluation and used to identify growers that applied the pesticide(s) of concern in months preceding the monitoring data. Use reports were then used to develop management plans to educate growers and certified pesticide applicators in the region so as to reduce the transport of the pesticide(s) into surface waters. This process has resulted in dramatic reductions in observed toxicity for the Coalition. However, continued monitoring allows for ongoing evaluations of any changes that may translate into toxicity observations in water samples.

**MP003 Building a bigger picture: Exploring effects of realistic resource and chemical environments on population-level ecotoxicology of D. magna**

A.M. Isabella, A. East, Towson University / Environmental Sciences; C.J. Salice, Towson University / Environmental Science & Studies Biology

Traditional toxicity testing is used to assess adverse effects of chemicals on environments using tests of individual organisms. However, traditional toxicity tests largely fail to account for ecological factors such as predation and resource environment, as well as the effects of multiple chemical stressors. In this study, a binary mixture of two environmentally relevant chemicals was used to create a complex but realistic stressor environment. A pulse of pyraclostrobin, a fungicide, was applied to aquatic laboratory systems chronically stressed with high conductivity due to sodium chloride, which is common in aquatic systems from road de-icing activities. These compounds were selected due to their contrasting physiochemical attributes but also their likelihood to co-occur in many rural waterways. To first assess these stressors, we conducted a series of 48-hour acute studies with Daphnia magna exposed to various concentrations of sodium chloride and pyraclostrobin. The first study used the algae Raphidocelis subcapitata as a food source and the second study used homogenized waste from Lymnaea stagnalis, as a lower quality, but environmentally relevant, carbon source. Both food sources decreased toxicity of both chemicals and the mixture, but high-carbon quality R. subcapitata increased the LC50 significantly more, suggesting an important effect of resource quality. We then initiated a series of laboratory-population experiments with full factorial designs to evaluate the effects of both chemicals and food sources under more ecologically realistic conditions. Results for the laboratory-population experiment in which daphnia were fed algae showed that chloride delayed time to first reproduction and the addition of pyraclostrobin increased acute mortality in individuals that manifested at the population level. Average length of individuals increased after pyraclostrobin application due to size-specific toxicity but then plummeted as the population recovered. Interestingly, the acute data allowed for the estimation of outcomes from the population experiment with regard to the toxicity of the mixture. A similar population-level experiment is planned in which snail waste will be used as a carbon source. In conclusion, these increasingly complex ecological scenarios will provide ecologically relevant data, and can also be used to help inform and evaluate standard toxicity test designs.

**MP004 Climate Change Indices-Polycyclic Aromatic Hydrocarbons-Fisheries Nexus in Coastal Ecosystems and Vulnerable Economies: A Conceptual Framework**

T.O. Sogbanu, University Of Lagos / Zoology; W.W. Cheung, C.W. Lam, U.R. Sumaila, University of British Columbia / Institute for the Oceans and Fisheries; J.J. Alava, Simon Fraser University

Coastal ecosystems are one of the most sensitive and vulnerable environments to both climate change and pollution. While coastal ecosystems contribute substantial benefits to people which include fisheries, recreational activities and transportation as well as serving as a major regulator of anthropogenic pollution, anthropogenic pollutants are affecting the ability of marine ecosystems to deliver such services. Climate change can exacerbate such impacts. A specific concern of such climate change pollutant interactions is polycyclic aromatic hydrocarbons (PAHs). Specifically, the increase in shipping activities, oil and gas exploration and industrialization in the Global South, where people are highly dependent on local living marine resources, lead to increasing levels of PAHs and their subsequent biological effects at all levels of biological quality, but environmentally relevant, carbon source. Both food sources decreased toxicity of both chemicals and the mixture, but high-carbon quality R. subcapitata increased the LC50 significantly more, suggesting an important effect of resource quality. We then initiated a series of laboratory-population experiments with full factorial designs to evaluate the effects of both chemicals and food sources under more ecologically realistic conditions. Results for the laboratory-population experiment in which daphnia were fed algae showed that chloride delayed time to first reproduction and the addition of pyraclostrobin increased acute mortality in individuals that manifested at the population level. Average length of individuals increased after pyraclostrobin application due to size-specific toxicity but then plummeted as the population recovered. Interestingly, the acute data allowed for the estimation of outcomes from the population experiment with regard to the toxicity of the mixture. A similar population-level experiment is planned in which snail waste will be used as a carbon source. In conclusion, these increasingly complex ecological scenarios will provide ecologically relevant data, and can also be used to help inform and evaluate standard toxicity test designs.
organization. However, the interactions of these stressors and their effects on the abundance and diversity of marine species have not been well studied. Here, we developed a conceptual framework for the potential interactions of these stressors, their effects on marine species abundance and diversity, fisheries and subsequent impacts on the sustainability of the society and economies. We provide a roadmap for integrated assessment models, empirical studies and policy needs. The implications of these effects for sustainable development of vulnerable economies and environments are critical to the United Nations Sustainable Development Goals 13 (i.e. urgent action to combat climate change and impacts) and 14 (life below water).

**MP005 Copper and zinc concentrations in seawater, sediment and gastropod, Burnupena spp. from the coast of the Cape Town, South Africa**

J. Odendaal, Cape Peninsula University of Technology / Department of Environmental and Occupational Studies; R.G. Snyman, Cape Peninsula University of Technology / Biodiversity and Conservation; W. Fru, Cape Peninsula University of Technology / Department of Environmental Health

Copper (Cu) and zinc (Zn) concentrations were measured in intertidal waters, sediment and marine gastropod Burnupena spp. (soft tissue and shells) by using Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Samples were collected once in the dry season (March) and wet season (September) in 2016 from eight sampling points in four sites along the coast of Cape Town. Mean concentration (mg/L) in water ranged from not detected (ND) to 0.0818±0.0494 for Cu and ND to 1.7679±0.6393 for Zn. Mean concentrations (mg/kg dry weight) in sediment were ND to 757.93±531.95 for Cu and 1.20±1.53 to 1340.78±1585.74 for Zn. Mean concentration (mg/kg dry weight) ranges in the soft tissue were 57.16±14.39 to 147.49±26.63 for Cu and 94.54±30.95 to 1010.79±93.79 for Zn, whereas that in shells were 0.48±1.08 to 15.32±1.02 for Cu and ND to 51.18±101.74 for Zn. Mean Cu and Zn concentrations in the soft tissue were significantly higher (p<0.05) than in the shells. The highest mean Cu and Zn concentrations were recorded in the sediment which may suggest that metal concentrations are from anthropogenic and lithogenic sources. Pollution Load Index (PLI) in sediment were in the range of 0.04 to 6.02 which showed that sediment was unpolluted to polluted and may have deleterious effects on marine biota. The results showed that several sampling points exceeded the environmental levels for Cu and Zn used in this study. Therefore, continuous monitoring of metals in all environmental compartment is needed.

**MP006 Effects of Wastewater Treatment Plant Effluent Exposure in Daphnia magna and Gambusia affinis**

E. Pocasangre, L.M. Jackson, University of Cincinnati / Biology

While the effects of effluent contamination have been tested and observed, there is scarcely any existing gradient exposure/effects to treated wastewater effluent that compares the effects of model invertebrate and vertebrate organisms. Treated effluent from wastewater treatment plants (WWTPs) is known to contain contaminants that may produce adverse effects on fish populations. Modern WWTPs are capable of filtering various contaminants such as heavy metals, organic compounds and solid wastes (also called biosolids), but certain synthetic organic compounds are still present in trace concentrations in the treated effluent. The aim of the present study is to investigate the possible consequences of short- and long-term exposures of different concentrations of treated effluent from a WWTP that services a large urban population on *Daphnia magna* and *Gambusia affinis*. An examination of 48 hours, 10 days, and one-month (multiple generations) experiments will examine exposure effects on *Daphnia magna*’s growth, survival, fecundity, and offspring survival. *Daphnia magna*,

**MP007 Effects-based monitoring of bioactive contaminants discharged to the Colorado River before and after upgrades to a wastewater treatment facility**

Recent monitoring of surface water from the Colorado River near the wastewater treatment plant (WWTP) outfall in Moab, UT, detected chemicals of emerging concern and estrogen-receptor (ER)-, glucocorticoid receptor (GR)-, and peroxisome proliferator activated receptor-gamma (PPARg)-mediated biological activities. In 2018, the Moab WWTP was modernized and upgraded to accommodate the increased influent associated with tourism in the area. The present, multi-year study aimed to determine whether the plant upgrade reduced bioactive contaminant loading and if so, over what geographic area relative to the discharge site. Water samples were collected bimonthly, pre- and post-upgrade, at 10 sites along the CO River, upstream and downstream of the Moab WWTP. Water samples were analyzed for in vitro biological activities (e.g., ER, GR, and PPARg). To evaluate the potential in vivo bioavailability of contaminants and potential impacts of the WWTP upgrade, adult fathead minnows were caged at five or six sites at various proximities to the WWTP pre- (2018) and post- (2019) upgrade. After four days of exposure, muscle, livers, gonads, and brains were collected for measurement of targeted gene expression. An autosampler was simultaneously deployed at each site to collect a composite water sample representative of the fish exposure. Composite water samples were analyzed for a suite of pharmaceuticals, pesticides, steroid hormones, wastewater indicators, and in vitro biological activities. Prior to the WWTP upgrade, in vitro ER, GR, and PPARg activities were associated with the surface water at the WWTP outfall site, but activities rapidly diminished with downstream dilution. Based on bioanalytical equivalents, estrone and estriol (38 and 66 ng/L) were the prominent drivers of in vitro ER activity at the WWTP site. No dramatic responses were observed in ER-, GR-, and PPAR-related gene expression in male livers of caged fish prior to the facility upgrade; however, 100% mortality was observed at the WWTP site, likely due to ammonia toxicity (0.91 mg NH3/L measured in the composite sample). No treatment-related mortalities were observed in the post-upgrade fish exposure. Results from 2018 and 2019 will be compared to evaluate effects of the upgrade on ER, GR, and PPAR-related bioactive contaminant loading. The contents of this abstract neither constitute nor reflect USEPA policy.

**MP008 Examining Effects of Agricultural Runoff on Daphnia at Individual and Population Levels to Better Understand Stressor Effects on Aquatic Ecosystems**

J. McNulty, University of Cincinnati; L.M. Jackson, University of Cincinnati / Biology

Multiple stressors, such as agricultural runoff, have the potential to greatly affect aquatic ecosystems, many times orders of magnitudes higher. Limited data on agricultural runoff poses challenges to identify clear stressor-response relationships between individuals and populations in the aquatic ecosystems affected. Also, the lack of data minimizes the knowledge and identification of the potential harmful effects of the runoff in our aquatic environment. This present study examines the effects of agricultural runoff in rural Ohio on *Daphnia magna*, a model toxicity test organism. Samples of runoff from a heavily farmed, agricultural area at multiple distances upstream and downstream of the point source of that
agricultural runoff will be taken and their effects on *D. magna* survival, growth, fecundity, and multi-generations will be observed. Acute (48 hour) and chronic (28 days) studies on individuals and populations of *D. magna* will be measured in response to the runoff exposure. The results from this study are being generated presently and will be presented at the SETAC North America 40th Annual Meeting in Toronto, Canada.

**MP009 Impacts and interaction effects of sediment contamination and ocean acidification on Eohaustorius estuarius**

*A.N. Parks*, D.J. Greenstein, S.M. Bay, Southern California Coastal Water Research Project / Toxicology

Contamination of aquatic and sediment habitats in southern California is widespread and a focus of multiple programs to monitor and restore sediment quality. Stressors associated with global climate change, including ocean acidification (OA), warming, and hypoxia, are of great concern in coastal waters, and these stressors have the potential to influence the impacts of environmental contamination. Although much research has been done to determine the toxicity of contaminants and OA in water column exposure conditions, little is known about their potential interactions in the benthic environment. Contaminated coastal sediments in upwelling zones are expected to be at greatest risk due to more frequent encroachment of corrosive waters. It is unknown how the dual stressor exposure will impact organism health. However, such information is essential to developing accurate vulnerability assessments and potential management actions to protect benthic communities and the many beneficial uses they support. The overall goal of this work is to investigate the effects of sediment contamination and OA conditions on widely-used sediment quality test species, *Eohaustorius estuarius*, using a multi-stressor approach. A 3x3 factorial design was implemented to evaluate the effects of ocean acidification and sediment contamination on the survival of *E. estuarius*. OA conditions, as a function of pCO2, encompassed a range of exposures found in local upwelling areas (400, 800, and 1200 ppm pCO2). Sediments were spiked with contaminants of concern in CA, either copper (0, 400, 800 mg/kg dry sediment) or cyfluthrin (0, 4.0, 7.5 µg/kg dry sediment), at concentrations expected to result in low to moderate toxicity during the 10-day survival test. A flow-through microprocessor-controlled exposure system was used to maintain desired pCO2pH, temperature, and dissolved oxygen levels throughout the exposure period. Results of this work will be evaluated to determine the presence/magnitude of an interaction between OA and contaminant exposure. Sediment quality objectives have already been adopted for California enclosed bays and estuaries, and this work will help inform whether such objectives will be protective of the coastal shelf sediments under current and expected OA conditions.

**MP010 Impacts of road runoff: A cocktail of multiple anthropogenic stressors and the subsequent response of macroinvertebrate communities**

*R.K. Giles*, University of Toronto / Department of Ecology and Evolutionary Biology; J.L. Ruppert, Toronto and Region Conservation Authority / Research and Knowledge Management, Planning Policy; A. Wallace, Palmer Environmental Consulting Group, Inc.; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C.M. Rochman, University of Toronto / Department of Ecology and Evolutionary Biology

Globally, urbanization continues to increase and produce elevated levels of contaminants (e.g., metals, pesticides) in the air, soil, and water within and around urban centers. In particular, heavily trafficked roads are a major source of anthropogenic contaminants, including polycyclic aromatic hydrocarbons, heavy metals, tire dust, and road salt. This mixture, herein referred to as road runoff, represents one of the largest contributors of diffuse-source toxicants in urban areas, and yet is seldom studied as a contaminant mixture. Here we investigate how road runoff could impact ecosystem structure and function in urban stream ecosystems. Specifically, we (1) investigate contaminant fluctuations over the winter, a time of intense road salt application, (2) assess community-level invertebrate responses to contamination loads in urban streams, and (3) assess the effect of road runoff-associated chemicals to early life stage freshwater mussels. Preliminary results demonstrate that chloride concentrations in urban sites are an order of magnitude greater than rural sites. Additionally, the amount of chloride has a strong relationship with temperature, where chloride concentrations increase with air temperature during the winter season. Last, we detected differences in community composition of benthic macroinvertebrates between rural and urban sites. Future work will determine how early life stage freshwater mussels respond to environmentally relevant concentrations of each road runoff contaminant both singly and combined in a full factorial experiment. This will provide insight into potential stressors that can impact these and other sensitive species. Such work builds on our understanding of how multiple anthropogenic stressors impact stream communities as a mixture, and has the potential to help inform future policy and urban development decisions.

**MP011 Impacts of wastewater discharges on freshwater mussels in a watershed within Southern Ontario, Canada**

*E. Hayward*, Trent University / Environmental and Life Sciences; C.D. Metcalfe, Trent University / Water Quality Centre; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R.S. Prosser, University of Guelph / School of Environmental Sciences; J.E. Salerno, Environment Canada / Ecotoxicology and Wildlife Health Division; C.J. Bennet, Environment and Climate Change Canada

Wastewater treatment lagoons serving communities across rural Canada were originally constructed to serve smaller populations. Growth and insufficient financial resources for upgrades have caused many communities to discharge treated wastewater that does not comply with current federal regulations for wastewater quality. Aquatic organisms in water bodies receiving wastewater are often negatively impacted by exposure to these discharges. Exposure to associated contaminants, including ammonia, chloride, metals, and contaminants of emerging concern (CECs) have been associated with effects on the health of freshwater mussels. The Grand River watershed located in southern Ontario, Canada supports one of the richest assemblages of freshwater mussels in Canada, including several Species at Risk. In previous studies, freshwater mussels exposed to wastewater have exhibited negative effects across multiple levels of biological organization; from sublethal responses to population alternations. In this study, caged adult freshwater mussels (Lasmigona costata) and passive samplers (POCIS) were deployed in Boston Creek, a tributary of the lower Grand River for a two-week period at locations both upstream and downstream of the seasonal discharge of a wastewater treatment lagoon serving the Mississaugas of the Credit First Nation. Although POCIS revealed that CECs were elevated 1km downstream of the lagoon, analysis of tissues for biomarkers of lipid peroxidation (i.e. HNE), as well as levels of metallothionein and vitellogenin-like proteins indicated that these parameters were not correlated with exposure to CEC microcontaminants and metals known to be discharged in wastewater. Pollution from other point and non-point sources, including runoff from roads, agriculture and pasture lands, as well as discharges from a gypsum plant may be contributing to poor water quality in Boston Creek and the observed biological impacts in caged freshwater mussels.

**MP012 Microplastics as vector for endocrine disrupting compounds in marine environment**

*E. Elsayed*, University of Guelph / School of Engineering; A. Cundy, University of Southampton; S. Bray, National Oceanography Center; R. Rudra, B. Abbassi, University of Guelph; L. Allen, University of Southampton

The improper disposal of microplastics in the ocean coupled with insufficient wastewater treatment and coastal littering, have led to the presence of plastic debris in marine waters, sediment and in aquatic life through ingestion. Recent research suggests that microplastics could pose a risk to human health if transported via food chain. Therefore, laboratory experiments were carried out to estimate the concentrations of endocrine disrupting chemicals (EDCs) in weathered microplastics.
collected from Quayside Road along River Itchen. Following the extraction of EDCs, desorption experiments were conducted to estimate the amount of EDCs released from weathered microplastics under sea water conditions (pH = 7). Results showed that fairly amounts of phthalates were released in the solution after 24 hours; indicating the potential risk of the presence of microplastics in the marine water. Additionally, sorption and desorption isotherms were carried out to basically indicate the effect of the presence of multiple EDCs as mixture and their competitive sorption to pristine microplastics. Results showed that sorption of hormones and bisphenol was significant. However, in the desorption experiments, the release of phthalates was much higher compared to hormones and bisphenol compounds.

MP013 Physiological and biochemical comparison of Lake Chub in different reaches of the Ells River in the Athabasca Oil Sands Region

E. Ussery, Environment and Climate Change Canada / Biological Sciences; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; G. Tetreault, Environment and Climate Change Canada / Water Science and Technology Directorate; J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.G. Wynia, Environment and Climate Change Canada / Aquatic Contaminants Research Division; T.W. Clark, Environment Canada

The Fort McMurray deposit is part of the larger Athabasca Oil Sands formation found in northeastern Alberta, Canada. Exposed bitumen found in this region are rich in natural sources of polycyclic aromatic hydrocarbon (PAH) compounds. Numerous oil companies conduct surface mining in the areas around Fort McMurray and adjacent to the Athabasca River, extracting this naturally occurring bitumen for its petroleum. Thus, resident wild fish in the Athabasca and its tributaries may be exposed to either naturally occurring sources of bitumen or anthropogenically refined sources through surface mining. The Canadian and Alberta governments developed monitoring programs aimed to investigate fish health, of the lower Athabasca River and its tributaries in 2009. The Ells River serves as the predominant drinking water source for the community of Fort McKay. Although this research does not focus specifically on drinking water, investigating the health of forage fish provides information as to the health of the tributary. This work compares the physiological responses of 20 male and 20 female lake chub (Couesius plumbeus) from three different reaches of the Ells River across the years 2013, 2014, and 2015. The three reaches consist of a reference/baseline site (upper), a middle reach, which runs through natural bitumen deposit, and a lower reach, which may receive increased sources of contaminants associated with the refining of bitumen due to development and anthropogenic influences. Endpoints assessed in this study were age of fish, growth metrics (length at age, weight at age, condition factor, gonadosomatic index, and hepatosomatic index), and hepatic 7-ethoxyresorufin-O-deethylase (EROD) activity. Results suggest significant site differences in age, length and weight by age, and EROD differences in both male and female fish depending on site location for 2013 and 2015 sampling years. These site differences were not observed in 2014.

MP014 Role of agricultural intensities on sediment inputs and fish communities in the Upper Cache River Watershed, Arkansas

A.K. Atwell, Arkansas State University / Ecotoxicology Research Facility; J.L. Bouldin, Arkansas State University / Biological Sciences

Nearly 50% of all assessed streams in the United States are impaired for not meeting their designated use. The leading cause of impairment is non-point source pollution from agricultural land use. One common practice of streams draining agricultural lands is channelization, a process that involves widening and deepening stream channels to increase the hydraulic loading during flood events. This process can lead to increased stream sedimentation, reduced stream water quality, homogenization of the substrate, and negatively impact aquatic biota. The presence of intolerant fishes has been shown to decrease once agricultural land usage exceeds 30-50%. In the Cache River Watershed, located in northeast Arkansas, approximately 70% of the 230-km-long watershed is used for agricultural purposes. Nearly 150 river-km are channelized and over 200 river-km are listed as impaired for not supporting aquatic life, with sedimentation from agriculture the leading cause. The goal of the project is to monitor sediment contributions and water quality of the Cache River Watershed and determine if fish communities vary with increasing agricultural land use. Turbidity and total suspended solids (TSS) have been analyzed weekly since October 2017 in 12 spatially independent tributaries in the Upper Cache River Watershed while fish sampling took place June 2019. When grouped by agricultural intensity, there is a significant difference in turbidity between low intensity and moderate or high intensities. Results suggest that fish communities in the Cache River tributaries may be affected by intensity of agricultural land use and channel alteration which result in increased sediment contributions.

