Evaluating the thousands of chemicals in commerce at a global scale for their potential hazards and risks to humans and the environment presents many challenges. Environmental biodegradation half-lives are important parameters for performing chemical hazard and risk assessments. For instance, in Canada a chemical is considered “P” in water if its degradability half-life is in water is >182 days. Chemical half-lives in air, water, soil and sediment are also required input parameters for multimedia fate models, e.g., EUSES, RAIDAR, CalTox, ACC-Human, etc. which are routinely used for environmental fate and exposure and risk estimation. These models require reliable input parameters to give reliable calculations, which is a challenge because there is a paucity of environmental biodegradation half-lives for relevant chemicals in commerce. Quantitative Structure Activity Relationships (QSARs) for predicting environmental biodegradation half-lives from chemical structure are also quite limited. To help address these challenges, here we summarize the development of a new database of environmental biodegradation half-lives, focusing on water as a starting point, including information collected from publicly available sources. The database includes empirical estimates as well as professional expert judgment values. The half-lives in the database span about 5 orders of magnitude and represent a diverse range of chemical classes and structures. Using the database, preliminary QSARs are developed and tested following the “OECD guidelines on the Validation of (Q)SAR Models.” Recommendations for improving the database and QSARs are provided.

MP106 A robust, sensitive, and fast method to determine illicit drug and cannabis metabolites for wastewater based epidemiology studies
E. Aydin, AGAT Laboratories, Ltd / Ultra-trace Organics

In this study, we developed a robust measurement method to monitor cocaine metabolites (benzoylcegonine, and cocaethylene), heroine metabolites (morphine and 6-acetylmorphine), codeine, MDMA, methamphetamine, amphetamine, LSD and its metabolite (2-oxo-3-hydroxy-LSD), fentanyl and its metabolite (norfentanyl), and cannabis metabolite 11-nor-9-carboxy-A9-THC (THC-COOH) in wastewater for wastewater based epidemiology (WBE) studies. Among target compounds, the most challenging to measure was THC-COOH. High matrix effect brought elevated uncertainties from instrumental analysis (lower recovery, higher variation, and higher detection limits). This is a common problem for THC-COOH analysis in wastewater. Therefore, there is a demand for a robust measurement method of THC-COOH with lower...
For decades, Environment and Climate Change Canada (ECCC) has employed monitoring programs for known and potential chemicals of concern. Because of extensive data gaps on chemical use, release, fate and transport in the Great Lakes ecosystems, and exposures and potential risks to a myriad of ecological receptors (e.g., plants, invertebrates, fish and wildlife), it is not technically possible nor feasible to measure all of the anthropogenic chemicals released to the Great Lakes. Mass balance exposure and risk-based models can be used to estimate concentrations and the potential for deleterious effects to the Great Lakes ecosystems and humans. Furthermore, mass balance models can provide understandings for key processes affecting the concentrations in the environment and exposures to receptors, as well as provide estimates for times for recovery from unacceptable levels of contamination and guidance for source mitigation. In turn, models can be evaluated using monitoring data. Combined, these complementary data sources can identify and reduce potential risks to the health of the Great Lakes ecosystems. The Risk Assessment IDentification And Ranking (RAIDAR) model is a screening-level tool that combines user-supplied information on chemical emissions and chemical properties (e.g., partition coefficients, medium-specific half-lives) with a mechanistic description of chemical phase distribution, inter-media transport and degradation processes to calculate concentrations in air, water, soil and sediment of a default generic regional-scale (100,000 km²) environment. RAIDAR uses the predicted concentrations in the physical environment to calculate intake rates and exposure concentrations in a range of ecological receptors (e.g., plants, invertebrates, fish, birds and mammals) comprising aquatic and terrestrial food webs. The chemical intake rates and biological concentrations can then be compared with toxicity data, which can be entered included in the model, for screening-level risk estimates. In this project we parameterize and apply the RAIDAR model to demonstrate how it can be used to address data gaps and provide holistic exposure and risk-based information to aid decision-making for chemicals entering the Great Lakes ecosystems. The framework is applied here as a case study for polybrominated diphenyl ethers (PBDEs).