MP015 Temporal biological responses of caged yellow perch (Perca flavescens) environmentally exposed to a major urban effluent

M.A. Defo, University of Quebec in Montreal (UQAM) / INRS-ETE; L. Mercier, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C. Beauvais, Environment and Climate Change Canada; R. Brua, Environment and Climate Change Canada / Watershed Hydrology and Ecology Research Division; J. Miller, Environment and Climate Change Canada / Water Science & Technology Directorate; A. Fontaine, Institut National de Recherche Scientifique; G. Tetreault, Environment and Climate Change Canada / Water Science and Technology Directorate; P. Couture, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; J. Verreault, University of Quebec, Montreal / Sciences Biologiques; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Municipal wastewater treatment plant (WWTP) effluents represent important sources of environmental contamination for a range of organic and inorganic pollutants. These complex chemical mixtures can affect the health of aquatic organisms residing in the receiving waters. High-throughput tools such as metabolomics can help identifying and understanding the interactions of contaminant mixtures and their exposure-related effects on aquatic organisms. The aim of this study was to examine the effects of in situ exposure of juvenile yellow perch (Perca flavescens) to a major WWTP effluent. Commercially purchased young-of-the-year perch were acclimated in the lab for two months prior to the study. Perch were then caged at a reference site and at a WWTP effluent-impacted site located downstream of the Montreal’s WWTP effluent point of discharge in the St. Lawrence River (Quebec, Canada). Responses at the gene transcription, metabolite, and protein levels were investigated as well as body condition of perch after 1, 3 and 6 weeks of exposure. Stable isotopes, flame retardants and metals were also analyzed in perch tissues. Body condition of perch caged downstream of the effluent increased after 3 and 6 weeks of exposure compared to that of fish exposed at the upstream reference site. Moreover, fish caged in the effluent plume had higher muscle δ13C and slightly depleted muscle δ15N after 3 and 6 weeks of exposure, suggesting possible diet differences between sites. Moreover, perch caged for 3 weeks downstream of the effluent had lower levels of metals in kidney than fish from the reference site. However, kidney Cd, Cu, Se, As, Zn and Fe were higher at the impacted site after 6 weeks of exposure, suggesting that metal accumulation could be time- and element-specific. Results indicated that glutathione reductase activity in gills increased with exposure time. Negative relationships between total kidney concentrations of non-essential metals and gill glutathione reductase activity were also observed, suggesting potential perturbation of these inorganic contaminants on oxidative stress responses in perch. Relationships between metal and flame retardant accumulation, transcription levels of stress-related genes and cellular metabolites will be discussed. The
of exposure of these herbicides to early life stages (ELS) of the African Catfish, Clarias gariepinus. Therefore, the effects of environmentally relevant concentrations Glyphosate (0.27 and 53 µg/L) and Paraquat (3.14 and 17.5 µg/L) on catfish ELS (Age: 2 wks, Length: 18-22 mm) were investigated following a 63 d exposure. The fishes were randomly sacrificed at 21, 42 and 63 d post exposure to analyse histopathological effects in the gills and liver, levels of the lipid peroxidation product, malondialdehyde-MDA and liver function enzymes; Aspartate aminotransferase-AST,Alanine aminotransferase-ALT and Alkaline phosphatase-ALP. The Micronucleus assay was also conducted to determine their genotoxic effects on their erythrocytes (ERT). The gill MDA levels, liver AST, ALT and ALP as well as micronuclei and bi nucleated cells in the ERT of exposed catfishes were significantly higher (P< 0.05) compared to control for both concentrations of the herbicides. Histopathological assessment revealed increasing incidence of shortening/blunting of secondary lamellae (SL), inflammation, mild lamellar necrosis, severe lamellar necrosis and destruction of both primary and SL. Only liver samples in those exposed to 53µg/l of Glyphosate showed fat vacuoles indicative of damage to some hepatocytes after 63 d. These findings call for cautious introduction of herbicides into farmlands especially in the face of global agro-intensification and quest for conservation of fisheries resources.

MP020 Tributary input effects on water quality and fish assemblages in the Strawberry River, Arkansas

A. Alves Augusto, J.L. Bouldin, Arkansas State University / Biological Sciences

The Strawberry River is a tributary of the Black River within the White River basin in northern Arkansas. The river distance from source to mouth is about 177 km, and it is considered by the ADEQ as an extraordinary resource and ecologically sensitive waterway. In order to protect the water quality, it is important to determine which tributary is adding to the impairment due to siltation. Water quality in eight tributaries (Piney Fork, Mill Creek South Big Creek, North Big Creek, Clayton Creek, East Cooper Creek, Reeds Creek, Sleep Bank Creek, and Caney Creek) were collected, from October 2016 to September 2019, prior to the confluence with the Strawberry River. Water quality variables included total suspended solids (TSS), turbidity, pH, conductivity, dissolved oxygen, PO4, TP, TN, NO2, and NO3. Sites location and agricultural land use influences sedimentation and nutrients. Upstream sites had lower sedimentation values than downstream sites as the watershed transitions from the Ozark Highlands to the Delta Ecoregion. TN was significantly different among sites whereas TP was not. The major cause of the impairment is thought to be from excessive sedimentation due to agricultural runoff. A fish survey was also conducted in seven sites of the Strawberry River to assess population size and biodiversity at each site. This project will help us to monitor the water quality of this extraordinary resource, protecting over 100 species of fish and other indigenous species as they are being threatened by agriculture runoff.

MP021 Utilizing Transcriptomics to Evaluate Environmental Determinants of Oyster Health at an Implanted Bed in Newport Bay, CA

A. Russell, C.R. Whitcraft, E.B. Holland, California State University, Long Beach / Department of Biological Sciences

Estuarine ecosystems have historically faced severe degradation, and traditional restoration techniques using man-made structures have been scrutinized for ecological damage. Living shorelines, using objects such as oyster beds, reduce shoreline erosion and are supplements to man-made structures while also restoring ecological communities. Living shorelines were established in Upper Newport Bay (UNB, CA) in 2016 to restore native Olympia oysters, Ostrea lurida. One goal was to understand potentially important factors for optimal restoration conditions for O. lurida, including effects of plot design and sublethal concentrations of existing pollutants. Current methods to evaluate oyster health include recruitment and size; however, these metrics cannot anticipate sublethal stress effects prior to impacts on survival or fitness. Instead, high-throughput
transcriptomics techniques are powerful tools for assessing organismal health. This study will use whole transcriptome analysis and modeling to examine oyster health. Specifically, it will describe differential gene expression observed between (Aim 1) oysters recruited to beds in the presence or absence of neighboring eelgrass and (Aim 2) oysters with varying organic or inorganic pollutant burdens. I have already sampled gill tissue from oysters recruited to UNB shorelines and oysters maintained under clean conditions for three months as contaminant free controls. I have also gained preliminary results on pollutant burdens that may be present in UNB oyster tissue. This research will provide deeper understanding into the dynamic relationship between estuaries such as UNB and pollutants, and their influence on O. lurida conservation. Additionally, it will help inform future restoration strategies and support genomic analysis as a formidable tool for evaluating the health status of wild populations.

Mollusca Toxicology: An Ecological Important and Imperiled Phyla but Often Left Out

MP022 Adaptive Tolerance to Zinc in Freshwater Snails (Physa acuta) Across a Contamination Gradient
J.B. Belden, J. Hickey, S.T. McMurry, Oklahoma State University / Integrative Biology

The Tri-State-Mining district is an area of northeast Oklahoma, southwest Missouri, and southeast Kansas in which zinc and lead mines operated for over 100 years. Metal contamination from wastes left behind by these historic mining operations has polluted the Neosho and Spring Rivers, the Grand Lake o’ the Cherokees, and resulted in the EPA designating the Tar Creek Superfund site in 1983. The receiving watershed has a gradient of contamination from likely toxic concentrations to background concentrations. The purpose of this study was to determine if native populations of aquatic snails have developed tolerance to environmental metal concentrations and, if present, the extent of the metals tolerance across a downstream gradient from the metals-contaminated area. Freshwater snails (Physa acuta) were collected from sites representing the gradient of metals contamination and field sediment and water samples were analyzed for zinc. These populations were cultured in the lab and zinc toxicity tests were conducted with F1+ juveniles collected from those cultures. We found that snails cultured from populations collected from contaminated, upstream sites were more tolerant to zinc exposure than snails cultured from populations collected from clean, downstream sites. Additionally, zinc tolerance was found in snails collected from a site that represented a midpoint geographically, although environmental zinc levels were below levels likely to cause toxicity. Our results suggest that, despite past studies showing sediments from Grand Lake to be relatively nontoxic to sediment-dwelling organisms, aquatic organisms may still be experiencing selective pressures as a result of metals contamination and this may warrant further investigation.

MP023 Assessing the Impacts of Wastewater Effluent on the Growth of the Truncate Soft-Shelled Clam Mya truncata in Frobisher Bay, Nunavut
C. Schaefers, K. Jeffries, University of Manitoba / Biological Sciences; D. Deslauriers, Fisheries and Oceans Canada

Frobisher Bay, Nunavut, has historically had a large population of the soft-shelled clam Mya truncata, a popular food among locals. Lately, M. truncata’s populations are undergoing a steep decline throughout their circumboreal distribution. While climate change is a contributing factor, our study will focus on the interaction between climate change and wastewater effluent in this region. In Iqaluit, water and waste management have become increasingly complicated as the population continues to rise and the primary treatment system periodically gets overwhelmed leading to episodes of raw sewage pouring into the marine ecosystem. The input of wastewater effluent, whether raw or primarily treated, brings potential stressors of reduced salinity, increased temperature, low levels of dissolved oxygen, effluent toxicity, contamination of sediments, and increased nutrient loading leading to harmful algal blooms. These challenges bring an urgency to study the ability of M. truncata to physiologically cope with local conditions while addressing the concerns associated with contamination in a popular Arctic country-food. To address this, soft-shelled clams were sampled from several locations in Frobisher Bay that are exposed to varying levels of wastewater effluent, as well as from two nearby reference sites. We took a field study approach by investigating the relationship between periodic sewage effluent release and the effects on the bivalve’s annual shell growth and population-size structure. The widths of internal growth bands in the chondrophore were analyzed with the hypothesis that unregulated wastewater release would negatively impact the clams in terms of growth. Future research will endeavor to characterize the effluent release on the overall health of the truncate soft-shell clam. This work contributes to a baseline monitoring project for the protection and conservation of Canadian marine environments and investigates how chronic wastewater effluent exposure, alongside temperature increase, will negatively impact the soft-shell clam, Mya truncata.

MP024 Chronic toxicity from environmentally relevant concentrations of copper and zinc on freshwater mudsnail Potamopyrgus antipodarum
M. Subba, CAPIM, The University of Melbourne / Biosciences; M.J. Keough, The University of Melbourne / School of Biosciences; V.J. Pettigrove, RMIT University / Sciences; C. Kellar, Aquatic Pollution Prevention Partnership / RMIT University

Heavy metals are the most common pollutants in water around the world. Increasing concentration of these pollutants in aquatic environment has a serious threat to aquatic ecosystem because they are persistent, toxic, bioavailable and can biomagnify in food chain. Assessing the effect of common heavy metals on test species is important to get an understanding on the impact these metals can have on the aquatic species, and the aquatic environment. We modified OECD (2016) procedure and conducted a chronic (28 d) exposure of commonly detected heavy metals, copper (Cu) and zinc (Zn), and evaluated survivorship, growth and reproduction of freshwater mudsnail Potamopyrgus antipodarum under laboratory conditions. We selected this species because they are widely distributed, are used in ecotoxicology studies and are known to be a sensitive species. This mudsnail are ooperculate (has operculum) and undergoes asexual reproduction by parthenogenesis and ovoviviparity (produces live embryos). Adult snails (3.5 - 4 mm), were exposed to 4 concentrations of Cu (0, 0.002, 0.0125, and 0.025 mg/L) and Zn (0, 0.01, 0.05 and 0.4 mg/L) at concentrations detected in freshwater around the world. Each treatment had 3 replicates. This current test is valid because there was 100 % survival in the controls for both the metals. Both the metals had a negative impact on its mortality. A significant effect on the survival of P. antipodarum was observed at the top most concentration of Cu and Zn (p < 0.05). Both the metals had no significant effect on its growth (shell height). This species has a long-life cycle (> 2 y, personal observations) under laboratory conditions so it is expected it will not show a significant growth in 28 d. However, hormesis effect on its reproduction was observed at the lowest concentration of Zn (0.01 mg/L) with a significantly greater number (8.45 ± 1.09, mean ± standard error) of embryos than the control (5.75 ± 1.05, mean ± standard error) (p ≥ 0.05). The hormesis process explains lower concentration of toxicants having a positive effect while higher dose having an inhibitory effect. This result agrees with several previous findings. Our study demonstrates the effect from 2 common metals on an ecologically important species. Overall, our study found the endpoints sensitive and proposes to include these endpoints in risk assessment and in predicting effect of heavy metals in the aquatic environment.
MP025 Sensitivity of larval and juvenile mussels (Unionidae) to ammonia, chloride, copper, potassium, and selected binary chemical mixtures

J. Salerno, P. Gillis, H. Khan, E. Burton, Environment and Climate Change Canada / Aquatic Contaminants Research Division; L. E. Deeth, University of Guelph / Department of Mathematics and Statistics; C. J. Bennett, Environment Climate Change Canada / Aquatic Contaminants Research Division; P. K. Sibley, R. S. Prosser, University of Guelph / School of Environmental Sciences

In aquatic environments, organisms such as freshwater mussels are likely exposed to complex contaminant mixtures related to industrial, agricultural, and urban activities. With growing interest in understanding the risk that chemical mixtures pose to mussels, this investigation focused on the effects of various waterborne contaminants (ammonia, chloride, copper, and potassium) and selected binary mixtures of these chemicals following a fixed-ratio design to *Villosa iris* glochidia and juvenile *Lampsilis fasciola*. In individual exposures, 48-h EC$_{50}$ values were determined for *V. iris* glochidia exposed to ammonia chloride (7.4 [95% confidence interval (CI) 6.6-8.2] mg N/L), ammonia sulfate (8.4 [7.6-9.1] mg N/L), copper sulfate (14.2 [12.9-15.4] μg Cu$^{2+}$/L), potassium sulfate (12.8 [11.9-13.7] mg K$^+$/L), potassium sulfate (10.1 [8.9-11.2] mg K$^+$/L), and sodium chloride (480.5 [435.5-525.5] mg Cl$^-$/L). The 7-d LC$_{50}$ values for juvenile *L. fasciola* were determined for potassium sulfate (45.0 [18.8-71.2] mg K$^+$/L), and sodium chloride (1738.2 [1418.6-2057.8] mg Cl$^-$/L). These waterborne contaminants have been reported to co-occur in the Canadian province of Ontario, with concentrations exceeding the EC$_{50}$ for both life stages at some locations. Data from binary mixture exposures for *V. iris* glochidia (ammonia-chlorine, chloride-copper, and copper-ammonia) and juvenile *L. fasciola* (chloride-potassium) were analyzed using a regression-based, dose-response mixture analysis modeling framework. Results from the mixture analysis were used to determine if an additive model for mixture toxicity [concentration addition or independent action] best described the toxicity of each mixture and if deviation towards dose-ratio or dose-level synergism/antagonism occurred. For all glochidia binary mixture exposures, concentration addition was the best fit model with dose-level deviation reported for the chloride-copper mixture and dose-ratio deviation reported for the copper-ammonia mixture. Using the model deviation ratio, the observed toxicity in all three glochidia mixture exposures were adequately described by both concentration addition (mean = 0.71) and independent action (mean = 0.97) whereas the juvenile mixture exposure was only adequately described by concentration addition (mean = 0.64; independent action mean = 0.05).

MP026 The effects of chloride on a freshwater mussel (Lasmigona costata): A non-targeted metabolomics study

B. Atkinson, University of Guelph

Acute and chronic exposure to roadside runoff poses concerns for populations of aquatic organisms. There is a need to investigate new screening tools for describing and measuring organism response in toxicological studies. These tools need to be able to assess stress sub- lethally, be cost effective, and reproducible. An analysis of circulatory fluid (hemolymph) from freshwater mussels offers a non-lethal sampling alternative that is simple to conduct, non-intrusive and provides reliable data. Metabolomics is a technique that provides insight into biochemical pathways being affected in response to the toxic stressor. This research will evaluate the effects of a 28-day exposure of chloride on the metabolism of the freshwater mussel Lasmigona costata (flutedshell). Sodium Chloride (known as rock salt) is commonly used as a deicing agent on roads and bridges and can be released in significant pulses after rainfall events. The study will explore the differences found on the metabolome of test animals at two environmentally relevant concentrations of chloride to a control group. The anticipated outcome of these results will confirm that examining hemolymph as a non-lethal sampling technique through metabolomics studies provides value added information for assessing risk and toxicity.

MP027 Environmental Concentration and Partitioning of Organic UV-filters in Seawater

C. L. Mitchelmore, A. Heyes, M. Gonsior, A. Conway, C. Clark, University of Maryland Center for Environmental Science / Chesapeake Biological Laboratory; K. He, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering; E. Hain, University of Maryland, Baltimore County / Chemical, Biochemical, and Environmental Engineering; A. Feerick, University of Maryland Baltimore County; L. Blaney, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering

The organic UV filters contained in sunscreen products are under scrutiny regarding their environmental risk to aquatic organisms, especially sensitive coral. However, very limited or no information on the environmental concentrations of these chemicals in seawater and sediment around coral reefs is available, which is a critical component needed for environmental risk assessments. Furthermore, the partitioning of UV filters in seawater between dissolved and particulate phases has not been addressed and critical information in toxicological and environmental modelling assessments. To address these knowledge gaps, replicate surface seawater (dissolved and particulate fractions) and sediment samples were collected from multiple sites and State Parks (n=29) in Oahu, Hawaii including the popular tourist destinations of Hanauma Bay and Waikiki Beach. Surface seawater samples were filtered using glass fiber filters (GF/F) to result in dissolved and particulate fractions for analysis. All samples were analyzed for 13 UV filters using LC-ESI-MS/MS techniques. Up to nine UV filters were detected in both seawater and sediment and concentrations were very variable between sites, time of day and in some cases between replicates at a site. The highest detection frequencies and concentrations of UV filters in all matrices was homosale (HMS), octisalate (OS), BP-3 and octocrylene (OC). BP-3 was ubiquitous in surface seawater as it was detected at all sites with the highest concentrations found in the late afternoon samples from Hanauma Bay, Waikiki Beach and Ko’olina Beach Park, however, at 15 of the 29 sites, aqueous concentrations were less than 10 ng L$^{-1}$. However, BP-3 was only measurable in sediment samples at 16 out of 29 sites at < 4 ng g$^{-1}$ (dw). No quantifiable levels of EHMC were recorded for the seawater samples, although it was quantified in a few sediment samples (e.g. from Kaneohe Bay) at concentrations less than 13 ng g$^{-1}$ (dw). We also report on the ratio of the UV filter concentrations between the dissolved and particulate phases. This study provides insight as to the environmentally relevant concentrations in seawater and sediment in Hawaiian coral reef locations in addition to seawater partitioning data relevant to bioavailability and modelling for coral reef ecosystems. These data provide an important baseline for future risk assessments of the potential toxicological effects of UV-filters on coral reefs and other marine organisms in Oahu, Hawaii.

MP028 Occurrence and Partitioning of Emerging Ultraviolet Absorbers in the St. Lawrence River

A. Dalpé, Université du Québec À Rimouski / Océanographie; Z. Lu, University of Quebec, Rimouski / Aquatic Contaminants Research Division Canada Centre for Inland Waters; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Ultraviolet absorbers (UVAs) are widely used as industrial additives because of their ability to reduce impacts of the natural light, such as UV-induced color change or photodegradation of commercial products. These compounds are therefore globally produced in large volumes and have been detected in the environment. Some UVAs have been shown to induce adverse effects such as hepatotoxicity and endocrine disruption in fish and mammals (e.g., rat), as well as coral bleaching, making these contaminants of emerging environmental concern. However, the fate of these contaminants, particularly their concentrations and partitioning behavior...
Environmental chemical contaminants have been of major concern as they can cause adverse health effects in single or multiple forms – even at trace levels. They are derived from different activities; and they include pesticides, personal care products, pharmaceuticals, and byproducts of various industrial processes. The contaminants often referred to as contaminants of emerging concern (CEC) are of growing awareness and concern because of their possibilities of interacting with biological systems to cause serious health issues. CEC are used daily and are continuously released into the environment via various waste streams. Galveston Bay and Clear Creek receive waters from several sources including runoffs which may contain a significant number/concentration of contaminants with a high possibility of human exposure. The potential adverse effects of the contaminants on humans, human environment, and the ecosystem can range from acute to chronic and are of significant importance. This study analyzed the presence of selected CEC: oxybenzone, sulfamethoxazole, and clofibrate in the water, sediment, and fish samples from the Galveston Bay and Clear Creek areas. Samples were collected from the identified locations, extracted using standard protocols, and analyzed using high-performance liquid chromatography coupled with an ultraviolet/visible detector. Results quantified, and bioaccumulation calculated. The results showed the presence of the contaminants in the samples analyzed. The concentration of oxybenzone in water and sediment samples was 1.85 ± 0.82 and 1.30 ± 1.55 ppm respectively. Oxybenzone in fish tissues/organs was 38.49 ± 14.64 ppm, this is 2,081% and 2,961% its concentration in water and sediment samples. Clofibrate was detected at a concentration of 0.45 ± 0.31 and 2.28 ± 3.76 ppm in water and sediment samples. Its concentration of 7.76 ± 2.46 ppm found in the fish tissues/organs is 17 and 3 times more than the levels in water and sediment. Sulfamethoxazole was below detection limits. Thus, the results revealed that oxybenzone and clofibrate are present in the locations analyzed and they bioaccumulate in fish tissues/organs with a high probability of biomagnification in higher animals. Oxybenzone has a higher bioaccumulative capacity and may produce more toxic interactions. The data from this research is an impetus for the continuous monitoring of the levels of CEC in the Galveston/Clear Creek areas bodies of water and the aquatic environment.

Photochemical reactions are a major degradation pathway for natural and xenobiotic organic chemicals in the coastal environment. These reactions are important in understanding the persistence and environmental compartmentalization of the parent compounds and/or their photochemical products, ultimately potentially changing their bioavailability and toxicology to resident organisms. Photochemical reactions may result in less or more toxic chemical products. To date, very limited information is available on the photochemical degradation of sunscreen organic UV-filters such as oxybenzone (benzophenone 3 or BP-3) and octocrylene in fresh and seawater. We used a custom-designed photodegradation system that is able to continuously photo-irradiate samples with simulated sunlight and quantify the changes in optical properties throughout 24h irradiation experiments. This system avoids inner filtering effects and starvation of oxygen, which have previously been limiting factors. Additionally, subsamples were collected during irradiation experiments at 5 different time points to determine the concentrations of the examined UV-filters using LC-qqq MS and to search for photo-products using non-targeted ultrahigh resolution mass spectrometry (FT-ICR MS). Results revealed accurate photochemical decay kinetics data of the two examined filters oxybenzone and octocrylene. A diverse suite of photo-products were found, which potentially has implications for risk assessment.
MP032 Are sunscreen UV filters polluting our beaches? A case study from consumer habits to recommendation for safe-by-design products

J. Labille, CNRS; A. Tagliati, Herriot Watt University; R. Catalano, D. Slomberg, CEREGE/Aix-Marseille University; S. Robert, Aix-Marseille University, CNRS, UMR ESPACE / CIRSEE; J. Boudenne, Aix Marseille Université; M. Apres-Tremelo, Aix-Marseille University, CNRS, UMR ESPACE; T.F. Fernandes, Herriot-Watt University / Centre for Marine Biodiversity and Biotechnology, Institute of Life and Earth Sciences; S.J. Hennige, University of Edinburgh, School of GeoSciences; L. Hedouin, CNRS CRIOBE

Sunscreens are of emerging concern regarding both human and environmental health. Their regulation is constantly evolving largely due to the potential risks related to the ingredients contained. They typically consist of an oil-in-water emulsion in which the major active ingredients are UV filters, incorporated in high concentration, up to 25wt%. UV filters are of organic or mineral nature, in agreement with country regulations, and provide the desired solar protection factor. After leaving the skin either through bathing, the UV filters contained in the sunscreen can be released into the marine environment. This scenario is of particular interest since serious concern over the potential harm of UV filters to coral reefs is continuously being raised. Nevertheless, very few data are available to enable us to quantify the source of this pollution on field. In this work, we developed lab and field studies to give insights on (i) consumer sunscreen use on the seashore and its release into the water; (ii) the advantages and disadvantages of sunscreen mineral UV filters along the product lifecycle; and (iii) how to develop an eco-designed sunscreen. A field campaign was completed on three French beaches during summer recreational activities. A social survey on the sunscreen use by bathers was carried out in order to better understand the relation between the quantities and types of sunscreen used on the beach and the environmental concentrations of UV filters actually detected in the water at the same time. In a parallel lab approach, relevant sunscreens were formulated in-house in order to evaluate the benefits and costs of ingredients like nano-TiO2 UV filters and emulsifiers. Their roles in the sunscreen efficiency were evaluated, as well as their impacts on coral larvae survival. By considering each development stage of the sunscreen, from the choice of ingredients integrated into the cosmetic formulation, to the knowledge of the risk involved in this choice all along the product lifecycle, an eco-design approach can be proposed to minimize the risk. This work was cofunded by Labex Serenade Ecosun, Labex DRIHUM through OHM Lititoral, and IRCP-CRIOBE grant 2018.

MP033 Environmental release and fate of nanoparticulate titanium dioxide UV filters from sunscreen

D. Slomberg, R. Catalano, CEREGE/Aix-Marseille University; P. Hennebert, INERIS; A. Masion, CEREGE/Aix-Marseille University; J. Labille, CNRS

Although a strong focus has been placed on addressing the impact of mineral nanoparticulate UV filters in personal care products and sunscreens, their fate and behavior are not fully understood and resulting regulation is still under consideration due to their potential risk to consumers and the environment. For example, nanoparticulate titanium dioxide (nano-TiO2) UV filters in sunscreens may leave the skin either through swimming or everyday use and subsequent washing, thus being released into rivers, lakes, sea shores, and/or sewage treatment plants. Their fate and impact in these different aquatic systems are largely determined by the nanomaterial’s chemical properties (e.g., nanomaterial coating), lifetime, and aging. In this work, impacts on the direct aquatic environment were assessed by evaluating the release of two relevant nano-TiO2 UV filters with different surface coatings (i.e., silica and stearic acid) from sunscreens formulated in-house in a simulated laboratory aging procedure. The size distribution, surface charge, and degradation state of the by-products, as well as their nanomaterial concentration and colloidal behavior were determined in a variety of aqueous environments (e.g., sea water, fresh water). Our results demonstrate that TiO2 surface coating drives behavior and that aging of the passivation layer can result in photoactive by-products. Additionally, in an end-of-life scenario, we considered the potential release of these nano-TiO2 UV filters from sunscreen containers after disposal in a landfill. The hydrophilic, silica-coated nano-TiO2 was easily dispersed in the landfill leachate, followed by a rapid sedimentation while the majority of the hydrophobic, stearic-acid coated nano-TiO2 remained associated with the container after leachate exposure. These insights on nano-TiO2 UV filter environmental fate and behavior will help guide regulations, provide better information for consumers, and assist manufacturers in incorporating an eco-design approach in consumer product development. This work was funded by Labex Serenade.

MP034 In vivo benzophenone-3 exposure alters gene regulation in eastern mosquitofish

T. Bargard, US Geological Survey / The Wetland and Aquatic Research Center; N.D. Denslow, University of Florida / Physiological Sciences; K. Kroll, University of Florida / Center for Environmental and Human Toxicology; C. Wieser, USGS / The Wetland and Aquatic Research Center

The ultraviolet light screen chemical benzophenone-3 (BP3) has been the focus of sunscreen chemical bans (Hawaii, Key West in Florida, Palau) due to concern for environmental risk in aquatic systems, particularly in the marine environment. Monitoring data for marine environments indicate environmentally relevant BP3 concentrations (16 - 6073 ng/L) span from much lower to within the range of concentrations reported in the literature (2280 ng/L - 7544 μg/L) for effects upon growth, survival, and development. Since BP3 concentrations in waters are known to vary with the time of day coinciding with the number of bathers in the ocean, we exposed newly hatched eastern mosquitofish to diurnally varying, environmentally relevant BP3 concentrations for 8-weeks and conducted RNA sequencing in liver tissue to determine molecular response. Eastern mosquitofish were used for this study due to availability of genomic information for the species and its availability for the study. The average 24h BP3 concentration during the exposure was 545 ng/L, while the diurnal concentrations ranged from 45 - 3827 ng/L. Significant changes in gene regulation were observed, with the primary direction of change being down regulation. Pathway analysis identified cellular processes affected by the gene regulation changes. Generally, those processes grouped within several physiological functions including those of the renal, endocrine, digestive, nervous, muscle, and immune systems. Results of this study can be used to identify the physiological systems that should be monitored in whole organism studies involving BP3 either in the field or the laboratory.

MP035 Photo-Induced Toxicity of UVA Filters Under UVA Radiation

T. Walton, J.B. Belden, Oklahoma State University / Integrative Biology

As the use of personal cosmetic care products (PCCPs) with organic ultraviolet (UV) filters is increasing, so is the exposure risk of these compounds to aquatic ecosystems. In addition, environmental factors, such as UV radiation, have the potential to increase toxicity of these compounds. This study focuses on induced photo-toxicity of common UV filters found in PCCPs in the presence of UVA radiation. The freshwater microalga, Scenedesmus acutus, was exposed to individual UV filters during a 96-h period. Fluorescence of chlorophyll a was used as a measure of growth, and inhibition of growth was utilized as the endpoint. Homosolate and oxybenzone inhibited growth with increasing concentration under non UVA conditions with EC50s of 404 μg/L and 1940 μg/L, respectively. Avobenzone and octisalate did had no observed effect up to water solubility. Further testing will compare each of the UV filters under UVA and non-UVA conditions to see if UVA radiation increases toxicity.
MP036 Risk evaluation of commercial nano-rutile based UV filters used in sunscreen. Sea water environmental release and ecotoxicological impact

R. Catalano, CEREGE / Cerege; J. Labille, CNRS; D. Slomberg, CEREGE/Aix-Marseille University; A. Pinsino, A. Alijagic, IBIM CNR Palermo

Among cosmetics and personal care products, sunscreen products are of emerging concern regarding both environmental and human healths. While some organic UV blockers have been accused of undergoing rapid photodegradation, inducing allergenic skin reactions due to dermal penetration, or of causing deleterious effects on marine system, the fate of mineral UV blockers is still under consideration from a regulatory perspective. This is largely related to the potential impact of nanotechnology-based products on both environment and human health. The nano-TiO₂ UV-blockers typically used in sunscreen usually consist of rutile nanoparticles coated with a first mineral layer of silica or alumina aimed at blocking the photocatalytic character, and thus passivating the nanomaterial. In addition, the grafting of a second layer of organic coating is aimed at favoring the nanomaterial dispersion in the cream formulation. Once drained from the skin either through bathing activity or everyday usage and cleaning, the nanomaterials contained in the sunscreen can be released to the sea shore. Their behavior in this system is largely determined by this industrial coating and by their initial dispersion in the formulation. The release and the impact on the marine environment are mainly considered and studied using the following approaches. In order to estimate the environmental concentration of nanomaterials from sunscreen in sea water we carried a field campaign on three beaches of the southern french coast. The titanium concentration was measured in the sea water. The sampling were performed at 2 depths (40 cm and surface layer) and at three distances from the shoreline (2 m, 50 m, 200 m). More than 700 litres of sea water were collected and filtered in order to separate different size fractions (< 500 nm and > 500 nm) and to localise the UV filters. The impact on marine living organism was studied by toxicological tests on the Mediterranean sea urchin (Paracentrotus lividus) used as a biological model. In particular, the impact on the sea urchin embryos development was evaluated, exposing them to 4 commercial TiO₂-based sunscreen UV filters, using the same concentrations range as evaluated in the field campaign. The effect of the different nanoparticle coatings and of their dispersing medium in the formulation (oil or water) were studied. Acknowledgements. This work was funded by: Region PACA; European Commission; Labex SERENADE and Labex DRIIHM via OHM Littoral Mediterranean.

MP037 Environmental risk assessment of oxybenzone (benzophenone-3) and coral

J.K. Saxe, Self-employed; K. Reynerton, Johnson & Johnson / Product Stewardship; C.L. Mitchelmore, A. Conway, UMCES / Chesapeake Biological Laboratory; R.L. Jones, L.A. Mullins, Battelle Memorial Institute / CBRNE Defense

Several researchers recently identified the sunscreen active ingredient, oxybenzone (benzophenone-3), as a potential risk to reef-building coral using ad hoc toxicity test methods and exposure modeling or environmental monitoring. As a result, state and local legislators in the US have either enacted or are considering enacting bans on the sale of sunscreens containing oxybenzone. There is a tension between the potential benefit to coral by using this precautionary approach - which has thus far relied on highly uncertain data - and the expected adverse human health outcome due to a reduction in the sun protection factor (SPF) of sunscreen products lacking oxybenzone. To address this uncertainty, a comprehensive database of all relevant published data addressing environmental exposure and hazard of oxybenzone to coral species, plus newly generated oxybenzone toxicity data using adult coral nubbins, form the basis of this environmental risk assessment (ERA). The worldwide reasonable worst case exposure scenario was identified as the southeastern US during summer and is the focus of this evaluation. The ERA uses multiple regulatory paradigms from Europe and the US and the full aquatic toxicity database for oxybenzone with hard corals and surrogate species to characterize hazard potential. A combination of modeling using oxybenzone wash-off measurements from skin to which sunscreen was applied and environmental monitoring studies are used to characterize exposure potential. The ERA results are meant to inform legislative and regulatory efforts by identifying conditions under which there is any potential benefit expected to coral from restrictions on the sale of oxybenzone-containing sunscreens. This information is intended to assist decision-makers in balancing against the potential human health cost of any such restriction.

MP038 UV filters: can we estimate the risk to coral reef based on currently available effect and monitoring data?

V. Poulsen, L’Oréal / Environmental Safety; M. Leonard, L’Oréal / Environmental Research

Coral bleaching is a global environmental issue that we should address to ensure the preservation of this fragile ecosystem and source of biodiversity. It is recognised by experts that the cause of coral bleaching is multifactorial, mainly due to global warming, overfishing, and marine pollution. It is therefore important to take adapted mitigation measures to reduce the harmful impact of human activities. UV filters used in cosmetics are currently under scrutiny due to few published papers relating their toxicity towards coral and their potential impact on coral reef bleaching. This led to a ban of two compounds used in sunscreens in several states. The question is to understand what the real environmental benefits of these bans are. Chronic effects of UV filters can be measured using a specific test method developed by L’Oréal and the Scientific Center of Monaco. In addition, several compounds were recently monitored in marine environment in coral reef areas and reported in several publications. For a couple of compounds, based on these data, it is possible to conclude that they represent negligible to moderate risks to coral reefs. For others, the lack of data doesn’t allow to draw any conclusion. In order to take robust and efficient measures that induce a real benefit for the protection of coral, decision making should be risk based, taking into account real sunscreen contribution to measured concentrations, and therefore significantly reduce the ecological impact. Many uncertainties, as well as the lack of data, don’t allow to robustly conclude on this point, leading to potential useless bans. To improve the risk assessment, there is therefore a need for robust additional effect data, complementary monitoring studies, and adapted exposure models with representative scenarios.

MP039 Assessing the risks and identifying the knowledge gaps for UV filters in the freshwater environment

E.E. Burns, I. Davies, Personal Care Products Council / Science

There has been growing scientific, public and regulatory concern over the perceived risk of UV filters in the marine environment. The majority of these concerns focus on the potential detrimental impacts of UV filters on coral. Coral are present near popular marine aquatic recreational areas that could be an important environmental source of these compounds. In contrast, the freshwater environment has received less attention in terms of the risk organic UV filters may pose. UV filters can be found not only in sunscreen formulations but also in a wide range of personal care products that can enter the environment through domestic wash-off and eventual wastewater treatment plant (WWTP) effluent release. In the US, the majority of these effluent releases are to the freshwater environment. Additionally, UV filters can be directly released via bathing which is of particular importance to popular aquatic recreational areas, such as the Great Lakes. Therefore, we conducted a review of the literature and brought together existing exposure and hazard data to perform a freshwater risk assessment according to regulatory approaches used in the US. We assessed the reliability and relevance of current hazard and exposure data and identified knowledge gaps pertaining to how comprehensive these datasets are across UV filters used in the US. Clear knowledge gaps emerged that introduced significant uncertainty into our risk assessment approach. The exposure data is scarce and when available, was limited to the site and environmental conditions where it was measured. To address this, we ran the iSTREEM exposure model for the US. A variety of input
scenarios were applied representative of worst-case exposure through to more refined exposure estimates. The relevance of these exposure scenarios will become clearer as more monitoring, WWTP removal and partitioning data emerge. A probabilistic risk assessment was performed to identify the 95th percentile risk quotient for UV filters in the US freshwater environment. Our results suggest that chronic endpoints for freshwater species are more sensitive to organic UV filters than current ecotoxicological data for coral species. This work forms an important part of furthering our understanding of the risks posed by UV filters in the environment as a whole.

Advances in Ecotoxicology and Risk Assessment of Reptiles and Amphibians

**MP040 Development of an in vitro diagnostic method to determine the genotypic sex of Xenopus laevis**

*A. Eimanifar, J. Aufderheide, S.Z. Schneider, EUROFINS / Aquatic; H.O. Krueger, Eurofins Agroscience / Science and Reg Affairs; S. Gallagher, EUROFINS / Aquatic*

A genotypic sex determination assay provides accurate gender information of individuals with well-developed phenotypic characters as well as those with poorly developed or absent of phenotypic characters. Determination of genetic sex for *Xenopus laevis* can be used to validate the outcomes of Tier 2 amphibian assays, and is a requirement for conducting the larval amphibian growth and development assay (LAGDA), in the endocrine disruptor screening program (EDSP), test guidelines. The assay we developed uses a dual-labeled TaqMan probe-based real-time polymerase chain reaction (real-time PCR) method to determine the genotypic sex. The reliability of the assay was tested on 37 adult specimens of *X. laevis* collected from in-house cultures in Eurofins EAG Agroscience, Easton. The newly designed *X. laevis*-specific primer pair and probe targets the DM domain gene linked-chromosome W as a master female-determining gene. Accuracy of the molecular method was assessed by comparing with phenotypic sex, determined by necropsy and histological examination of gonads for all examined specimens. Genotypic sex assignments were strongly concordant with observed phenotypic sex, confirming that the 19 specimens were male and 18 were female. The results indicate that the TaqMan(R) assay could be practically used to determine the genetic sex of animals with poorly developed or no phenotypic sex characteristics with 100% precision. Therefore, the TaqMan(R) assay is confirmed as an efficient and feasible method, providing a diagnostic molecular sex determination approach to be used in the amphibian endocrine disrupting screening programs conducted by regulatory industries. The strength of an EDSP is dependent on a reliable method to determine genetic sex in order to identify reversals of phenotypic sex in animals exposed to endocrine active compounds.

**MP041 Evaluation of malformations induced by ibuprofen and naproxen in Xenopus laevis**

*H. Islas-Flores, National Autonomous University of Mexico / Toxicología Ambiental; T. Pérez-Alvarez, Universidad Autónoma del Estado de México / Toxicología Ambiental; L.M. Gómez-Oliván, National Autonomous University of Mexico / Farmacia; O. Dublán-García, Universidad Autónoma del Estado de México / Facultad de Química; M.D. Hernández-Navarro, Autonomous University of Mexico State Fac de Química*

Mexico is the second largest market in Latin America in the pharmaceutical industry, on the other hand, it has also been shown that this is one of the main ways of entry of medicines to water bodies, which in recent years has been demonstrated in reports of trace concentrations in different bodies of water around the world, which has gained significant relevance for eco-surveillance because it has also been shown that these are not eliminated in conventional wastewater treatment plants (WWTP) and that were designed to produce an effect on biological systems, represent a risk to the health of all organisms that come into contact with them in an ecosystem. On the other hand, several studies have reported that they cause different types of damage such as oxidative stress, cytogenotoxicity, kidney damage and in the reproduction of different aquatic organisms; and since by bioaccumulation processes or biomagnification, they could also represent a risk to the human being, its study is important. The objective of the present work was to evaluate the toxicity of two drugs widely used due to their analgesic and antiinflammatory properties, ibuprofen and naproxen, using the Frog embryo teratogenic assay - Xenopus (FETAX) in order to obtain its teratogenic index, the malformations generated and compare their toxicity. For this purpose oocytes in mid-blastula transition were exposed for 96 h to six different concentrations of naproxen and ibuprofen (1, 4, 8, 16, 32 and 62.5 mg/L), subsequently, the mean lethal concentration (LC50) effective concentration inducing 50% malformation (EC50), and the teratogenic index (TI) was obtained. Results indicates that lower concentrations of the two NSAIDs (ibuprofen and naproxen) induced slightly higher malformations and lethal effects in X. laevis, while the main alterations being microcephaly, cardiac and facial edema, malformations in the eye, notochord, tail, fin and intestine. The highest TI of ibuprofen indicates a higher probability that embryos exposed to this NSAID will be malformed in the absence of mortality compared to X. laevis exposed to naproxen, and therefore, can be considered more toxic for this species.

**MP043 Do Standard Toxicity Tests Reflect Ecologically Relevant Conditions? Xenopus laevis vs. Native Anuran Sensitivity to Chloride with Varied Resources**

*P. Ribeiro, Towson University / Environmental Science; C.J. Salice, F. Green, Towson University / Environmental Science & Studies; A. East, Towson University / Environmental Sciences*

Xenopus laevis (African clawed frog) is the standardized amphibian globally, making it the most common species in many ecotoxicology experiments. *X. laevis* is a relatively tolerant amphibian species in terms of chemical stressors and this raises the question of whether they can be used as reasonable representation of native amphibians that are potentially more sensitive to environmental stressors. An example of an increasingly important environmental stressor is the use of road-deicing salts near many North American amphibian breeding habitats. These salts, typically NaCl, runoff into freshwater ecosystems causing an increase in salinity; elevated salinity is a known stressor to freshwater aquatic organisms including amphibians. In this study a series 7-day toxicity studies were conducted using a range of chloride concentrations on *X. laevis* tadpoles and Lithobates sylvaticus tadpoles (an amphibian species native to North America). *X. laevis* larvae were exposed to Cl- concentrations of 2500, 3250, 4000, 4750 mg Cl-/L and *L. sylvaticus* was exposed to 2000, 2500, 3000, 3500 mg Cl-/L. Additionally, we explored the influence of food on Cl- toxicity. Standard protocols indicate that animals should not be fed but resources are always available in most habitats. Concentrations that caused 50% mortality (LC50) were obtained using exposure-response models in RStudio. *X. laevis* in fed treatments had an LC50 of 3475.29 mg Cl-/L (±460.5) and 3939.41 mg Cl-/L (±366.3) in unfed treatments. For *L. sylvaticus*, the LC50 in fed treatments was 2536.39 mg Cl-/L (±219.7) and 3148.98 mg Cl-/L (±169.7) in unfed treatments. We observed a statistically significant difference in survival between unfed and fed treatments as well as survival between the two species. Our data indicate a consistently higher LC50 values for *X. laevis* tadpoles when compared to *L. sylvaticus*. This suggests *X. laevis* does not necessarily provide an accurate representation for this amphibian species native to North America and potentially other, similar species native to this region. Additionally, the apparent increase in sensitivity to Cl- in fed animals was a surprising results and warrants additional attention as it also suggests that current test designs in which animals are not fed may underestimate toxicity. Further research is being conducted to determine how Cl- toxicity interacts with other environmentally relevant stressors such as, temperature variation and larval density.
MP044 Boreal chorus frog larval development in urban stormwater wetlands

R. Krohn, University of Calgary / Dept. of Ecosystem & Public Health / Faculty of Veterinary Medicine; A. Yaghi, University of Calgary / Dept. of Ecosystem and Public Health / Faculty of Veterinary Medicine; J.E. Smits, University of Calgary / Ecosystem and Public Health

In Calgary, Alberta, approximately 90% of pre-settlement wetlands have been drained and filled in, or modified to perform storm water management functions. The potential for these urban wetlands to support biodiversity has not been assessed. Amphibians are valuable sentinels reflecting ecosystem health, particularly because they are exposed to potential pollutants via diet, and absorption through their skin. Frog development from tadpole to adult may be affected by undesirable conditions in wetlands and can indicate health risks to other vertebrate species. 59 city wetlands were surveyed by citizen scientists in the past 2 years, with boreal chorus frogs (Pseudacris maculata) being observed in 50% of the wetlands. Interestingly, frog presence does not appear to be associated with riparian health assessment scores or connectivity. Other factors, such as water quality may have more influence on frog presence. To assess which water characteristics in these urban wetlands predict successful frog development, we are conducting an in situ frog metamorphosis assay. We are rearing boreal chorus frog tadpoles in 4 selected wetlands, 2 with and 2 without frogs. In this pilot study, tadpoles are housed in fiberglass mesh enclosures with bamboo frames; 3 enclosures per wetland house 25 tadpoles each. Tadpoles are fed and closely observed until metamorphic climax. Throughout the study water quality is being assessed including nitrate, phosphate and metal concentrations. Related abiotic and habitat features are analysed in the context of developmental markers in tadpoles, survival, behaviour, time to metamorphosis, and physiological markers, such as thyroid hormone expression and body energy stores. Results will be presented. The aim of this pilot study is to identify wetland features that foster frog populations or exert adverse effects on frog development. The findings of this study will guide further field and laboratory studies and will directly inform storm water wetland management decisions.