MP108 Biomonitoring, toxicological and stakeholders’ environmental risks knowledge evaluations at a sawmills-impacted site on the Lagos lagoon, Nigeria
T.O. Sogbamu, O. Faremii, University of Lagos / Department of Zoology

The Lagos Lagoon receives direct inputs from sawmills at the Okobaba hub among other anthropogenic influences. The study aim was to evaluate the potential effects of sawmill activities on species diversity and biomarkers in common macroinvertebrates and fish species at the Okobaba hub of the Lagos lagoon, Nigeria. Also, stakeholders’ environmental risk perception was investigated. Six (6) stations (3 stations each around the test (Okobaba) and reference (Beyond Third Mainland Bridge - BTMB)) sites were sampled. A cross-sectional questionnaire was administered to stakeholders from which data were gathered from 123 respondents. Most of the surface water physicochemical parameters at the test site were higher than the reference and Federal Ministry of Environment set limits. A total of 193 fishes (109 fishes at the reference and 84 fishes at the test site) comprising of 11 species were identified. 53 macrobenthos of 6 species were identified at the control site while none were found at the test site. Dominant fish species identified at the test and reference sites were Caranx hippos (Cravelle jack) and Sarotherodon melanotheron (Blackchin Tilapia) respectively. Histological evaluations showed mild lamellar necrosis and hepatic necrosis in the gill and liver of the dominant fish, C. hippos from the test site while the control was normal. The biochemical evaluations showed a significant difference (p<0.05) in malondialdehyde and reduced glutathione activities in C. hippos sampled from the test site compared to the reference site. The analysis of the questionnaires showed that the frequency of catarrh ranked first with 43.1% as the health symptoms common among the residents, 46.3% account for improper waste disposal as the major cause of the Okobaba waterbody pollution and 66.7% of the respondents agree that sawmill wastes are disposed off by burning while the residue run off into the lagoon. The results revealed the impacts of sawmilling wastes especially in fishes as well as its potential effects on the health of the residents of Okobaba environs. Further studies on human health risk assessment are recommended to enable evidence-informed decision making on the appropriate interventions to safeguard fisheries and human health.

MP109 Characteristics of giant-Miscanthus-biochar derived DOC extracted from methanol-water mixture and water
C. Kim, S. Hyun, Korea University / Department of Environmental Science and Ecological Engineering

When biochar is applied to soil, biochar-induced dissolved organic carbon (biochar-DOC) can affect the mobility of hydrophobic organic contaminants (HOCs). The sorption of biochar-DOC is related to its physico-chemical properties such as, hydrophobicity, functional groups. Organic solvent such as methanol can be introduced in aqueous solution, and affects DOC extraction. However, characteristics of biochar-DOC in these system are unknown. In this study, biochar-DOC was isolated from aqueous solution and cosolvent and analyzed for characteristics. Giant-Miscanthus derived biochars (GMBs) were produced by various pyrolysis temperature from 400, 500, 600 and 700 °C (GMB-400, GMB-500, GMB-600 and GMB-700 respectively). DOCs were extracted from GMBs and farm soil was extracted with 10mM CaCl2 and methanol volume fractions (f) of 0-0.6, and were quantified using a TOC analyzer. The functional group of biochar-DOC was analyzed by Fourier-transform infrared spectroscopy (FT-IR). The biochar-DOC concentrations in aqueous solution were higher than farm soil-DOC, except for GMB-700. Biochar-DOC concentration decreased with increasing pyrolysis temperature, that is related to degree of carbonization. High carbonization at high pyrolysis temperatures increase stabilized carbon, which causes a decrease in DOC concentration. For all samples, DOC concentrations in cosolvent system were lower than aqueous solution. As a result of FT-IR analysis, GMB-400 derived DOC observed carboxylic C in aqueous solution (1600-1660cm⁻¹) and aromatic ether in cosolvent system (1030-1070cm⁻¹), which means that hydrophobicity of cosolvent extractable biochar-DOC was more than water extractable biochar-DOC. This study
shows that 1) biochar-DOC concentration was related pyrolysis temperature and hydrophobicity of solvent, 2) functional group of biochar-DOC is determined by hydrophobicity of solvent. Therefore, the mobility of HOCs by cosolvent extractable biochar-DOC might be more than water extractable biochar-DOC.