MP045 Development and testing of a mesocosm design for conducting developmental toxicity tests using cricket frogs (Acris crepitans blanchardi)

S. Windle, S.T. McMurry, Oklahoma State University / Integrative Biology; R. Brain, J.D. Maul, Syngenta Crop Protection, Inc. / Environmental Safety; J.B. Belden, Oklahoma State University / Integrative Biology

The potential for developmental effects of contaminants on the amphibians has received increasing attention, particularly regarding exposure to pesticides. Ideally, developmental toxicity tests with amphibians would be performed on species native to the area of concern. However, due to the dependence on both terrestrial and aquatic environments during development and a relatively long developmental stage, these tests are challenging. Consequently, standardized developmental testing thus far has focused primarily on aquatic species such as Xenopus spp., raising questions about geographic/life history representativeness. Thus, there is a current need to develop better approaches for developmental toxicity testing of native amphibians. We have developed and are conducting tests on a mesocosm design that allows for monitoring cricket frog growth and development from free-swimming tadpoles to sexually developed frogs over a 5 month period. The mesocosm includes a 20-l stainless steel vessel that allows for exposing larval amphibians to organic contaminants. The larger structure allows for a terrestrial environment that prevents escape, but facilitates augmented feeding and observation during the duration of the study. Mesocosms are located outdoors in a partially screened environment to allow for natural lighting and temperature patterns without overheating. Time to metamorphosis, size at metamorphosis, sex ratio, growth rate following metamorphosis, darkness of throat patch, and gross development of gonads are all being measured to generate background data on this species in our system. Successful development of the mesocosm will allow future studies evaluating the toxicity of organic compounds on the development of cricket frogs.

MP046 Identifying Amphibian Receptors of Concern for an Environmental Risk Assessment via eDNA Sampling: The Lower Seymour Conservation Area Study

J. Ward, AECOM / Impact Assessment & Permitting

Environmental DNA (eDNA) sampling and analysis is a cutting-edge tool that provides an efficient alternative to time-intensive field surveys. eDNA offers increased efficacy for detection of receptors of concern for an environmental risk assessment when target species are rare, endangered, or cryptic, and when those species are of social, economic, or cultural importance. In a recent application of eDNA sampling, the tool was used to inform and shape the environmental protection measures for site remediation work within Metro Vancouver’s Lower Seymour Conservation Reserve (LSCR). The LSCR is home to a diverse assemblage of amphibians, reptiles, fish, and mammals, many of which are protected in Canada federally through the Species at Risk Act (SARA). Among the species that potentially inhabit the remediation area are the SARA-listed Coastal Tailed Frog (Ascaphus truei), Red-Legged Frog (Rana aurora), and Pacific Water Shrew (Sorex bendirii). The author led a team that implemented an eDNA program, combined with a detailed site assessment, to determine whether the above species were present and, if so, the potential for site remediation works to adversely affect them. As eDNA analyses were non-detect for all target species, the assessment team avoided the need for an expensive and time-consuming amphibian salvage survey entailing attempted trapping of target species that were not present, while still adopting all appropriate mitigation measures to avoid harming other species. While eDNA sampling and analysis was applied following an environmental risk assessment in the study, this presentation will describe how the tool can be applied to inform conceptual-exposure models in ecological risk assessment, for environmental impact assessment, and prior to risk-based remediation of contaminated sites. This approach can increase confidence in the decision to include or exclude receptors of concern that are of rare, endangered, or cryptic, or species of social, economic, or cultural importance.

MP047 Dynamic screening of agricultural contaminants in fresh water ecosystems as part of amphibian biodiversity conservation

T. Goesens, Ghent University; L. Vanhaecke, Ghent University / Department of Veterinary Public Health and Food Safety / Laboratory of Chemical Analysis; P. Spanoghe, Ghent University / Department of Plants and Crops; L. Lens, Ghent University / Terrestrial Ecology Unit Biology Department; P. Goethals, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; A. Martel, F. Pasmans, Ghent University / Department of Pathology, Bacteriology and Avian Diseases; S. Croubels, Ghent University / Department of Pharmacology Toxicology and Biochemistry

In recent years the presence of agricultural contaminants such as pesticides, antimicrobial drugs, mycotoxins, coccidiostats, anthelmintics and heavy metals in the aquatic environment have gained more interest. Research has shown negative effects on fitness of aquatic amphibians. Because most amphibians reside in aquatic habitats during breeding season and because they have a highly permeable skin, these species tend to be more exposed to environmental toxins than other aquatic and terrestrial vertebrates. Furthermore, agricultural contaminants have a negative impact on zooplankton as part of the aquatic food web. These organisms are related with reduced chytrid infections in amphibians through the predation of chytrid spores. In this way agricultural contaminants have the ability to affect amphibians in a direct and indirect manner. The overall objective of this project was to assess the dynamic level of contamination of amphibian breeding ponds in relationship to the surrounding zooplankton and amphibian community. For this reason, 25 amphibian breeding ponds were selected across Flanders and sampled three times, at three different locations in the pond over a period of three months. Pesticides
mydas environment, their presence in plasma samples is evidence of recent pollutants like PCB and pesticides. Considering their persistence in the conclusion, Kemp’s Ridley population is exposed to persistent organic management of polychlorinated biphenyls (PCB) containing wastes. In 2015 and 2016 ΣCOP and atrazine median concentrations. Atrazine and atrazine [2015 (2.40 ng/ml); 2016 (39.26 ng/ml], α Endosulfan [2015 (1.55 using the Mann-Whitney U test. Results showed median concentrations of 2015 and 2016 nesting seasons. The POP quantification method in plasma samples from female turtles’ dorsal venous sinus during the 2015 and 2016 nesting seasons. The POP quantification method in plasma samples included focused ultrasound-assisted extraction and gas chromatography coupled to a mass detector with electron impact ionization. Nonparametric statistics were used to compare two independent samples using the Mann-Whitney U test. Results showed median concentrations of atrazine [2015 (2.40 ng/ml); 2016 (39.26 ng/ml], α Endosulfan [2015 (1.55 ng/ml); 2016 (1.55 ng/ml], ΣDDT [2015 (4.13 ng/ml); 2016 (3.45 ng/ml)], ΣPCB [2015 (7.57 ng/ml); 2016 (7.69 ng/ml)] and ΣCOP [2015 (30.42 ng/ml); 2016 (58.26 ng/ml)]. Significant differences were observed between 2015 and 2016 ΣCOP and atrazine median concentrations. Atrazine and endosulfan are two of the most widely used active ingredients in Mexico; on the other hand, there is also an environmental problem due to the poor management of polychlorinated biphenyls (PCB) containing wastes. In conclusion, Kemp’s Ridley population is exposed to persistent organic pollutants like PCB and pesticides. Considering their persistence in the environment, their presence in plasma samples is evidence of recent exposure; more interestingly, it is the fact that some of them are prohibited in Mexico and in the USA, where these turtles travel to eat. These results are the first data for Kemp’s Ridley population in Mexico, and are relevant for the protection and conservation of this endangered species.

MP048 Persistent organic pollutants in Kemp’s Ridley Turtles (Lepidochelys kempii) from Mexico
A. Nava Montes, P. Ramirez Romero, Metropolitan Autonomous University / Hidrobiologia; G. Espinosa-Reyes, Autonomous University of San Luis Potosi / Centro de Investigación Aplicada en Ambiente y Salud; R. Flores Ramirez, Autonomous University of San Luis Potosi / Catedras CONACyT

Sea turtles are at the highest levels of the food chain, making them more vulnerable to exposure to contaminants, including persistent organic pollutants (POP). Kemp’s Ridley turtles (Lepidochelys kempii) are the most critically endangered species of sea turtles; they have a restricted distribution, mainly in the Gulf of Mexico, which has been disturbed by anthropogenic activities. Studies reporting contaminant concentrations in sea turtle are limited. This study objective was to evaluate POP concentrations in Kemp’s Ridley turtles from Rancho Nuevo, Tamaulipas, Mexico in order to generate a baseline for these chemicals. We collected 79 blood samples from female turtles’ dorsal venous sinus during the 2015 and 2016 nesting seasons. The POP quantification method in plasma samples included focused ultrasound-assisted extraction and gas chromatography coupled to a mass detector with electron impact ionization. Nonparametric statistics were used to compare two independent samples using the Mann-Whitney U test. Results showed median concentrations of atrazine [2015 (2.40 ng/ml); 2016 (39.26 ng/ml], α Endosulfan [2015 (1.55 ng/ml); 2016 (1.55 ng/ml], ΣDDT [2015 (4.13 ng/ml); 2016 (3.45 ng/ml)], ΣPCB [2015 (7.57 ng/ml); 2016 (7.69 ng/ml)] and ΣCOP [2015 (30.42 ng/ml); 2016 (58.26 ng/ml)]. Significant differences were observed between 2015 and 2016 ΣCOP and atrazine median concentrations. Atrazine and endosulfan are two of the most widely used active ingredients in Mexico; on the other hand, there is also an environmental problem due to the poor management of polychlorinated biphenyls (PCB) containing wastes. In conclusion, Kemp’s Ridley population is exposed to persistent organic pollutants like PCB and pesticides. Considering their persistence in the environment, their presence in plasma samples is evidence of recent exposure; more interestingly, it is the fact that some of them are prohibited in Mexico and in the USA, where these turtles travel to eat. These results are the first data for Kemp’s Ridley population in Mexico, and are relevant for the protection and conservation of this endangered species.

MP049 Alkoxyresorufin-O-dealkylase activity in multiple organs of the three predominant Gulf of Mexico sea turtle species
C.S. Calvin, C.M. Mello, Texas Tech University / Environmental Toxicology; B.M. Higgins, NOAA National Marine Fisheries Service; C.A. Godard, Texas Tech University / Environmental Toxicology/The Institute of Environmental and Human Health

The three predominant sea turtle species inhabiting the waters of the Gulf of Mexico are the Loggerhead (Caretta caretta), Green (Chelonia mydas) and Kemp’s Ridley (Lepidochelys kempii). They are classified as vulnerable, endangered, and critically endangered, respectively, by the International Union Conservation of Nature Red List. Sea turtles are considered a keystone species in the marine environment and the subject of global conservation efforts. Marine chemical pollution is an environmental hazard that increases overall risk for sea turtle health, but little is known about its potential adverse effects. Common marine contaminants, such as polycyclic aromatic hydrocarbons and polychlorinated biphenyls, have been detected in sea turtle organs, blood, and eggs. The induction of Cytochrome P450 1A (CYP1A) enzymatic activity is a well-established biomarker of exposure to aforementioned marine contaminants and other select chemicals. One aim of this project is to quantify baseline enzymatic activity of various organs in these sea turtle species using alkoxyresorufin-O-dealkylase (AROD) assays. A series of up to ten organs (bladder, gonad, heart, intestine, kidney, liver, lung, muscle, skin, and stomach) were collected at the NOAA Sea Turtle Facility in Galveston, Texas from loggerhead, green, and Kemp’s ridley sea turtles that failed rehabilitation due to swimming issues but were otherwise healthy. Samples were processed as S9 or microsomes at 4°C following previously published methodology. Protein concentrations were quantified using the Bradford assay and 40ug of sample protein was used for analysis. In mammals, it is established that induced CYP1A1 & CYP1A2 enzymatic activities are best measured by ethoxyresorufin O-deethylase (EROD) and methoxyresorufin O-demethylase (MROD) assays. Reptilian enzymatic activities related to CYP1A are not fully characterized but our preliminary data indicate that multiple alkoxyresorufin-O-dealkylase (AROD) activities are involved. Hence, we analyzed sample enzymatic activity using EROD and MROD, as well as benzyloxyresorufin O-debenzylase (BROD) and pentoxyresorufin O-depentylase (PORD) assays by spectrophotometry. Preliminary results in liver confirm multiple AROD activities. Further analyses on all organs will investigate correlations between organ types and differences between species. Lastly, this project is part of a larger study on sea turtle metabolism and toxicology that includes contaminant burden analysis.

MP050 Using plasma vitellogenin in loggerhead sea turtles to assess reproductive maturation and as a biomarker of estrogenic contaminant exposure
R. Corniuk, Hawaii Pacific University; J.M. Lynch, National Institute of Standards and Technology / Chemical Sciences Division; M.D. Arendt, Marine Resources Research Institute, South Carolina Department of Natural Resources; J. Braun-McNeil, National Oceanic and Atmospheric Administration; D.W. Owens, College of Charleston; J.R. Kucklick, National Institute of Standards and Technology / Chemical Sciences Division; P.D. McClellan-Green, North Carolina State University / Ctr for Marine Sciences & Technol

Vitellogenin (VTG), a protein precursor to egg yolk, is normally expressed in adult oviparous females in response to estrogen; however, males and juveniles can produce VTG when exposed to estrogenic compounds, including environmental contaminants. This study sought to measure plasma VTG in threatened loggerhead sea turtles (Caretta caretta) to 1) further our understanding of their reproductive maturation, and 2) investigate VTG as a non-invasive biomarker of estrogenic contaminant exposure. Using a polyclonal antibody produced against VTG from the red-eared slider turtle (Trachemys scripta) in Western blots, we screened for the presence or absence of VTG in the plasma of 402 loggerhead sea turtles captured along the U.S. southeast coast which represented a wide range of size classes. VTG was detected in all 5 nesting females, in 90% of females captured offshore that were greater than 87 cm standard carapace length (SCL) (n=10), 73% percent of large juvenile females between 77 cm and 87 cm SCL (n=15), 2.3% of females less than 77 cm SCL (n=215), 5% of the turtles of unknown sex (n=60), and 1.0% of males (n=96). The VTG expression observed in the larger females (>77 cm SCL) is expected, but it is abnormal in the one male and could be considered precocious in the five smaller females with SCL of 52, 61, 64, 66, and 74 cm, especially the smallest of these. Organochlorine (OC) and polychlorinated biphenyl (PCB) concentrations were measured in whole blood and/or fat biopsies of >58 of these turtles using gas chromatography with electron capture detection and mass spectrometry. The nine precocious or abnormal juveniles had total PCB concentrations in their blood 65% higher than 49 juveniles that were not producing VTG, albeit not significantly different (p = 0.125). A fat biopsy taken from the smallest precocious female had the second highest total
PCB and 4,4’-dichlorodiphenyldichloroethylene (DDE) concentrations on a wet mass basis among 44 juveniles. These data suggest that loggerhead sea turtles inhabiting this region of the Atlantic Ocean begin reproductive maturation around 77 cm SCL and it is inconclusive whether these environmentally relevant concentrations of contaminants could disrupt their endocrine system.

**MP051 Biomarkers of oxidative stress and persistent organic pollutants in nesting Chelonia mydas from the southern Gulf of Mexico**

G. Rivas-Hernández, Autonomous University of Carmen; E. Norena-Barroso, National Autonomous University of Mexico / Unidad de Química Sisal; V. Cobos-Gasca, Autonomous University of Yucatan / Facultad de Medicina Veterinaria; G. Rodríguez-Fuentes, National Autonomous University of Mexico / Unidad de Química Sisal

The coast of Campeche on southern Gulf of Mexico is one of the world’s major breeding areas for green turtles, Chelonia mydas. Legendary pollutants such as organochlorine pesticides (OCPs) and polycyclic aromatic hydrocarbons (PAHs) have been periodically detected in this area. Although green turtles are regarded as species of conservation concern and are considered as sentinel organisms in marine biomonitoring, little is known about the relationship between exposure to OCPs and PAHs and biomarkers of oxidative stress in C. mydas. Since the alterations in antioxidant protection and oxidative damage have been used as reliable biomarkers for monitoring oxidative stress in aquatic organisms, the aim of this study was to assess oxidative stress in plasma in relation to pollutants concentrations in plasma and eggs. Blood samples were collected from 29 female green turtles (Chelonia mydas) nesting in three sites along the Campeche coast in the southern Gulf of Mexico, once the female laid her eggs, blood was collected on each female and was immediately centrifuged to obtain plasma and then frozen until analysis. One egg per female was also collected for pollutant analysis. Results indicated differences between sites in OCPs and PAHs concentrations in plasma and eggs. Total egg concentration of OCP were higher at Sabancuy site, and total PAH concentrations were lower in eggs collected from turtles at Carmen. Antioxidant response presented also significant differences between sampling sites. Samples from Carmen and Sabancuy were related to super oxide dismutase (SOD) glutathione-S-transferase (GST) and glutathione peroxidase (GP) activities and to the concentration of lipid hydroperoxides. These results could help to improve the understanding of antioxidant defense responses in C. mydas and their potential to be used as biomarkers.

**MP052 Exploring the effects of exposure from common perfluorooalkyl substances (PFASs) on Brown Anoles (Anolis sagrei)**

C. Furst, Towson University / Environmental Science; C. Weible, Towson University; A. East, Towson University / Environmental Sciences; C.J. Salice, Towson University / Environmental Science & Studies Biology

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental contaminants. Perfluorooctane sulfonate (PFOS) and perfluorohexane sulfonic acid (PFHxS) are PFAS that have been key ingredients in aqueous film forming foams, which have been heavily used at military bases for fire suppression activities. As a result, PFOS and PFHxS are common environmental contaminants and there is concern about their potential toxicological impacts on humans and wildlife. While there has been some data generated on effects of these PFASs on the most common ecological receptors, there is no data available on the toxicity of PFOS or PFHxS to reptilian species. We used the brown anole as a model laboratory reptile species to help develop PFAS ecotoxicity data for reptiles. In total, three PFAS reptile toxicity studies were conducted: 2 PFOS studies (90-Day /35-day exposures) and one 63-day PFHxS dosing study. Here we report primarily the results from the 90-day PFOS study and compare to results from the other studies. All animals were dosed via pseudo-gavage. The 90-day PFOS dosing study was performed with fifty fully mature, male brown anole lizards separated into 5 dosing groups with 0, 0.05, 0.15, 0.45 or 1.35 mg/kg per day exposure concentrations. We collected mass and snout-vent length weight data weekly, organ weights and necropsy and also measured feeding rate. While analyses are ongoing, the preliminary analysis suggests that there were no strong effects of PFOS on the mass of exposed lizards nor the mass of organs. So far this suggests that PFOS is not toxic to mature male lizards at relatively high exposure levels. In comparison, the 35-Day PFOS study showed an apparent effect on the growth of younger, growing lizards at 2 mg PFOS/kg per day. In the PFHxS study male and female lizards were dosed with 0, 0.02, 0.2, or 2 mg/kg per day. The results of the PFHxS study showed no effects on body or organ size but there was an observed effect on the production of viable eggs by female lizards. Future studies will include PFOS+PFHxS mixture toxicity as these commonly co-occur. Collectively, these data are providing valuable insights into the effects of PFAS on reptilian species and should be useful for ecological risk assessment.

**MP053 Temporal trends in mercury tissue concentrations in the Brown watersnake (Nerodia taxispilota) from the Savannah River Site**

D.L. Haskins, T. Tuberville, University of Georgia / Savannah River Ecology Laboratory

Mercury (Hg) is a ubiquitous environmental contaminant that poses a significant threat to aquatic systems globally. Mercury can bioaccumulate and biomagnify in vertebrates, which may negatively impact a variety of health parameters (e.g., behavior, immune function, growth, reproduction, and overall survival). While studies that focus on Hg in snakes have increased in number in the last two decades, the paucity of data relative to other vertebrate taxa limits the inclusion of snakes in risk assessments. Brown watersnakes (Nerodia taxispilota) possess many traits that may make them susceptible to Hg bioaccumulation. These large-bodied snakes are long-lived (> 10 years), are entirely piscivorous, and are important predators in streams and rivers in the southeastern United States. The species is also common and easy to collect, making them potentially valuable for risk assessments. We compared Hg tissue concentrations in Brown watersnakes collected on the Savannah River Site, SC, during 1983-1986 and in 2019. Our objectives were to: 1) Quantify total Hg (THg) concentrations in blood, kidney, liver, muscle, and tail tips; 2) evaluate the ability to use tail tips and blood to approximate THg burdens in destructive tissue types (kidney, liver, and muscle); and 3) document changes in THg concentrations in Brown watersnakes over three decades. Mean THg values (in all tissues) in snakes sampled in the 1980s ranged from 0.570 - 50.4 mg/kg (dry weight). The highest value in our dataset represents the highest Hg measurement reported in a snake species to date. Preliminary data from snakes collected in 2019 suggest that historical tail THg values were > 4 times higher than contemporary THg concentrations. We will also present on predictive relationships among multiple tissue types. Our dataset presents a unique opportunity to not only provide critical Hg bioaccumulation data for use in risk assessments, but also to evaluate how the regulation of Hg in the United States has impacted Hg exposure in this snake species.
Emerging Contaminants? Emerging Tools: Effect-Based Surface Water Quality Assessment

**MP054 Endocrine disrupting chemicals (EDCs): Detection of the ‘estrogenic’ properties of water**

Z. Siddiqua, Wayne State University / Pharmaceutical Sciences; T. Baker, Wayne State University / Institute of Environmental Health Sciences; C. Akemann, Wayne State University / Pharmacology; M. Monshi, N. Reddy, Wayne State University / Pharmaceutical Sciences; K. Gurdziel, Wayne State University / Applied Genomics Technology Center; J. Shields, Wayne State University / Institute of Environmental Health Sciences; K. Alame, Wayne State University / Pharmaceutical Sciences; D. Meyer, Wayne State University / Pharmacology; A. Wahls, Wayne State University / Civil & Environment Engineering; F. Saad, J. El–Nachef, M. Antoon, R. Nakhle, Wayne State University / Pharmaceutical Sciences; E. Crofs, N. Hijazi, Wayne State University / Institute of Environmental Health Sciences; M. Hamid, H. Nasser, Wayne State University / Pharmaceutical Sciences; S. McElmurray, Wayne State University / Civil & Environment Engineering; D. Kashian, Wayne State University / Biological Sciences; D. Pitts, Wayne State University / Pharmaceutical Sciences

Nine structurally diverse CECs that are known or suspected to be estrogenic and/or anti-androgenic were selected: 4-nonylphenol, atrazine, chlorpyrifos, dieldrin, bisphenol-A, estrone, metformin, triclocarban and triclosan. The two organisms were found to be sensitive to environmentally relevant concentrations (e.g., parts per trillion range, ppt) and a large number of significant alterations in gene expression were detected for all 9 CECs using QuantSeq. This study has clearly demonstrated the feasibility of the two organism bio-assay approach to identifying EDC activity in water and pathway analysis is currently underway to enable further development of the bio-assay as an EDC detection tool. The Detroit River receives a large number of contaminants from treated wastewater effluent, combined sewer overflows, urban and agricultural runoff, and landfill leachate. These contaminants include contaminants of emerging concern (CECs) that are not typically regulated and/or monitored by the governing agencies. Some CECs disrupt normal endocrine function and have been called Endocrine Disrupting Chemicals (EDCs). Feminized aquatic vertebrates have been reported all over the world (for e.g., reports of elevated levels of the yolk protein, vitellogenin [biomarker for estrogenicity] in male fish), particularly near areas where there is significant urban or agricultural impact on the environment, and this has been attributed to EDC activity. Our hypothesis is that a bio-assay system based on Daphnia pulex (waterflea) and Danio rerio (zebrafish) can be used for a molecular identification tool and can detect estrogenic and anti-androgenic activity in water using behavioral, morphological, and differential gene expression data.

**MP055 Application of an Integrative Zebrafish Embryo approaches on the Toxicity Assessment of Chemical Mixtures in Surface Waters**

Y. Peng, X. Zhang, Nanjing University / Environmental Science

p.pl {margin: 0.0px 0.0px 0.0px 0.0px; line-height: 19.0px; font: 13.0px ‘Helvetica Neue’} Wide variety of emerging organic pollutants (EOPs) frequently detected in surface waters, it will pose a great threat to human and ecological health. However, lack of understanding of chemical mixtures and cumulative exposures. Effect-based tools such as in vitro bioassays were used to monitoring chemical pollution of waters. However, there are limitations to the application of bioassays directly for water quality assessment, which often fail to identify pollutants of concern, since the defined priority and monitored pollutants often fail to explain the observed toxicity. A Full dose-response reduced zebrafish embryo transcriptome (RZT) method could prioritize potential biological end point and provide more sensitive biological molecular pathway profile compared to in vitro bioassays. In this study, for identifying multiple potential adverse effect of concern and prioritizing surface waters with the greatest potential adverse effects, an integrative zebrafish embryo toxicity approaches were used to systematic assess adverse effects of surface water from YRD area, which include high content imaging test (HCT), locomotor response test (LMR) and RZT method. Four types of surface samples and control samples (n = 9) were collected by large-volume SPE device (LVSEP), include waters from urban, aquaculture, farmland and wastewater treatment plants in chemical industry park (WWTP). Among all tested samples, HCT and LMR tests demonstrated that only water samples from WWTPs presented lethal effect to zebrafish embryo (LC50= 5.2 to 7.4 in REF). WWTP1 showed teratogenic effect (NOEC = 8 in REF) and neuroactivity (NOEC = 1 in REF); WWTP2 showed teratogenic effect (NOEC = 2 in REF) and neuroactivity (NOEC = 2 in REF); WWTP3 showed teratogenic effect (NOEC = 5 in REF). p.p1 [margin: 0.0px 0.0px 0.0px 0.0px; line-height: 19.0px; font: 13.0px ‘Helvetica Neue’] Further, based on the PODpath values calculated by biological molecular pathway analysis of RZT test, WWTP2 was the most potent sample (PODpath=0.078 in REF), the sensitive response genes, such as rps11, ppp4ha, mad2l1, snrpd1, raplaa, rps4x were related to the development and endocrine biological pathway (cell division, nervous system and organ development, cellular metabolism, signaling pathway and oocyte meiosis). These results were associated with teratogenic effect observed in individual level. As a result, the integrative zebrafish embryo testing technology can be applied to evaluate and prioritize chemicals mixtures in future water quality assessment.

**MP056 Recovery of wild fish in response to wastewater treatment plant upgrades**

K. Nikel, P. Marjan, University of Waterloo / Biology; K. Hicks, Alberta Environment and Parks / Biology; M. Fuzzen, McMaster University / Biology; N. Srikantan, E.K. McCann, H. Dhiyebi, L. Bragg, University of Waterloo / Department of Biology; P. Law, Region of Waterloo; J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants and Research Division; T. Clark, Environment and Climate Change Canada / Water and Science Technology Directorate, Aquatic Contaminants Research Division; G. Tetreault, Environment and Climate Change Canada / Water Science and Technology Directorate; M.R. Servos, University of Waterloo / Biology

Municipal wastewater treatment plant (WWTP) effluent contains a variety of contaminants, including nutrients and pharmaceuticals, that are a concern for the health of aquatic ecosystems. The biological effects of effluent from two large WWTPs (Kitchener and Waterloo) which discharge into the Grand River in southern Ontario, have been reported in many previous studies. Wild rainbow darter (Etheostoma caeruleum) collected downstream of these discharges have demonstrated disruptions at multiple levels of biological organization, ranging from altered gene expression to tissue-level changes (i.e., intersex). The Region of Waterloo has recently invested in major treatment upgrades at both plants to improve effluent and river water quality by including additional nitrification and extended solids retention time. The initial facility upgrades came on line in 2012 at Kitchener but major additional changes are still ongoing. The major upgrades at the Waterloo WWTP came on line in late 2017. This has created a unique opportunity to investigate whether responses in rainbow darter previously associated with effluent exposure will resemble upstream reference levels following the upgrades. Analytical chemistry of effluent samples at both plants demonstrated that the upgrades resulted in an immediate reduction of many chemicals in the effluent including ammonia, selected pharmaceuticals (e.g. ibuprofen, naproxen) and estrogenicity. After the upgrades at Kitchener, stable isotope signatures of nitrogen in fish muscle tissue and in vitro sex steroid production of 11-ketotestosterone and testosterone in rainbow darter shifted to upstream reference conditions, and there was a significant reduction in intersex incidence and severity. The more recent upgrades at the Waterloo WWTP have resulted in similar recovery of both stable isotope signatures of nitrogen in muscle and steroid production in males. Histological assessment for intersex is ongoing. These major capital investments in WWTP
upgrades targeted at improving conventional effluent quality (e.g. Total Suspended Solids (TSS), ammonia, etc.) have the co-benefit of reducing or even eliminating key adverse biological responses in fish in the receiving environment.

**MP057 Effects-based analysis of agricultural runoff and environmental DNA biomonitoring in the Salinas Valley, California (USA)**

S. Stinson, University of California, Davis / VMAPC; X. Deng, California Department of Pesticide Regulation; S. Hasenbein, Technical University of Munich / Lehrstuhl für Aquatische Systembiologie; E.B. Holland, California State University, Long Beach / Department of Biological Sciences; S.P. Lawler, University of California, Davis / Entomology and Nematology; R.E. Connan, University of California, Davis / Anatomy, Physiology & Cell Biology, School of Veterinary Medicine

The Salinas River watershed is an important riparian corridor within the Central Coast region of California, and drains some of the most intensively farmed regions in the United States. Complex mixtures of agricultural pesticides are frequently and regularly detected within the watershed. To understand how these mixtures affect aquatic life, we collected water samples from six representative sites, analyzed pesticide concentrations, tested toxicity with model species *Daphnia magna*, *Hyalella azteca* and *Pimephales promelas*, and analyzed expression of selected genes involved in general stress responses. Recovery after an influx of pesticides is influenced by the regional pool of taxa (via drift and dispersal). To assess the recovery potential of invertebrate populations at impacted sites, we assessed biodiversity within the metacommunity, using environmental DNA (amplicon sequencing of CO1) and traditional kick-net sampling methods. Organisms were exposed to a geometric dilution series of field water in 96-hour, static renewal tests. Following exposures, we evaluated mortality and expression of genes involved in general stress responses, acetylcholine receptor, and ryanodine receptor pathways, which are expected to be impacted by emerging pesticides of concern that have been regularly detected at these sites, such as imidacloprid and chlorantraniliprole. There was significant *D. magna* and *H. azteca* mortality (100%) at three of the six sites. Gene expression data shows significant differential expression for several genes of interest including HSP90, RyR1, CYP1a and BCL-2, even at sites/concentrations without significant mortality. Biodiversity data indicates the presence of sensitive invertebrate taxa (*Ephemeroptera*, *Plecoptera*, *Trichoptera*) located upstream from chemically impacted sites. These data suggest that a) complex chemical mixtures impact aquatic life in the Salinas river watershed, even at sublethal exposure levels, and b) the surrounding metacommunity can potentially repopulate impacted sites, provided that sufficient connectivity and habitat exists. This research provides novel baseline biodiversity data for the Salinas watershed and will inform future bioassessment and monitoring efforts. As molecular bioassessment tools such as environmental DNA and gene expression assays become widespread, studies that link molecular data to ecological effects are increasingly necessary.

**MP059 Conclusions from Five Years of Chemical and Biological Effects Monitoring around the Great Lakes Basin**

D.E. Villeneuve, US Environmental Protection Agency / Mid-Continent Ecology Division; S.R. Corsi, US Geological Survey / Upper Midwest Water Science Center; C.M. Custer, US Geological Survey / Upper Midwest Environmental Sciences Center; E. Johnson, NOAA / National Centers for Coastal Ocean Science / NCCOS Mussel Watch Program; S.E. Hummel, US Fish and Wildlife Service; H.L. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory; E.J. Perkins, US Army Engineer Research and Development Center / Environmental Laboratory; E. Murphy, US Environmental Protection Agency / Great Lakes National Program Office

Under Action Plan I of the Great Lakes Restoration Initiative (GLRI), Federal and Academic partners investigated the presence, distribution, and potential impacts of chemicals of emerging concern (CECs) in Great Lakes tributaries. Over a span of five years, a range of CECs were monitored in surface waters, sediment, and in tissues of fish, invertebrates, and birds. Chemical monitoring was complemented with biological effects measurements in resident organisms, mussels and fish caged in situ, and in vitro assays. Detected chemical concentrations were compared with water quality benchmarks, literature-based screening values, and/or pathway-based biological potency estimates from high throughput screening data (e.g., ToxCast, Tox21). Concentrations of CECs exceeding water quality benchmarks or screening values were detected at multiple sites, with the most frequent exceedances detected for five PAHs, five pesticides, and the detergent metabolite 4-nonylphenol, as well as the pharmaceuticals, ibuprofen and venlafaxine. Consideration of ToxCast bioactivity screening data that are now available for thousands of chemicals nearly doubled the number of Great Lakes CECs for which a risk-based screening and prioritization approach could be employed. Overall, effects detected in resident and caged organisms were modest and sublethal. Nonetheless, considering multiple lines of evidence including biological effects and their statistical associations with measured exposure concentrations, PAHs were identified as an on-going threat to Great Lakes fish and wildlife that likely contributes to the persistence of beneficial use impairments in several tributaries of the Great Lakes Basin. Likewise, at least 10% of tributary streams surveyed were estimated to be at risk for estrogenic effects in vertebrates. These and other key findings of this five-year interagency research effort integrating chemical and biological effects monitoring are captured in a report scheduled for release in fall 2019. This presentation will highlight key findings, on-going challenges in the use of effect-based approaches, next steps for...
Fate and Effects of Metals: Mechanisms of Dietary Bioavailability and Toxicity

MP060 Ameliorative Effect Of Gallic Acid Against Sodium Fluoride-Induced Hypertension And Hepato-renal Complications In Wistar Rats

O.E. Ola-Davies, University of Ibadan, Nigeria / Veterinary Physiology and Biochemistry; S.G. Oluokole, University of Ibadan, Nigeria / Department of Veterinary Anatomy; A.A. Oyagbemi, University of Ibadan / Veterinary Physiology and Biochemistry; T.O. Omobowale, University of Ibadan / Veterinary Medicine; B.O. Oke, University of Ibadan / Department of Veterinary Anatomy

Sodium fluoride (NaF) is used globally as an important element in the prevention of tooth decay, and it has proven its effectiveness in dental caries prevention when its low level is maintained in the oral cavity. However, detrimental effects associated with prolonged exposure to NaF include gastrointestinal disturbances, deranged cerebrovascular and cardio-renal integrity, initiation of anomalies in the chromosomes thus inducing genetic damage, muscular wasting, mineralization of myocardium as well as testicular necrosis. Gallic acid (GA) derivatives occur naturally in plants and has been reported to possess antioxidant properties against various disease conditions. Here, the ameliorative effect of GA on sodium fluoride (NaF)-induced hypertension and hepato-renal toxicity was studied. Four groups of seven rats each were used in this study. Group A received distilled water (control), group B received NaF (300 ppm), groups C and D received NaF + GA (60 mg/kg) and NaF + GA (120 mg/kg), respectively, through oral gavage, for 7 days. Blood pressure parameters were taken, the liver and kidney samples were harvested for markers of oxidative stress and histology using standard procedure. All data were expressed as mean ± standard deviation (SD). All results were analyzed using student’s t-test and one-way ANOVA followed by Tukey’s post-hoc test using Graph prism 6 and p-values < 0.05 considered to be statistically significant. The results showed that NaF alone significantly increased systolic, diastolic and mean arterial blood pressure. Administration of NaF also significantly raised both renal and hepatic hydrogen peroxide, malondialdehyde, protein carbonyl, serum myeloperoxidase and significantly decreased reduced glutathione, glutathione peroxidase, superoxide dismutase and glutathione-s-transferase when compared to the control and co-administered with GA. However, concomitant administration of Gallic acid with NaF reduced high blood pressure, markers of oxidative stress and improved antioxidant defence system. It also ameliorated structural changes in renal and hepatic tissues. Our findings thus suggest that Gallic acid is a potential drug candidate in the treatment of sodium fluoride induced hypertension and hepato-renal toxicity.

MP061 C. virginica physiological analysis after ingestion of Cu and Cd through Chlorella

G. Barrera Escorcia, UAMI / Hidrobiologia; F. Mares-Guzman, Metropolitan Autonomous University Iztapalapa / Hidrobiologia; X. Guzman-Garcia, Metropolitan Autonomous University Iztapalapa / Hidrobiologia; I. Hernandez-Calderas, Metropolitan Autonomous University / Hidrobiologia

Several human activities contribute to increase the load of metals in aquatic environments. The algae Chlorella is a primary link in the trophic chain. Being in direct contact with the environment, it can incorporate contaminants by absorption or adsorption. The organisms that feed on them, like the oyster Crassostrea virginica, can incorporate them and could present physiological problems. The objective of this work was to evaluate the possible damages derived from the trophic transfer of copper and cadmium, from Chlorella sp. to C. virginica. The algae were cultivated for 110 hours at a sublethal dose of 0.0254 mg/L of copper and 0.0493 mg/L of cadmium. Chlorella sp. in a concentration of 30 X 10^6 cells were proportionated to C. virginica daily. Relevant physiological parameters (filtration rate, feed intake, oxygen consumption, nitrogen excretion and O: N ratio) were analyzed during 21 days. The most notable physiological damages observed were: reduction of cell consumption, increase in the filtration rate as well as increase in the oxygen consumption. The biological responses associated with Cd exposure, could be observed in more than 50% of the organisms since day 11, while those associated to Cu exposure were deferred to day 16. Chlorella sp. is a algae resistant to Cu and Cd, but it was capable of transferring the metal to the oyster by trophic route. Despite Cu is an essential metal, its consumption generated physiological problems, however it was evident that Cd was able to enter quickly by the trophic via and it generated damages in a short time in C. virginica oyster, and compromised the health of the organisms.

MP062 Dietary Uptake of Metals from Periphyton into Midge (C. dilutes) and Mayfly (N. triangularis) Larvae

N. Faud, T. Vadas, University of Connecticut / Civil and Environmental Engineering

Healthy streams are vital components in healthy ecosystems. Metals can impair health of streams. USEPA sets regulatory limits for metals with the aquatic life criteria by testing toxicity of different organisms. Tools such as biotic ligand model are often used to modify acute concentration for some metals such as Cu. However, data is scarce for a family of organisms, insects, which is believed to have significant dietary uptake and bioaccumulation. Moreover, differences in metal speciation, caused by source water chemistry, or chronic exposure are yet to be fully accounted for in established toxicity assays. Hence, to protect stream health in chronic exposure cases, establishing different benchmarks and alternative means of assessment is necessary as opposed to setting daily average allowable concentrations. This requires a better understanding of metal speciation from different sources and biouptake via dietary pathways. Dietary uptake is known to be an important exposure pathway for macroinvertebrates. This study aimed at investigating uptake and assimilation of diet borne metals into midges (C. dilutes), a standard sediment toxicity test organism, and mayfly (N. triangularis) exposed to contaminated periphyton grown in different source waters. Uptake and elimination of metals into periphyton was also investigated in exposure experiments with 63Cu and 65Cu under different exposure conditions and durations. Collected stream water, wastewater treatment plant (WWTP) effluent and their mixtures were used as source waters. To investigate uptake into the macroinvertebrates, both the organisms and periphyton were exposed to reconstituted exposure water. Extracted organic matter (OM) from wastewater effluent and stormwater was used. Results showed Cu in periphyton equilibrated with environmentally relevant exposure water in about two days with ~ 90 µg/g internalized and similar surface bound Cu. Exchangeable Cu, weakly bound to OM, was identified as the most bioavailable fraction. Waterborne 65Cu uptake into midges from OM free water with 10 µg/L Cu was linear. Dietborne-only uptake was found to be slightly higher than waterborne uptake alone in 24 hours. Upon withdrawal of exposure conditions, Cu internalized into midges slowly dropped near initial in 44 hours. Ongoing experiments with varying metal concentrations in combined waterborne and dietborne uptake experiments are expected to show lower dietary uptake in experiments with effluent OM as a source.

MP063 Effect of environmental chloride concentration on copper and silver bioavailability and bio-reactivity in bluegill (Lepomis macrochirus) fish

M. Ibrahim, E. Bates, T. Black, M. Minghetti, Oklahoma State University / Integrative Biology

Chloride is an inorganic ligand that forms complexes with metals. In general, it is known that metal complexes are not bio-available, but
some recent studies have shown the potential of bio-availability of metal complexes in fish. Moreover, it was hypothesized that copper and silver may require a chloride dependent symporter mechanism to enter into cells. While several studies have investigated the effects of chloride on metal toxicity, very few have looked into its role in metal bio-availability and bio-reactivity in fish. In this study, we are investigating the effects of chloride in the exposure media on the bio-availability, and bio-reactivity of copper and silver in bluegill (Lepomis macrochirus) fish. Based on the USEPA freshwater formula for toxicity tests, we prepared three exposure media containing 0.05, 3 and 40 mM of chloride. Using a chemical equilibrium software, Visual MINTEQ, we calculated the speciation of copper and silver at a non-toxic concentration (300 nM) in each medium. The toxicity of the exposure media with and without metal were tested showing that the fish were able to tolerate the exposure conditions. The major Ag species formed in 0.05, 3, and 40 mM Cl media are Ag+ (90%), AgCl\(_2\) (69%), and AgCl\(_2\) (74%), respectively. For copper, in 0.05 and 3 mM Cl media, the dominant species were Cu\(^{2+}\) (~25%) and CuCO\(_3\) (~60%) whereas in 40 mM Cl medium, Cu\(^{2+}\) increased to ~35% and CuCO\(_3\) was reduced to ~50%. The bioavailability of silver and copper species will be determined by quantification of the gill, intestine and liver metal accumulation (by ICP-OES) in fish exposed for 48 hours. Metal bio-reactivity (i.e. induction of a metal-specific biological response) will be determined in the same set of samples by measuring metallothionine mRNA levels (by quantitative PCR). The outcomes from this experiment will shed light on the role of environmental chloride concentration on silver and copper bioavailability and bio-reactivity which is relevant for environmental risk assessment.

**MP064 Engineered nanoparticles alter insect emergence and result in flux of metals from aquatic to terrestrial food webs**

B. Perrotta, Baylor University; M. Simonin, Duke University / Biology; B. Castellon, Baylor University / Environmental Science Department; S.M. Anderson, Duke University / Biology; C.W. Matson, Baylor University / Environmental Science; E. Bernhardt, Duke University / Biology; R.S. King, Baylor University / Department of Biology

Freshwater ecosystems are exposed to engineered nanoparticles through discharge from wastewater and agricultural runoff. We conducted an experiment to examine the combined effects of chronic dosing of nanoparticles and nutrients on insect emergence. Three levels of nanoparticles (control, gold, copper) were crossed by two levels of nutrients (ambient vs. enriched nutrient dosing) in 18 outdoor wetland mesocosms. We estimated emergent insect abundance, community structure and flux of copper and gold nanoparticles from aquatic ecosystems to adjacent terrestrial environments, monthly over a nine-month experiment. We detected significant decrease in insect emergence after exposure to nanoparticles in some months and a flux of nanoparticles from treated mesocosms. These results have implications for terrestrial subsidies and contaminations in insectivorous terrestrial and riparian food webs.

**MP065 Heavy Metal Concentration Of Well Water In Ogolonto, Ikorodu Lagos, Lagos, Nigeria**

T. Folarin, University of Lagos, Akoko / Chemistry

The determination of heavy metal composition of Ogolonto, Ikorodu well water has been carried out using standard analytical procedure. This result of the heavy metal determination of Ogolonto, Ikorodu well water was reviewed that the concentration of Lead in the water is 2.2mg/L, Iron is 5.3mg/L, Zinc is 2.1mg/L, Copper is 0.1mg/L, Nickel is 0.2mg/L, Cadmium is 0.001mg/L, Manganese is 0.0130mg/L and Chromium is 0.02mg/L. the result of the analysis has shown that some of the heavy metal concentration in the well water is within the limit of WHO and SON. While some such as Lead and Iron is above the limit stated by WHO and SON. Adequate treatment measure must be carried out on the well water before using them so as to reduce the concentration of Lead and Iron in the water. Hence, with the result of the heavy water concentration of the well water, it has shown that the well water is not ideal for drinking, but it can be used for mixing concrete and washing.

**MP066 Interaction Effects of Dietary Nutrients Modulation And Cadmium Toxicity Against Algae And Daphnia**

O.M. Awoyemi, Texas Tech University / Environmental Toxicology; K. Thompson, Harvard School of Public Health / Biostatistics; A. Velazquez, Texas Tech University / Department of Environmental Toxicology; M.D. Hassan, A.L. Peace, Texas Tech University / Department of Mathematics and Statistics; G.D. Mayer, Texas Tech University / Department of Environmental Toxicology

Effective ecological risk assessment requires the understanding of complex ecological interactions, elemental cycling, and the interactive effect of natural stressors such as resource limitations and contaminants. The development of ecotoxicological models that incorporate such data would significantly contribute to interpreting how contaminants impact organisms and food webs in such a dynamic system. This study seeks to develop and analyze a series of empirically testable and robust mathematical models of population dynamics subject to stoichiometric nutrient modulation and contaminant stressors. Specific empirical measurements include: physiological traits (growth, survival, reproduction, respiration, heartrate), behavioral (distance moved, velocity), elemental-(C:P) and toxicant (Cadmium-Cd) uptake in primary producer, Algae (S. acutus) and primary consumer, Daphnia pulex. S. acutus and D. pulex were cultured in Cd-containing (25%, 50% and 100% of daphnia-exposed LC50 values) media with varying P-nutrient ratios [Low P (20% P) and COMBO (100% P as control)] media for acute (24 h and 96 h) and chronic (21 d) durations, according to USEPA methods. Acute toxicity results showed a concentration-dependent increase in the toxicity of Cd against S. acutus with higher in Low P media compared to the control. The survival of D. pulex reduced temporally with Cd exposure and Low P media further reduced the survival. Other toxicological endpoints (respiration, heartrate, growth, reproduction, and behavior) were also impacted by Cd exposure with enhanced impact in the Low P media, compared to control. Studies are currently underway to determine the effects of the stoichiometric modulation of the mineral nutrients (C:P:N) on the toxicities of Cd, Arsenic and Copper against S. acutus and D. pulex.

**MP067 Linking extracellular metal speciation to intracellular metal bioavailability and toxicity: An in vitro approach**

D. Oldham, M. Minghetti, Oklahoma State University / Integrative Biology

Ecotoxicology prediction models such as the Free Ionic Activity Model (FIAM) and Biotic Ligand Model (BLM) associate the free metal ion in solution as being the primary driver of toxicity. The FIAM and BLM assume that the metal is in equilibrium with all ligands and with the biotic ligand. However, studies have shown that free ions are not the only toxic species and that the cell can affect the equilibrium between metal and the biotic ligand. To evaluate the bioavailability and toxicity of neutral and charged metal complexes, as well as free metal ions, Visual Minteq, a chemical equilibrium model, was used to design different exposure media presenting a variety of metal species. Two non-essential (silver and cadmium) and two essential (copper and zinc) metals were selected. The rainbow trout (Oncorhynchus mykiss) gut cell line (RTgutGC) was used to investigate the bioavailability and toxicity of the different metal species. Dose response curves were calculated using a multiple endpoint cytotoxicity assay based on the dyes Alamar blue, CFDA-AM, and Neutral Red, which are indicators of metabolic activity, cell membrane and lysosomal integrity, respectively. Bioavailability of different metal species was measured by ICP-MS in cells exposed to an identical non-toxic dose of metal. Bioreactivity was measured by quantification of mRNA levels of genes that respond to metal intoxication, such as metallothioneins. Speciation calculations showed a wide range of metal species depending on anionic media composition. Silver and cadmium showed affinity for chloride, copper for phosphate, and zinc remained primarily in its free ionic form. Silver and copper, toxicity was not affected by extracellular change in metal speciation, whereas cadmium and zinc toxicity were reduced by chloride complexation and/or concentration. Bioavailability of the essential metals appeared to be tightly regulated as the metal.
concentrations remained constant throughout all media. The bioavailability of the non-essential metals was affected by the media composition. For silver, neutral chloride or cysteine complexation reduced bioavailability. Similarly, cadmium bioavailability was reduced by cysteine complexation but was also increased by the presence of bicarbonate in the media. This study demonstrates that speciation alone is not sufficient to explain metal bioavailability and toxicity, and that many factors play a role in metal-cell interactions.

**MP068 Sex-Specific Gene Expression Associated with Zinc Homeostasis in Squirrelfish**

D. Thompson, T. Riker, Northern Kentucky University / Biological Sciences; H. Veilleux, University of Alberta

Zinc (Zn) is a micronutrient required by all organisms for a range of essential processes. Studies of the reproductive physiology of squirrelfish (Holocentrus adscensionis) have shown that females preferentially increase Zn uptake during reproductively active periods, initially accumulate Zn in the liver, and ultimately redistribute this Zn to the ovary. This hyperaccumulation is likely caused by physiological differences between males and females, as it occurs when both are exposed to the same environmental Zn concentrations. An efficient uptake and shuttling system would be central to the ability of female squirrelfish to extract, accumulate, and utilize Zn from food and/or water. This project examined the hypothesis that the changes in maternal Zn homeostasis that occur during reproduction result from differential expression of Zn transporters between the sexes due to reproductive status. Male and female squirrelfish collected from the Florida Keys were compared for gonad size, liver and gonad Zn, and plasma sex steroids. Genetic analyses were conducted on RNA extracted from gill, anterior intestine, liver, and gonad samples. Female squirrelfish accumulated significantly more Zn in the liver and gonads compared to males. Females expressed higher levels of multiple Zn transporters, including the ZIP4 transporter that is known to play a pivotal role in intestinal Zn uptake. Furthermore, females that were reproductively active, as evidenced by gonad size and sex steroid levels, expressed ZIP4 to a greater extent than reproductively inactive females. The potential for hormonal regulation of Zn transporter expression in these animals warrants further investigation.

**MP069 Bioaccumulation and trophic transfer dynamics of heavy metals in food web assemblage in intertidal mangrove ecosystem, Sungai Puloh, Malaysia**

B.E. Udchukwu, Kampala International University- Western campus, Ishaka / Pharmacology/Toxology; A. Ismail, Universiti Pertanian Malaysia / Biology; S.Z. Zulkifli, H. Omar, University Putra Malaysia / Biology

In recent times the ever increasing anthropogenic activities associated with industrialization, population increase, and urbanization in developing countries which leave chemical footprints behind, pose risk to aquatic ecology. Among these chemical pollutants are heavy metals which are bioaccumulative, persistent and toxic. This consequently impacts aquatic organisms through bioaccumulation, trophic interactions, and dietary exposure. The aim of this research is to evaluate heavy metals (Cu, Ni, Pb, and Zn) and to assess their bioaccumulation patterns in surface sediments and some key ecological food chains in Sungai Puloh estuary. Also to characterize the trophic positions of samples viz: Periophthalmodon schlosseri, Osteoglossus militaris, Teleostei telescopium, Nerita lineata, Polymesoda coxans, Penaus monodon, Uca annulipes, Dotilla lineata, Polymesoda coxans, Penaus monodon, Uca annulipes, Dotilla lineata, and some key ecological food chains in Sungai Puloh estuary. The direct aqua regia method was employed for the metal level estimation. Samples were determined for heavy metal concentrations (u/g, dry weight) by using an Atomic absorption Spectrophotometer and Isotope Ratio Mass Spectrophotometer for the stable isotopes. The result revealed elevated Cu level in Penaus monodon, (47.19 ± 1.13) u/g and high levels of Pb (15.23 ± 1.93, 16.86 ± 0.52, 8.91 ± 1.06) μg in catfish (Osteoglossus militaris), Uca and Dotilla respectively. With the help of stable isotope ratios of δ13C and δ15N analysis, two distinct food chains and four trophic positions were determined, with catfish occupying the highest trophic level. By using catfish as a model for trophic web system, the result showed that the carbon source for catfish (-17.30 ± 0.91‰) is discretely from crabs (-17.93 ± 0.90‰, -18.03 ± 0.90‰) for Uca and Dotilla respectively with an enrichment of δ13C values of ~1.0‰, complementing the idea that crab found in the stomach content is its staple food. It is arguable that the major source of Pb in catfish comes from crab especially Dotilla and not from the surface sediment, since the biota sediment accumulation factor (BSAF:0.2) recorded a very low ratio compared to that of trophic transfer factor (TTF:1.7). We concluded that heavy metal contamination in Sungai Puloh estuary stems from the release of untreated or poorly/improperly treated effluents, and Pb in catfish is considered to be the element of much concern, and therefore should be strictly monitored.

**MP070 Using selenium: Mercury molar ratios to understand methylmercury toxicity in marine forage fish and their offspring**

X. Ye, N.S. Fisher, Stony Brook University / School of Marine and Atmospheric Sciences

The interaction between mercury (Hg) and selenium (Se) has been investigated for decades in mammals and aquatic organisms. The antagonistic effects have been commonly described as Se playing the protective role in Hg toxicity, with the Se/Hg molar ratio >1. We previously conducted a maternal transfer experiment to evaluate the impact of dietary methylmercury (MeHg) on marine fish reproduction and transgenerational effects on their offspring, but none of the reproductive endpoints were impaired and the larval fish displayed only a little hyperactivity. We hoped to use Se/Hg molar ratios to understand whether the fish were protected from Hg toxicity. Previously, the juvenile sheepshead minnow Cyprinodon variegatus were exposed to a control or MeHg diet from an age of 3-5 months. After the dosing period, female fish were paired with Hg-free male fish for spawning. Egg production, hatching success of embryos, time to hatch, the survival of larvae, growth and swimming behavior of larvae were assessed. We then examined Hg levels in the whole larvae and adult fish heads, intestines, ovaries, and muscles. Se levels were examined in the whole larvae and adult fish heads and muscles, then Se/Hg molar ratios were calculated. The Se/Hg molar ratios in the control treatment were all well above 1 while the Se/Hg molar ratios in Hg treatment were 0.31±0.08 in the female heads, 0.36±0.07 in female muscles. The Se/Hg molar ratio in larvae from Hg treatment were 4.48±2.0. It was difficult to use Se/Hg molar ratios to interpret the Hg effects on the sheepshead minnow which may be partially because we measured total Se levels while it was suggested that the antagonism between Se and Hg and their interactions also depend on the chemical species of both Hg and Se. Using Se/Hg molar ratio >1 might be insufficient to interpret whether fish experience more or less protective advantages of Se against Hg toxicity and more detailed studies should be conducted in the future.

**Environmental Considerations for the Risk Assessment of Polymers, Rubber and Macroplastics: State of the Science**

C.G. Eldridge, College of Charleston; B. Beckham, College of Charleston / Environmental Geosciences

Tire material has been studied for toxicity of leachates for decades, however there are still questions regarding fate and transport and the risks posed to aquatic life. This material carries potentially toxic chemicals resulting from production methods, but may also sorb them from the surrounding environment. PAHs are one class of hydrophobic organic contaminants that are associated with tire wear particles (TP) and crumb rubber (CR), and have the potential to exert narcotic, mutagenic and carcinogenic toxicity. This work determined crumb rubber (KCR-w) and tire wear particle (KTP-w) solid-water partitioning coefficients for PAHs that
were “native” (pre-existing on material) and spiked, and will assess bioaccessibility using single-point 24-hour TENAX extractions, an optimized method correlating to organism bioaccumulation. Sorption studies were conducted using a 3-phase mass balance approach with tire materials (63 – 150 micron size), polyethylene strips (PE, 76 micron thickness) and deionized water spiked with different levels of fluorene and 13C-pyrene and equilibrated for 7 – 21 d. PE serves as a passive sampler in the system, and extracted concentrations in PE are used to calculate K values. TENAX extracions follow established methods. 16 USEPA priority PAHs are analyzed by GC-MS with quantification by isotope dilution against 13C-PAH internal standards. Native PAH content of materials was determined following solvent-extraction by ultrasonication and clean-up by silica-gel column chromatography. Materials were further characterized for specific surface area and pore volume by a 40-pt N2 BET isotherm and composition (percent rubber, carbon black, and inorganic fillers) by thermogravimetry. Results with 1 representative end-of-life tire crumb rubber material showed Log KCR-w of PAHs, both spiked and native, were linearly correlated with Log KOW (R2=0.99). Fluorene sorption followed a linear isotherm (R2=0.999) over a 3-order of magnitude range in water concentration (CW at 14-d equilibrium, 0.1 to 217 µg/L), with an average Log KCR-w of 4.42 ± 0.15, which indicates that partitioning to the rubber fraction (60% material composition by mass) dominates sorption. Ongoing studies with additional crumb rubber and field-collected tire wear particles will expand upon this knowledge of sorption behavior and bioaccessibility, which can be applied to better understand contaminant fate and environmental risks from PAHs associated with tire materials. 

**MP072 Environmental Stewardship Program for Polymers Used in Cleaning Products—Polycarboxylate Polymers**

*P.C. DeLeo, Integral Consulting, Inc.; H. Summers, Integral Consulting Inc. / Institute of Environmental Toxicology and Chemistry; K. Stanton, American Cleaning Institute; M. Lam, Procter & Gamble / Global Product Stewardship; A. Carrao, Kao USA / R&D; N. Pechacek, Ecolab, Inc.*

Water-soluble polymers are important ingredients in cleaning products providing multiple functions and unique performance benefits. In some cases, polymers were developed as part of formulation changes needed to replace commodity chemistries for which environmental concerns were identified. Polymers historically were considered to pose de minimis environmental risks and, until recently, were exempted from regulatory actions globally. Registration of new polymers is now required in some countries (e.g., U.S., Canada, Australia, Japan, Korea). Polymers that are high volume, are estimated to have high consumer exposures, and contain reactive functional groups are expected to be prioritized for registration under REACh. Although data and assessments already exist for some polymeric materials, the cleaning products industry is generating more data to refine environmental risk assessments to support the safe use of polymers in its products. To that end, the American Cleaning Institute (ACI) is leading an environmental stewardship program for key polymers used by its members in the formulation of cleaning products. Through early efforts to understand key cleaning product polymer technologies and the landscape of data availability, the program was able to prioritize data generation needs to support environmental risk assessments, the results of which have been previously published. Currently, ACI leads ongoing efforts to support two categories of cleaning product polymers with widespread use in the U.S., polycarboxylates and polyquaterniums. Preliminary findings from sludge sorption studies on select variants of polyquaternium-10 will be shared here. ACI will also integrate data from other programs and projects including the European Chemical Industry Council’s (CEFIC) Long-Range Research Initiative’s (LRI) efforts evaluating the aquatic effects of cationic polymers into a robust risk assessment (presented during this meeting). ACI will also incorporate into its stewardship program an assessment to support the environmental safety of polycarboxylates that are widely used across the cleaning product industry (available during this meeting).

**MP073 Environmental stewardship program for polymers used in cleaning products**

*M. Lam, Procter & Gamble / Global Product Stewardship; A. Carrao, Kao USA / R&D; N. Pechacek, Ecolab, Inc.; K. Stanton, American Cleaning Institute*

Water-soluble polymers are important ingredients in cleaning products that have multiple functions and unique performance benefits. In some cases, polymers were developed as a components of formulation changes needed to replace commodity chemistries for which environmental concerns have been identified. Polymers historically were regarded to pose de minimis environmental risks and, until recently, exempted from regulatory actions globally. Registration of new polymers is now required in some countries (e.g., U.S., Canada, Australia, Japan, Korea). In Europe, polymers that are high volume, are estimated to have high consumer exposures, and contain reactive functional groups are expected to be prioritized for registration under REACh. Although data and assessments already exist for some polymeric materials, the cleaning products industry is generating more data to refine environmental risk assessments to support the safe use of polymers in its products. To that end, the American Cleaning Institute (ACI) is leading an environmental stewardship program for key polymers used by its members in the formulation of cleaning products. Through early efforts to understand key cleaning product polymer technologies and the landscape of data availability, the program was able to prioritize data generation needs to support environmental risk assessments, the results of which have been previously published. Preliminary findings from sludge sorption studies on select variants of polyquaternium-10 will be shared here. ACI will also integrate data from other programs and projects including the European Chemical Industry Council’s (CEFIC) Long-Range Research Initiative’s (LRI) efforts evaluating the aquatic effects of cationic polymers into a robust risk assessment (presented during this meeting). ACI will also incorporate into its stewardship program an assessment to support the environmental safety of polycarboxylates that are widely used across the cleaning product industry (available during this meeting).

**MP074 Risk Assessments of Polymeric Substances on the Canadian Domestic Substances List**

*N. Sundin, W. Lin, D. Porter, D. Gutzman, Environment and Climate Change Canada / Ecological Assessment Division*

Following a prioritization activity known as categorization of Canada’s Domestic Substances List (DSL), approximately 4300 substances were identified as requiring screening assessment of their potential to cause harm to human health or the environment. Approximately six hundred of these substances are identified as polymers. Due to the complexity of polymeric substances, a novel approach to risk assessment of polymeric substance was developed. This poster will present the approach developed to assess polymers on the DSL, and discuss the various risk assessment methodologies used, which included polymer rapid screening approaches, as well as full-scale screening assessments that were used for six groups of polymers. Through the two polymer rapid screening processes, more than 550 substances were identified to be of low ecological and human health concern, and have been concluded as not meeting any of the criteria set out in section 64 of CEPA. Fifty-one substances were identified as requiring further assessment after the Second Phase of Polymer Rapid Screening due to potential concerns for the environment [29 substances], human health [19 substances] or both [3 substances]. The fifty-one substances were divided into six groups for screening assessments, which are regulatory assessments that can lead to development of measures to manage any risks identified. These groups include: Poly(bios) Group [five substances], Epoxy Resins Group [four substances], Poly(amine) Group [nine substances], Phenol-Formaldehyde Resins Group [eight substances], Poly(alkoxylates/ether) Group [21 substances], and Other Polymers Group
Building Bridges Between Lab-and Field-Derived Data: Methods for the Assessment of Complex Environmental Issues

MP075 An exploratory comparison of toxicity assessment instrument outputs compared to traditional laboratory assays using Daphnia magna

K. Reilly, S. Marshall, I. Lynch, University of Birmingham / Geography Earth Environmental Science

The Daphnia Toximeter (DT) is an instrument designed to be used with wastewater treatment work (WWTW) outflows as a tool to measure water quality, and currently there is very little literature available regarding the use of this instrument within research applications. The purpose of the DT is to trigger an alarm to initiate a response if the water quality is too poor and the daphnia’s behaviour/movement in the test chambers changes significantly from the controlled behaviour. This is designed to be used as a monitoring tool but in this study, we are comparing this output with the standard assays conducted in the lab to determine if there are any points during the 48-hour LC_{50} calculation that could prompt an earlier response, or if there was any notable difference between the DT outputs compared to laboratory observations. The exposures compared included the chemical Sodium Lauryl Sulphate (SLS) and gold nanomaterials (NMs) to assess for both survival and behaviour/movement. SLS has LC_{50} values ranging from 1.2-7.5 mg/l using the OECD 202 acute toxicity assay, while gold NMs (spheres and rods with cationic surfaces) have previously been shown to cause a change in the daphnia behaviour with regards to the carapace moult, suggesting that energy is diverted from moulting as the organism deals with oxidative stress arising from positively charged gold NMs. The study aims to see if the DT can detect this response, observed anecdotally as a jerky movement of the daphnids, to a dispersed NM in addition to a typical dissolved chemical. The hypothesis for this exploratory study is that the DT will be more sensitive to the chemical toxicity of the SLS, but less responsive to the sublethal behaviour changes arising from the gold NM. All tests were conducted using controlled laboratory conditions as far as possible. WWTW often don’t have the capacity to remove NMs and therefore NMs have the potential to be present in the outflow in varying concentrations, so it will be interesting to see the DT detection limits for the sublethal effects of this type of water contamination compared to a more simplistic chemical exposure.

MP076 Toxicity of selenium to a boreal lake food web: Direct and indirect organism responses

S. Graves, K. Liber, University of Saskatchewan / Toxicology Centre; V. Palace, IISD-Experimental Lakes Area; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; L.E. Doig, University of Saskatchewan / Toxicology Centre; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences

Selenium (Se) is a contaminant of concern in Canada mainly due to its teratogenic effects on egg-laying vertebrates in aquatic ecosystems, with effects on invertebrates relatively under-studied. The objective of the present study was to assess the community-level effects of selenium on benthic macroinvertebrates and zooplankton following 63 d of exposure to Se using limnocorrals in Lake 239 at the International Institute for Sustainable Development - Experimental Lakes Area. From June 20 to August 22, 2018, limnocorrals were spiked with mean measured concentrations of 0.4, 0.8, 1.6, 3.1, 5.2 and 7.9 µg Se/L as selenite, with three untreated controls (background dissolved aqueous Se = 0.09 µg Se/L). Quantitative periphyton, phytoplankton, zooplankton and benthic macroinvertebrate samples were collected throughout and at the end of the 63 d exposure period. Zooplankton will be identified to family, counted and weighed. Taxa richness, density, and biomass will be determined for all invertebrates. Multivariate analysis of community-level impacts is in progress, but preliminary results show that density and biomass of Chironomidae decreased with increasing exposure concentrations, but Chironomidae were not affected by Se exposure. Phytoplankton and periphyton growth increased with elevated Se and were inversely correlated with invertebrate biomass. These results suggest that some invertebrates have greater sensitivity to Se than previously thought, and that Se can have both direct and indirect impacts on freshwater food webs.

MP077 A Review of Potential Impacts of Runoff from Refined Coal-Tar-Based Sealant Coating on Aquatic Organisms

S. Kane Driscoll, Exponent, Inc. / EcoSciences; K.J. Kulacki, Exponent / Ecological and Biological Sciences

Pavement sealants are widely used to improve the durability and appearance of asphalt parking lots and driveways. Concerns have been raised, however, regarding the potential for runoff from pavement sealant to cause adverse effects on aquatic organisms in urban and suburban streams. We performed a comprehensive literature review to summarize the potential for runoff from refined coal-tar-based sealants (RCTS) to impact aquatic organisms and evaluated the strengths and weaknesses of the lines of evidence presented in the literature. Several studies demonstrated that RCTS runoff can have detrimental impacts on aquatic organisms under controlled laboratory settings. The usefulness of laboratory data in predicting potential for effects in the field is limited, however, by lack of data on the influence of site conditions on the bioavailability of polycyclic aromatic hydrocarbons and other constituents of RCTS. Our review highlights the need for environmentally relevant study designs that demonstrate cause-effect relationships under field conditions.

MP078 Silver-selenium interaction and its effect on selenium metabolism studied using the Rainbow trout cell line- RTgutGC

D. Chanda, M. Minghetti, Oklahoma State University / Integrative Biology

Due to its anti-microbial properties, silver (Ag) has been used for medical and commercial purposes for several decades. With the increasing demand and use of silver containing products, its long-term adverse effects on human and environmental health is a concern. For instance, silver is known to be highly toxic to aquatic species. Moreover, recent research in mammalian cells has clearly indicated detrimental inhibitory effects on selenoenzymes. Selenoproteins are a group of proteins incorporating selenium (Se) as a structural and catalytic co-factor. Due to their role in removal of reactive oxygen species they are considered vital enzymes. Therefore, any disruption of selenoprotein function can be detrimental to organismal health. Our primary objective is to test the inhibitory effects of Ag exposure in the form of silver salt (AgNO3) and citrate coated silver nanoparticle (cit-AgNP) on selenoprotein function using a fish cell line derived from the Rainbow trout (Oncorhynchus mykiss) intestine (RTgutGC). Therefore, following exposure to non-toxic and toxic (EC50) concentrations of AgNO3 and cit-AgNP, selenoproteins (Glutathione peroxidase, thioredoxin reductase and selenoprotein P) function was evaluated by measuring their mRNA levels and enzyme activity.

In addition, oxidative stress was measured using the CM-H2DCFDA indicator assay. Intracellular accumulation of silver was measured by ICP-MS. From the results obtained, it was found that cells exposed to equimolar amounts of AgNO3 and AgNP accumulated the same amount of metal, however, AgNO3 was more toxic to the cells compared to...
cit-AgNP. Messenger RNA levels for the target selenoenzymes remained unchanged while that of Metallothionein increased indicating uptake of silver by cells but no effect on selenoproteins gene expression. An inhibition in activity of glutathione peroxidase was observed in cells exposed to toxic doses of AgNO3 when compared to un-exposed cells. Reactive oxygen species levels did not change after AgNO3 or cit-AgNP exposure. From the results obtained, we have concluded that AgNO3 is more toxic than AgNP when exposed to equivalent concentration. An inhibitory effect of Ag was observed at the post-translational level while no effects were observed at the transcription level. Moreover, an increase in the levels of Metallothionein was observed indicating the uptake of silver by the cells.

**MP079 Visualizing the transformation, transportation, and distribution of silver nanoparticles in Daphnia magna with a novel fluorescence technique**

N. Yan, W. Wang, The Hong Kong University of Science and Technology / Department of Ocean Science

While most current research focuses on the environmental behaviors such as dissolution and aggregation of silver nanoparticles (AgNPs), the fate of AgNPs and their correspondingionic counterparts in aquatic organisms has been rarely studied. In the present study, we employed a novel aggregation-induced emission (AIE) method by employing two AIEgens, namely, AIEgens coated AgNPs (AIE-AgNPs) and Ag+ sensor (tetrazole-functionalized tetraphenylethylene derivative 1, TET-TPE-1) for simultaneous detection of AgNPs and dissolved Ag+. We quantitatively monitored the time-dependent dissolution processes of AgNPs in Daphnia magna. When the bioaccumulation of AIE-AgNPs in Daphnia reached equilibrium, about 17.2% of AIE-AgNPs penetrated the gut membrane and was internalized, while 81.1% of AIE-AgNPs were excreted by daphnids into the surrounding environments, and 1.7% of AIE-AgNPs was dissolved to Ag+. Besides, the transformation process of AIE-AgNPs reached equilibrium at 48 h, and the concentration of Ag+ released reached 49.8-66.2 μg/g, which was 10.7% of AIE-AgNPs. These dissolved Ag+ ions were found to transport from gills to inner sides of Daphnia, in contrast to AIE-AgNPs, suggesting that Ag+ species was the major source of AgNPs toxicity. The present work lays the foundation for the elucidation of the use of AIE method as a non-invasive technique for simultaneous monitoring of transformation, transportation, and distribution of AgNPs in biological systems, addressing a critical technology gap in the field of nanotoxicology.

**MP080 Understanding Silver Nanoparticle Fate in Treatment Wetlands: Bioaccumulation dynamics by Daphnia magna**

Wetlands engineered for water purification are typically designed to allow for various physical and biological processes to reduce levels of organic contaminants, metals, bacteria, and suspended solids. In addition to the more common use of vegetation and associated microorganisms, recent studies have evaluated the utility of predation to remove these contaminants. Despite the various benefits of treatment wetlands, the reliability and efficiency of these systems can vary widely, and gaps in knowledge limit widespread application. Grazing by filter feeding zooplankton such as Daphnia magna, while less widely researched, can significantly contribute to treatment efficacy in wetlands through reduction of turbidity, removal of contaminants associated with particulate matter, and inactivation of microbial pollutants. Silver nanoparticles (AgNP) are widely used for their antimicrobial properties. Due to diverse application and increased production, the environmental concentrations of AgNPs are likely to increase, which is a concern as Ag is toxic to aquatic organisms. Developing a mechanistic understanding of the fate of AgNPs in treatment wetlands is thus necessary to improve treatment efficacy. Here we used isotopically labeled 109Ag to characterize the accumulation and elimination of AgNPs (20 nm polyvinylpyrrolidone coated) and AgNO3 in D. magna after environmentally relevant waterborne and dietborne exposures. Comparison of our rate constants to those from previous published studies that used different conditions (such as organism age, exposure concentration, duration, and sampling scheme) revealed differences, highlighting the conditional nature of bioaccumulation results. Future work with varying AgNP coating and size along with wetland mesocosm studies will be discussed.

**MP081 Uptake, transport and elimination of silver nanoparticles in oysters (Crassostrea hongkongensis) revealed by 110mAgNPs tracing**

Z. Shao, The Hong Kong University of Science and Technology; W. Wang, Hong Kong University Sci. Technol. / Department of Ocean Science

The prevalence of nanotechnology requires a comprehensive study on its biological impacts especially in marine and estuarine environments. Nevertheless, the background Ag concentration in the organisms may impede the accuracy of Ag determination when the accumulated Ag is extremely low. Here, a radio-synthesizing method was employed to trace the behavior of silver nanoparticles (AgNPs) with two sizes (15 nm and 60 nm) and two coatings (humic acid and citrate) in an estuarine oyster Crassostrea hongkongensis. Through biodynamic modelling, we demonstrated that AgNPs of smaller nominal size were more easily incorporated into the oysters, and humic acid capped AgNPs displayed higher biocompatibility than citrate capped AgNPs. Tissue distribution of Ag was also investigated at different time points of AgNPs exposure and depuration. Direct ingestion of nanoparticles dominated the uptake of 60 nm AgNPs, while dermal uptake and ingestion contributed equally to the uptake of 15 nm AgNPs. The digestive gland was the key detoxification organ of AgNPs with the greatest loss of Ag by the end of depuration. This highly sensitive radiotracing method serves as an effective tool to accurately quantify the bioaccumulation of AgNPs in aquatic organisms.

**MP082 Acute and chronic toxicity of citrate-coated silver nanoparticles to Hyalella azteca**

J. Kusi, K.J. Maier, Eastern Tennessee State University / Department of Environmental Health

The antimicrobial properties of silver nanoparticles (AgNPs) have increased their use in several consumer products. AgNPs are one of many emerging environmental contaminants, where the effects on biological systems are not fully understood, thus raising concerns about their release into the environment. Benthic invertebrates are likely to be affected by AgNPs exposure because they are highly sensitive to ionic silver. Hyalella azteca was used as a model species to evaluate the toxicity of AgNPs to benthic invertebrates due to their rapid response to contaminants. Test organisms (7-8 days old) were exposed to different concentrations of 10 nm citrate-coated AgNP with five replicate beakers for 10 and 28 days in a static-water-renewal system. Ten H. azteca were added to each replicate beaker containing 100 mL sand as a substrate. Aliquots of test solutions were centrifuged, digested, and analyzed using furnace atomic absorption spectrometer to measure dissolved Ag, which was used for all statistical analyses. One-way ANOVA and Dunnett’s test were used to determine effects of the citrate-coated AgNP on survival and growth of H. azteca. Median lethal concentration (LC50) for survival and median effective concentration (EC50) for growth were calculated using probit analysis and Toxicity Relationship Analysis Trap respectively. Citrate-coated AgNP significantly reduced growth (dry weight) from 0.15 to 0.07 mg at 10.8 μg/L (p < 0.05) for the 10-day acute exposure. For the 28-day chronic exposure, citrate-coated AgNP significantly reduced growth from 0.63 to 0.40 mg at 7.2 μg/L (p = 0.01). The LC50 (95% confidence interval) for survival in the acute exposure was 7.8 (7.2-8.4) µg/L and the EC50 (95% confidence interval) for growth was 3.4 (1.2-9.4) µg/L. The LC50 for survival in the chronic exposure was 4.1 (1.4-5.5) µg/L and the EC50 for growth was 1.0 (0.1-8.3) µg/L. Growth was more sensitive to citrate-coated AgNP compared to survival in both acute and chronic exposures. We conclude that citrate-coated AgNP poses a potential risk to survival and growth of freshwater H. azteca populations, thus there may be the need to monitor the release of AgNPs into aquatic systems.
MP083 The DeTER project: Detection, Toxicology, Environmental fate and Risk assessment of nanoparticles in the aquatic environment
E.J. McGillicuddy, Technological University Dublin / School of Chemical & Pharmaceutical Sciences; L. Morrison, National University of Ireland, Galway / Earth and Ocean Sciences; I. Murray, Athlone Institute of Technology / Bioscience Research Institute; D. Shevlin, University College Dublin / School of Biosystems and Food Engineering; M. Cormican, National University of Ireland, Galway / Discipline of Bacteriology; A. Fogarty, Athlone Institute of Technology / Department of Life & Physical Sciences and Bioscience Research Institute; E. Cummins, University College Dublin / Biosystems Engineering; P. Dockery, National University of Ireland, Galway / Discipline of Anatomy, School of Medicine; P. Dunlop, Ulster University / Nanotechnology and Integrated Bioengineering Centre; N. Rowan, Athlone Institute of Technology / Department of Life & Physical Sciences and Bioscience Research Institute; D. Morris, National University of Ireland, Galway / Antimicrobial Resistance and Microbial Ecology Group, School of Medicine

The DeTER project had three major aims to develop methods for the capture and detection of silver nanoparticles (AgNPs) in water, the determination of the toxicological effects of AgNPs in the aquatic environment and the development of risk assessment protocols which could be used to evaluate the environmental fate and likely risk from AgNPs through aquatic pathways. Milled activated charcoal was developed as a successful capture material for AgNPs from water samples. In order to quantify the captured silver a hydrochloric acid leaching procedure was developed which successfully removed the captured silver allowing the fraction captured by the charcoal to be quantified with an average of 94.8% recovery. To investigate the potential ecotoxicological impact of AgNPs on the aquatic environment a multi-trophic test battery which included three trophic levels was adopted to assess the ecotoxicity of AgNPs and AgNO3 to Pseudokirchneriella subcapitata, Daphnia sp. and Hydra attenuata. The standard media (Jaworski’s medium(JM)) and an EDTA-free media (Chu#10) were tested concurrently. An approximately 10-fold improvement in test sensitivity using EDTA-free media was observed overall. No significant difference between toxicities of AgNP and AgNO3 was observed. It was found that Daphnia pulex with its 24 hour IC₅₀ of 9.3 µg/L was less sensitive to AgNO₃ when compared to an IC₅₀ of 1.22 µg/L for Daphnia magna. When tested with AgNP, both species yielded similar results with an IC₅₀ for Daphnia magna of 7.85 µg/L and Daphnia pulex of 4.2 µg/L. As these IC₅₀ values were substantially higher than the PECs, sub-lethal endpoints were also investigated. Fecundity was assessed in Daphnia magna and showed that the number of offspring reduced by 50% after 14 days and 75% after 28 days when cultured in 100 ng/L AgNP. The risk assessment found that current environmental concentrations of AgNPs used in the model were at levels deemed unlikely to have toxicity concerns to aquatic organisms (mean levels in water of 4.34 µg/L). Therefore, at current predicted water concentrations, AgNPs are unlikely to present a toxic concern to the aquatic food chain. The potential human exposure through drinking water was also investigated. Risk to human health was calculated based on water consumption and potential exposure to residual AgNPs using the Hazard quotient (HQ). The predicted HQ indicated that there was no existing risk through consumption of drinking water.

MP084 Surface charge impact on nanoparticle biotransformation mechanisms in the environment
M. George, C.M. Sayes, Baylor University / Environmental Science

Nanoparticles are increasing in use in consumer products due to their high surface area, tailored surface functionalization, and ability to be excreted. Small particles of like surface charge are shown to display repulsive tendencies; but in the environment, these same particles form a double layer enabling particle stability. The electrostatic and magnetic forces are beneficial in the exploitation of homogenate and stable consumer products; however, when placed in biofluids or the environment, these forces are disturbed. When nanoparticles travel through the environment, they encounter many different aqueous environments which alters colloidal stability. We hypothesize that nanoparticles will become increasingly unstable as the matrix for which they are exposed becomes increasing complex. Specifically, the stability of the nanoparticles will be directly related to (1) the alteration in pH from pH 7.0, (2) the concentration of biomolecules, and (3) the ionic strength of the surrounding matrix. To test this hypothesis, we compared three different surface-functionalized silver nanoparticles coated with positive, negative, and neutral surface charge and characterized through electron microscopy and spectroscopic techniques. Each particle system was incubated in different environmental relevant matrices: strong ionic content, neutral biofluids, and basic surfactant fluid. The results indicate a mechanistic transformation where the surface charge significantly impacts nanoparticle transformation. The next step in this project is to simulate nanoparticle environmental fate to a combination of matrices sequentially. The information obtained from these studies will provide crucial insight into colloidal stability of consumer products, provide read-across comparisons between metal-based particles and the environment, and aid in filling the literature gap in colloidal stability effect on nanoparticle transformation, in situ.

MP085 Nano-CopperOxide Influences Rice (Oryza sativa japonica) Growth and Arsenic Uptake
J. Liu, M. Simms, Baylor University / Department of Environmental Science; K. Wolfe, Baylor University; B. Dhungana, Baylor University / Chemistry and Biochemistry; G.P. Cobb, Baylor University / Department of Environmental Science

Copper oxide nanoparticles (nCuO) may be used as a fungicide in agricultural systems, and has been shown to sequester arsenic (As) in remedial activities. These important features of nCuO led us to evaluate the ability of nCuO to mitigate phytotoxicity and accumulation of naturally occurring arsenic (As) in rice plants. A factorial study was conducted to evaluate the main effects of nCuO (0, 0.1, 1.0, 10, 50, and 100 mg/L) and As (0 and 10 mg/kg) and their interaction effects on the whole F0 life cycle and F1 germination of rice plants (Oryza sativa japonica). The Initial exposures were 131 d in length and were conducted in a greenhouse. After rice grain collection, Thereafter, germination of F1 seeds was tested for 18 d in an incubator. No significant effect was observed on the seed germination, in F0 or F1 generations. Both nCuO and As had a significant main effect on F0 fresh weights of rice straw (FW), the number of rice panicles (NRP), and various root growth parameters. A decrease in FW was observed in As alone treatment, while nCuO addition produced hormetic type effects. Importantly, increased concentrations on nCuO decreased As transport into rice grains. Intergenerational effects on root and shoot growth were observed for F1 seedlings that were repeatedly exposed to As and to high concentration nCuO in the same manner as were the F0 plants from which they were produced. In the higher nCuO treatments, arsenic concentrations were lowered below the WHO threshold for safe rice consumption. This has important implications for food safety in countries where rice is the primary staple grain.

MP086 Influence of organic ligands and environmental factors on metal sulfide nanoparticle precipitation
E. McKenzie, A. Donaghue, Temple University / Dept. of Civil and Environmental Engineering

In sediment porewaters, metal sulfides play an important role in the removal of many metals; however, understanding of the influence of environmental factors on multiple metal sulfide species released into aquatic waters is still needed. This study evaluates the competitive precipitation of metal sulfides as they are affected by organic ligands (cysteine, gallic acid, and Pahokee Peat humic acid), inorganics ligands (Cl⁻ and Cu²⁺), and oxidants. Centrifugation and ultrafiltration, coupled with inductively coupled plasma mass spectrometry (ICP-MS), was employed to characterize ZnS, PbS, CdS, and CuS particle size distributions (PSDs; i.e. 30, 60, and 100 nm) and differentiate between nanoparticle (NP) and dissolved concentrations (a component not typically examined when using TEM and light scattering techniques). The presence of the organic
ligand cysteine slows particle growth rates and limits bulk precipitation. Additionally, the presence of cysteine in 10-fold excess of initial metal/sulfide concentrations resulted in narrower PSDs (~3nm to 30 nm) for metals considered. However, for three-hour time scales, Pb and Zn sulfide particles demonstrate mixed trends with initial precipitation followed by subsequent dissolution even in the presence of excess organic ligands, which could be contributed to ligand promoted dissolution and/or chemical oxidation. This study illustrates that for multiple metal sulfide species in more complex aqueous matrices, several processes, including precipitation, dissolution, and chemical oxidation, can remain significant mechanisms in the lifetime of certain NPs even in the presence of excess capping agents.

### MP088 Revealing the Transformation and Fate of Black Phosphorus in Biological Environments

L. Zeng, G. Qu, G. Jiang, Research Center for Eco-Environmental Sciences / Chinese Academy of Sciences / State Key Laboratory of Environmental Chemistry and Ecotoxicology

Black phosphorus (BP) is a renewed 2D nanomaterial with excellent physicochemical properties, such as high electron mobility, tunable band structure and large anisotropy, which makes it advantageous in many fields. The widely potential applications of BP are likely to raise the exposure risks and health problems. Besides, BP is vulnerable to be oxidized in ambient environments due to the pair of lone electrons of each P atom. Thus, revealing the transformation, transport and fate of BP in biological environment is necessary to nano safety assessments and controllable designs of the environmentally unstable 2D materials. Here, we compared the time-dependent behaviors of BP with different sizes in biological environments from deionized water, salt solution with different pH/ion strengths to bovine serum albumin (BSA) solution systems. The morphology and defect of BP were revealed by atomic force microscopy (AFM), transmission electron microscopy (TEM), X-ray diffraction (XRD) and Raman spectroscopy, while the degradation products were identified by ion chromatography (IC) and nuclear magnetic resonance (NMR). Our results showed that degradation of BP in acid solution was faster than that in neutral and alkaline solutions. The existence of salt and BSA in solution had significant influence in degradation kinetics of BP. These results may have important toxicological relevance, and require further in vivo research in the future.

### MP089 Comparison of the effects of two different sized groups of metal oxide cobalt nanoparticles based on various biological activities

I. Kong, M. Kim, W. Wi, Yeungnam University / Environmental Engineering

The differences in the toxicity of cobalt metal oxide nanoparticles (Co-NPs) of two different sizes were evaluated in the context of bacterial bioluminescence activity, algal growth, plant activity (seed germination, root/shoot growth), xylene gene activity, enzymatic and biosynthetic activity of β-galactosidase, and bacterial gene mutation. Each size of Co-NP exhibited a different level of toxicity (sensitivity) in each bioassay. However, in all cases, the small Co-NPs showed statistically considerable higher toxicity than the large ones. However, in the case of gene mutation experiments, no revertant mutagenic ratio (greater than 2.0) of Salmonella typhimurium TA 98 was observed under the test conditions. Overall, the order of inhibitory effects has been roughly observed as follows: bacterial bioluminescence by xylene gene activity > bacterial bioluminescence by the growth activity > activity and biosynthesis of enzymes, bacterial gene mutation > algal growth, plant activity (seed germination, root/shoot growth). These findings demonstrate that particle size could be an important physical factor for evaluating the toxicity of NPs in environment. Moreover, combinations of results based on various biological activities, rather than just a single activity, would be better for the accurate assessment of NP toxicity in ecosystems.

### MP090 Aqueous instability of a complex metal oxide nanomaterial and adverse outcome pathway for its interaction with benthic organism Chironomus riparius

N. Niemuth, B.J. Curtis, University of Wisconsin, Milwaukee / School of Freshwater Sciences; M.N. Hang, University of Wisconsin, Madison / Department of Chemistry; M.J. Gallagher, H. Fairbrother, Johns Hopkins University / Department of Chemistry; R.J. Hamers, University of Wisconsin, Madison / Department of Chemistry; R. Klapers, University of Wisconsin, Milwaukee / School of Freshwater Sciences

A challenge for the field of nanotechnology is our understanding of how the chemical properties of engineered nanomaterials (ENMs) determine their fate in the environment and their subsequent interactions with organisms. Many ENMs are not stable in the aqueous environment and will aggregate and concentrate in the sediment, bringing them into direct contact with sediment-dwelling organisms at high concentrations. The goal of this study was to understand the aqueous stability of complex metal oxide ENM lithium cobalt oxide (LCO) and the molecular mechanism of its interactions with a model sediment-dwelling organism: Chironomus riparius. We show that transformations in aqueous media cause LCO to settle rapidly and concentrate at the bottom. Exposure to LCO causes significant, nano-specific effects on chironomid development, reducing larval size at 7 days and significantly delaying emergence of adult flies. Effects of LCO on other endpoints may point to the molecular mechanism underlying observed developmental impacts. Hemoglobin levels in larvae are significantly reduced by material exposure, and levels of genes involved in heme synthesis are also reduced, suggesting that LCO may negatively impact heme synthesis. Cobalt contained in LCO has previously been shown to disrupt the formation of Fe-S centers, which are cofactors in key regulatory and catalytic proteins, including the iron-responsive protein, which regulates the genes involved in heme metabolism. Transcriptomics experiments show disruption of expression of key Fe-S protein genes including those involved in Fe-S cluster formation as a result of LCO exposure, pointing to Fe-S cluster disruption as an important molecular mechanism of LCO impact. We propose an Adverse Outcome Pathway whereby LCO, by disrupting Fe-S centers of important enzymatic and regulatory proteins, may disrupt synthesis of heme, reduce synthesis of heme proteins, and affect synthesis of other key metabolites, which would result in disrupted animal metabolism and cause impacts on development like those we observe.
Across the treated groups, daphnid metabolomes were impacted on a dose-dependent manner. Compared to control, metabolomes of daphnids exposed to ions, 0.1 and 1.0 mg/l LCO nanoparticles exhibited 0, 2, and 182 metabolites, respectively, that were significantly different (p<0.05). The disproportionate impact on pathways seen between the ions and 1.0 mg/l LCO nanoparticles suggests a nano-specific impact. Analysis through partial least squares discriminant analysis revealed that metabolic profiles of daphnids exposed to 1.0 mg/l LCO were significantly different from both control and ion exposed profiles (p<0.05). Clustering of profiles from 0.1 mg/l LCO nanoparticle treated daphnids, while not statistically different from control, potentially indicate that differences observed in the 1.0 m/l profiles may be beginning to manifest.

**MP092 Mechanisms, Assessment, and Prediction of Toxicity of Multiple Engineered Nanoparticles to Aquatic Organisms**

F. Zhang, Z. Wang, Nanjing University of Information Science and Technology

Ecotoxicological studies to characterize engineered nanoparticles (ENPs) hazards have just been unfolding in recent years. The validation and prediction of ecotoxicity of multicomponent ENPs mixtures are a significant part of the solution to the challenge of carrying out ecological risk assessments on multiple concomitant ENPs. On the basis of in-depth analysis of ecosystem levels and joint toxicity mechanism, developing a predictive toxicology model for ENPs mixtures is a crucial problem in science, which begs for solutions. This work will be based on the combination of in silico and experimental studies and will select metal oxide nanoparticles (MeO-NPs) as model compounds. This research seeks to: a) investigate the acute and chronic toxicity of single, binary, and multiple MeO-NPs mixtures to aquatic organisms of different trophic levels; b) estimate toxicity endpoint of aquatic organism population based on simple population model and concentration-response data; c) develop and validate quantitative prediction models for the toxicity of aquatic organism population to binary and multiple MeO-NPs based on joint toxicity mechanism, respectively. This research can not only provide theoretical and methodological foundations for the hazard identification and the risk assessment of ENPs, but also offer an important scientific basis for their healthy development and security application.

**MP093 Advancing tools for hazard assessment of ingested nanomaterials: an Adverse Outcome Pathway approach**

K. Xu, McGill University / Food Science and Agricultural Chemistry; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; S. George, McGill University / Food Science and Agricultural Chemistry

Oral ingestion is one of the major routes of exposure for nanomaterials used in food products, and yet there are knowledge gaps on their potential to elicit health risks and mechanisms of toxicity. The overall objective of this study is to develop an adverse outcome pathway to predict the potential toxicity of dietary nanomaterials to gastrointestinal system. In this study, Caco-2 cell line exposed to incremental concentrations of food grade SiO2, TiO2 and silver particles was used to evaluate the molecular initiating events and key events that signify the early stages of adverse outcomes such as epithelial layer permeability changes, cell junction disruption, inflammatory responses and oxidative stress level. SiO2 and TiO2 particles didn't cause cytotoxic effects after 24 hours of exposure. However, nano-sized particles of SiO2 and TiO2 induced noticeable level of pro-inflammatory markers (IL-6, TNF-a) and intracellular H2O2 generation. Laser Scanning Confocal Microscopy analysis after immunofluorescence staining showed disruption in apical tight junction complex but not the basal adherens junction complex, thus maintaining the integrity of the intestinal epithelial layer. In contrast, silver nanoparticles induce significant cellular inflammatory responses and oxidative stress with the disruption of both tight junction and adherens junction, and subsequently cause leakiness and increased permeability of the epithelial layer. Results suggest nanomaterials could induce early signatures of adverse effects that may play a vital role towards the progression of diseases of relevance to gastrointestinal tract. The developed pathway could be used to perform hazard screening on other nanomaterials or novel chemicals for predictive hazard assessment and further risk assessment.

**MP094 Immunomodulatory Effects of Amine-capped Carbon dots on Murine Macrophages and Human Whole Blood Cell Cultures**

L. Leach, University of Western Cape / Medical Bioscience; K.L. Lategan, University of Western Cape; M. Bayati, M. Fidalgo, University of Missouri, Columbia / Civil and Environmental Engineering; E.J. Poo, University of The Western Cape / Medical Bioscience

Carbon dots (CDs) are nanoparticles used in various bio-applications such as drug delivery and bioimaging. Amine functionalization of carbon dots improve its use as nanosensors and also enhance the nanoparticles’ electrochemiluminescence. Few studies have evaluated the in vitro effects of these functionalized nanoparticles on the immune system. This study examined the in vitro effects of amine-capped carbon dots (a-CDs) on the immune system using the murine RAW264.7 macrophage cell line and human whole blood cell cultures. Effects of a-CDs on RAW cells were assessed under basal conditions and in the presence of the mitogen lipopolysaccharide (LPS). The whole blood cell cultures were exposed to a-CDs in the absence or presence of LPS and phytohaemagglutinin (PHA). Cell parameters such as cytotoxicity, inflammatory biomarkers, cytokines of the acquired immune system and a proteome profile analysis were monitored after a-CD exposure. The a-CDs were cytotoxic to RAW at concentrations ≥ 6.25 µg/mL and to whole blood cells at 500 µg/mL. Treatment of RAW cells with a-CDs under basal conditions did not affect nitric oxide (NO) and interleukin 6 (IL-6) synthesis, while a-CDs at concentrations ≥ 6.25 µg/mL decreased NO production by LPS stimulated RAW cells. Treatment of LPS stimulated RAW with a-CDs did not affect IL-6 synthesis. The a-CD did not affect cytokine production by whole blood cell cultures under basal conditions. Exposure of LPS stimulated whole blood cell cultures to a-CDs decreased IL-6 and macrophage inhibitory protein 1β (MIP-1β) significantly at concentrations ≥ 5 µg/mL and ≥ 50 µg/mL respectively. Exposure of PHA stimulated whole blood cell cultures to a-CDs decreased interleukin 10 (IL-10) and interferon gamma (IFNγ) significantly at concentrations ≥ 5 µg/mL and ≥ 50 µg/mL respectively. Proteome profile analysis of RAW cells under basal conditions at 25 µg/mL a-CDs indicated an upregulation of cytokines and chemokines associated with inflammation but no changes in the cytokine and chemokine production when in the presence of LPS when compared to their respective controls. Whole blood cell cultures exposed to 5 µg/mL a-CDs in the presence of LPS exhibit reduced inflammatory cytokines and chemokines compared to the LPS only control. This study clearly shows that a-CDs modulate various immune cell parameters in vivo and these should be investigated in more detail to evaluate potential adverse effects of these nanoparticles upon exposure in vivo.

**MP095 Low doses of multi-walled carbon nanotubes elicit hepatotoxicity in rats with markers of oxidative stress and induction of pro-inflammatory cytokines**

I.A. Adefara, University of Ibadan / Drug Metabolism and Toxicology Research Laboratories / Department of Biochemistry; O.A. Edene, Ibadan University / Drug Metabolism and Toxicology Research Laboratories / Department of Biochemistry; K. Patlolla, P.B. Tchounwou, Jackson State University / College of Science Engineering and Technology / NIH-RCMI Center for Environmental Health; E. Farombi, University of Ibadan, Nigeria / Veterinary Physiology and Biochemistry; K. Patlolla, P.B. Tchounwou, Jackson State University / College of Science Engineering and Technology / NIH-RCMI Center for Environmental Health; E. Farombi, University of Ibadan, Nigeria / Drug Metabolism and Toxicology Research Laboratories / Department of Biochemistry

The investigation into the potential health risks associated with the use of engineered nanomaterials is a major scientific interest in recent years. The present study elucidated the involvement of pro-inflammatory cytokines,
cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS) in carboxylated multi-walled carbon nanotubes (MWCNTs)-induced hepatotoxicity. Pubertal rats were exposed to purified MWCNTs at 0, 0.25, 0.5, 0.75 and 1.0 mg/kg for 5 consecutive days. Results indicated that exposure to MWCNTs caused liver damage evidenced by significant elevation in serum activities of aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP) and gamma glutamyl transferase (GGT) when compared with control. Moreover, MWCNTs significantly decreased superoxide dismutase (SOD) and glutathione S-transferase (GST) activities as well as glutathione level whereas it significantly increased catalase (CAT) and glutathione peroxidase (GPx) activities in liver of the treated rats. Moreover, the dose-dependent increase in hepatic hydrogen peroxide (H2O2) and lipid peroxidation levels were accompanied by marked increase in micromole per gram (μmol/g) liver (MMP) content of catalase activity and MDA levels. 

Administration of MWCNTs significantly increased serum concentrations of pro-inflammatory cytokines namely interleukin-1b (IL-1b), interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF-a) in the treated rats. Immunohistochemical analysis showed significantly increased COX-2 and iNOS protein expressions in the liver of MWCNTs-treated rats. In conclusion, carboxylated MWCNTs induces hepatic damage via disruption of antioxidant defense systems, such as gene expression and enzyme activity related to oxidative stress, consequently resulting in liver damage in rats.

The recent advances in engineered nanoparticles (ENPs) has propelled the production of thin-film liquid crystal displays (LCD) used in smart screens due to their small size, broad absorption and narrow emission spectra. If not properly recycled, under weathering conditions, ENPs have the potential to be released in the environment and interact with aquatic organisms and potentially cause toxic effects. The objective of this study is to use an aquatic test model (fish embryo test, FET, OECD TG 236) to assess the toxicity of cadmium-based ENPs (CdSe/ZnS/PEIEPoxy) used in LCD screen and released to liquid media through different treatments (not weathered, sonicated and sunlight simulator). Relevant outcomes will be measured in the embryos (cadmium uptake, viability, deformities, enzyme activity, and gene expression). This study has the potential to increase our understanding of the toxicity risks of cadmium-based ENPs in aquatic organisms under environmentally relevant exposure conditions.

**MP097** Impact of wastewater borne TiO2-ENP on plant uptake of heavy metals
A. Mawaf, S. Prasher, McGill University / Bioresource Engineering; S. Bayen, McGill University / Food Science and Agricultural Chemistry; E. ElSayed, University of Guelph / School of Engineering; C. Nzediegwu, McGill University / Bioresource Engineering; S. George, McGill University / Food Science and Agricultural Chemistry

The presence of contaminants including, heavy metals, hormones, and PPCPs in Wastewater (WW), are harmful to the environment and human health. Engineered nanoparticles (ENPs) have also been detected recently in WW and could have interactions with contaminants in soil-water systems affecting contaminants translocation. Titanium dioxide (TiO2) could reduce their mobility and uptake of heavy metals by plants. Therefore, this research aimed to study the interaction between TiO2-ENPs, a type of nanoparticles commonly-used in industries and reported in effluents and heavy metals in wastewater. A field lysimeter study was conducted for two years (2017 and 2018) to investigate the impact of TiO2 on the mobility of heavy metals and emerging organic contaminants on potato plants in field lysimeters. Potatoes were grown in sandy soil under controlled conditions and irrigated with WW with/out NPs. The synthetic WW contained organic contaminants and heavy metals (Cd, Zn, Cu, Fe, Pb, and Cr). Potatoes were harvested and heavy metals in edible parts of the potato plant (flesh and peels) and root were determined using ICP-MS. In 2017, the concentration of Cd in potato flesh were WW- 1.5 μg/g, WW+NP- 0.45 μg/g, and in 2018 were WW- 5.3 μg/g, WW+NP- 3.04 μg/g. In 2017, the concentration of Cd in potato peel were WW- 7.84 μg/g, WW+NP- 1.5 μg/g, and in 2018 were WW- 59.3 μg/g, WW+NP- 21.29 μg/g. Similar trend was observed for the root; in 2017 the concentrations were WW- 121.1 μg/g, WW+NP- 64.7 μg/g, and in 2018 were WW- 204.31 μg/g, WW+NP- 106.99 μg/g. The results in two years were similar, and indicated that presence of TiO2 NPs at the levels of 100 mg/L significantly reduced (P<0.05) plant uptake of Cd, Cu, and Zn, but there was no significant effect of on Cr, Pb and, Fe.

**MP098** Characterizing the effects of engineered nanoparticles released from painted surfaces due to weathering, in zebrafish (Danio rerio)
K. Mittal, McGill University / Natural Resource Sciences; A. Rahim, McGill University / Civil Engineering; S. George, McGill University / Food Science and Agricultural Chemistry; S. Ghoshal, McGill University / Department of Civil Engineering; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences

Engineered nanoparticles (ENPs) are used in the manufacture of industrial and consumer products to enable or enhance specific functions. Titanium dioxide (nTiO2) and silver (nAg) are among the most common nanoparticles (nps) used in paint for their whitening and anti-microbial properties. Such nps from outdoor painted surfaces may be released to aquatic systems due to weathering processes, though little is known about the fate, exposure, and toxicity of the released particles. Recently, there has been great interest in ecotoxicology in the development of alternative testing systems to examine the toxicity of such emerging environmental contaminants. The objective of this study is to use two alternative aquatic testing systems to examine the toxicity of emerging environmental contaminants. The objective of this study is to use two alternative aquatic testing systems to examine the toxicity of emerging environmental contaminants. The objective of this study is to use two alternative aquatic testing systems to examine the toxicity of emerging environmental contaminants. **MP099** Interaction of dietary nanoparticles with human salivary proteins: Profiling protein corona and alteration in structure and function of vital enzymes
S. George, McGill University / Food Science and Agricultural Chemistry; D. Srinivasan, McGill University Faculty of Agricultural and Environmental Sciences / Food Science and Agricultural Chemistry

Nanotechnology offers unprecedented benefits in improving the organoleptic characteristics and safety of food. Consequently nanoparticles (NPs) are copied incorporated into different food products and food contact materials. While entry of NPs through oral route is inevitable, their interaction with salivary proteins and its potential influence on
structure and function of salivary enzymes are largely unknown. We studied the profile of salivary proteins found on the surface of saliva. Specific proteins such as food-grade silicon dioxide (SiO2), titanium dioxide (TiO2) and silver (Ag). Analysis of the protein corona composition was carried out by employing 1D gel electrophoresis and LC-MS/MS. Several proteins with vital functions in digestion and host protection were found to be enriched on the surface of particles. For instance, Lysozyme, Lactoferrin, Apolipoprotein B100 & E, and Annexin A2 were the most enriched proteins on NPs of SiO2. In order to verify if the binding of proteins have any effect on their function, we tested the amylase and lysozyme activities of saliva in the presence and absence of NPs of SiO2 and TiO2. The substrate affinity for α-amylase was found to be significantly reduced when they were interacted with NPs of SiO2. The SiO2 NP-α-amylase and SiO2 MP-α-amylase complex exhibited non-competitive and competitive type of inhibition, respectively. Far-UV Circular Dichroism studies and FTIR Spectroscopy revealed conformational changes in the 2D structure of proteins. Overall, our study, identified salivary proteins involved in the protein corona of dietary particles and showed that vital functions of saliva such as digestion and antimicrobial properties could be partially affected by protein-NP interactions in saliva.

MP100 UV-induced toxicity of nano-enabled azoxystrobin on zebrafish embryos and larvae

Y. Zhang, University of Alberta / Biological Sciences; C. Sheedy, D. Nilsson, Agriculture and Agri-Food Canada (AAFC) / Trace Residue Analysis and Immunochromy; G. Goss, University of Alberta / Biological Sciences

The use of nanotechnology to enhance pesticide formulations holds the promise of reducing pesticide use, decreasing mobility in soils and overall improvements in agricultural practices while simultaneously maintaining yields. However, the toxicity of nano-enabled pesticides, including azoxystrobin, has not been well studied compared to their conventional formulation counterparts. This study investigates both lethal and sub-lethal endpoints in zebrafish embryos/larvae up to 120 hours post fertilization (hpf) under laboratory light or simulated UV light. The median lethal concentration (LC50) value of nano-enabled azoxystrobin was significantly lower than the conventional form counterparts and UV light significantly decreased LC50 values of both types of azoxystrobin. Malformations including pericardial edema, yolk sac edema, and spinal curvature were not observed during the exposure but the remaining yolk sac volume was significantly higher in both types of azoxystrobin at 120 hpf at both light conditions. This is partially in agreement with the metabolic result, which demonstrated co-exposure of nano-enabled azoxystrobin and UV light significantly decreased oxygen consumption rate. The co-exposure of conventional azoxystrobin at 100 μg L-1 and UV light significantly upregulated sodl, sod2 and gpx1b expression and both types of azoxystrobin significantly reduced gpx1a expression. Catalase enzyme activity was only increased by nano-enabled azoxystrobin at 100 μg L-1 while superoxide dismutase activity was significantly reduced by co-exposure of UV light and either type of azoxystrobin at a nominal concentration of 100 μg L-1. Lipid peroxidation was significantly increased in nano-enabled and conventional azoxystrobin at 100 μg L-1 under laboratory light and UV light induced a higher level of lipid peroxidation due to the generation of hydroxyl radical by UV light. This study will provide much-needed data of acute and medium-term hazards of nano-enabled and conventional azoxystrobin used in agriculture, demonstrate the importance of environmental factor (e.g. UV light) affecting the results of ecotoxicity study and help improving current regulatory guidelines on nano-enabled pesticides in more ecologically relevant conditions.

Contaminant Issues in Waste Streams

MP102 Chlorinated paraffins and organophosphorus flame retardants in automobile shredder residues from an end-of-life vehicle recycling facility in Japan

H. Matsukami, National Institute for Environmental Studies / Center for Material Cycles and Waste Management Research; N. Kaijiwara, H. Kuramochi, National Institute for Environmental Studies, Japan / Center for Material Cycles and Waste Management Research

Short-chain chlorinated paraffins (SCCPs) and certain brominated flame retardants (BFRs) were listed as Persistent Organic Pollutants (POPs) for elimination in the Stockholm Convention. Within Japan, domestic regulations on the production and import of the SCCPs and POP-BFRs entered into force in response to the convention and consequently the application of alternative medium-chain chlorinated paraffins (MCCPs) and organophosphorus flame retardants (OPFRs) in polymeric materials has increased. However, emerging concerns are being raised about overall persistence and long-range transport potential of certain MCCPs and OPFRs. In Japan, approximately three million of end-of-life vehicles (ELVs) have been collected and recycled properly every year since 2005 under the Law for the Recycling of End-Of-Life Vehicles. Automobile shredder residues (ASRs), which mainly consist of plastics, polyvinyl chlorides (PVCs), rubbers, polyurethane foams (PUF), fabrics and fibers, textiles, glasses, and metals remained after removing valuable rubber and metal fractions.
and reusable materials from ELVs, are required to be recycled instead of landfill due to shortage of final disposal sites. Information on levels and behaviors of CPs and FRs in ASRs is crucial to avoid indoor exposure and for planning appropriate measures for their emission control during ASR recycling. There is a report on levels and destruction behaviors of several BFRs in ASRs during their thermal treatment, nevertheless no definitive information exists for those of CPs and OPFRs in ASRs. We investigated the levels and behaviors of CPs and OPFRs in six ASR fractions after several sorting processes, such as air classification, magnetic separation, and float/sink separation in an ELV recycling facility in Japan. SCCPs were detected in the ASR samples with concentration ranges from 1.7 to 7.7 mg/kg. The levels of SCCPs in the ASR samples were lower than the Basel Convention provisional low POP content value of 100 or 10,000 mg/kg. MCCPs and OPFRs were also detected in the ASR samples with concentration ranges from 54 to 260 mg/kg and 14 to 870 mg/kg, respectively. The levels of MCCPs in the ASR samples were at least one order of magnitude higher than those of SCCPs. The highest concentrations of SCCPs and MCCPs were found in the heavy fraction containing mainly PVCs and rubbers, whereas those of OPFRs were found in the light fraction containing mainly PUFs.

MP103 Distribution of Bisphenol A (BPA) and 5 BPA Analogues in the Solid and Liquid Waste Streams of a Secondary Wastewater Treatment System
M. Woudryh, B. Chandramoul, SGS AXYS Analytical Services, Ltd.; C. Hamilton, SGS AXYS / Client Services; R. Grace, SGS AXYS Analytical Services Ltd.

The decision by various regulators to phase out certain uses of bisphenol A (BPA) has led to its gradual replacement with an increasing number of bisphenols. A number of these bisphenols are being detected in different components of the environment. Given that these bisphenols are often analogues of bisphenol A with small structural modifications, they also show estrogenic activity and some are more potent estrogens than BPA. In this study, a method for quantitative determination of BPA and five BPA analogues (BBP, BPE, BPF, BPS, and BPAF) was developed and applied for influent/effluent and biosolid samples from a secondary wastewater treatment plants (WWTP) in Canada. BPA and all five BPA analogues were detected in at least one of the three matrices studied. BPA and Bisphenol S (BPS) were detected in all the samples analyzed. BPE was mainly detected in effluent samples, whereas Bisphenol AF (BPAF) was predominantly detected in biosolid samples. Bisphenol F was detected in influent and effluent matrices but was not detected in biosolid samples. The highest concentration of bisphenol in the aqueous waste stream was detected for BPS (852 ng/L), followed by BPA (560 ng/L), BPE (365 ng/L), BPF (100 ng/L), and BBP (4.3 ng/L). In the solid waste stream, the highest concentration was detected for BPA (3,977 ng/g, BPS (852 ng/L), followed by BPA (560 ng/L), BPE (365 ng/L), BPF (100 ng/L), and BBP (4.3 ng/L). In the solid waste stream, the effect of sample storage on data quality will also be discussed in relation to the biodegradation of these analytes in WWTP samples.

MP104 Abatement of Amoxicillin, Ampicillin, and Chloramphenicol from Aqueous Solutions Using Activated Carbon Prepared from Grape Slurry
R. Chitongo, Cape Peninsula University of Technology Cape Town South Africa / Chemistry; B. Onuoha, Cape Peninsula University of Technology / Faculty of Applied Sciences; O.S. Olatunji, University of KwaZulu-Natal, Westville, Durban, South Africa / School of Chemistry and Physics

Pharmaceuticals are widely used in human and veterinary health. Residues of pharmaceutical compounds have been reported to be present in biological samples and environmental matrices globally. The occurrence of pharmaceuticals has been linked to many global health and ecological issues. As much as 60-80% of the orally administered doses may remain un-metabolized, and are excreted through sweat, urine and faeces. They therefore reach water and other environmental compartments through releases from various sources including domestic, agricultural and industrial discharges. Water is essential to sustain life, but its deterioration in quality and quantity is increasing pressure on water resources globally. The need to explore possible wastewater reuse is now a necessity globally. The adsorption of amoxicillin (AMX), ampicillin (AMP), and chloramphenicol (CHLR) from simulated antibiotic-contaminated water using adsorbents prepared from grape slurry waste is studied. Batch adsorption experiments are carried out to evaluate the adsorption capacity of the adsorbents for AMX, AMP, and CHLR. Adsorption isotherms are described by the Langmuir and Freundlich isotherms, while the pseudo-second order kinetics describe the sorption processes. Negative values of the enthalpy change show that the sorption processes are exothermic, and the positive values of the Gibbs free energy change indicates non-spontaneous but feasible nature of the adsorption. The study shows that grape slurry waste could be a good precursor to prepare effective adsorbents for the remediation of antibiotic-contaminated wastewater.

Challenges in Characterizing Exposures to Organic Chemicals: Multiple Sources, Multiple Pathways and Multiple Scales

MP105 A new database and preliminary QSARs for environmentally relevant biodegradation half-lives
T.N. Brown, TNB Research; A. Sangion, University of Toronto / Department of Physical and Environmental Sciences; J.A. Arnot, AR Arnot Research & Consulting