**MP110 Comparative Potency Estimates of an Expanded List of PAHs from a Community and Facility Fenceline Air Sampling**

K. Ellickson, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes; K. Kellock, Minnesota Department of Health / Environmental Health; G. Pratt, University of Minnesota / School of Public Health Division of Environmental Health; C. Herbrandson, Minnesota Department of Health / Environmental Health (retired); M. Krause, Minnesota Department of Health / Public Health Laboratory Organic Chemistry

There are few ambient air measurements of extended (beyond EPA Priority 16) lists of polycyclic aromatic hydrocarbons (PAHs), pollutants useful in source identification and significant contributors to cumulative inhalation cancer potency. We present the findings from comparative potency estimates from the results of a multi-year ambient air sampling study with a comparisons of mixed source, refinery, shingle manufacturers, and traffic. The cancer potency estimates were reported from both the straight 95% upper confidence limit of the mean and these results normalized by the percent of hours in the sampling period that the wind direction was from the source of interest. Below detection limit values were imputed based on regression on order statistics. Gas phase PAH concentrations were collected on XAD-4 and particulate phase collected as total suspended particulate on quartz fiber filters, and these results are based on the sum of the two physical phases. Potency was estimated for the entire suite of PAHs, the EPA-16, the EU-15, the EU-7 (ambient air), an estimate of potency from a scaling of Benzo[a]pyrene, and the IARC PAHS. Air concentrations were adjusted using Benzo[a]pyrene (BaP) equivalent relative cancer potency factors to estimate cancer potency equivalents. All cancer potency estimates were based on the WHO relative potency factors (check this) and the EPA IRIS inhalation unit risk factor. Benzo[c]fluorine (BeF) contributed the largest portion of the cumulative inhalation potency equivalence. Dibenzothiophene sulfone (DBTS) was a mass interferent in BeF measurement, and therefore included in the analyte list and is recommended for reporting BeF. Normalizing wind direction for risk estimates is one way of better understanding the impact of a cumulative PAH mixture from a specific source. We found a large impact of meteorological normalization for the traffic site and the refineries, but less informative for the refinery site and the mixed source sites, resulted in approximately half of the risk estimate than if BeF is included. The highest source types for BeF were traffic and the mixed source sites, and is recommended for reporting BeF.

**MP111 Determining Environmental and Individual Gestational Exposure Profiles of Healthy and Dysphagic Foals**

B.N. Rivera, Oregon State University / Environmental and Molecular Toxicology; K.R. Mullen, Littleton Equine Medical Center; L.G. Tidwell, Oregon State University / Environmental Molecular Toxicology; D.M. Ainsworth, Cornell University / Department of Clinical Sciences; S.C. Tilton, K.A. Anderson, Oregon State University / Environmental and Molecular Toxicology

Over the past two decades, there has been a rapid expansion in natural gas drilling in the United States. Shale gas made up 40% of U.S. gas production in 2012, compared to 2% in 2000, and is projected to grow fourfold by 2035. Exposure to natural gas drilling-related chemicals can occur through multiple exposure pathways, including water, soil, and air. A growing body of evidence suggests unconventional natural gas extraction emissions increases risk of adverse health effects in individuals who live less than 0.5 miles from an unconventional well. To assess for potential risks associated with this exposure, animals serve as ideal sentinels for humans since they are exposed continually and have shorter lifespans. In this study, foals at a location with an unconventional well within 0.25 miles, and another 5 within a 2.5 mile radius, had a high incidence of dysphagia (tracheal milk aspiration) compared to foals, bred by the same owner, in an area without active drilling, that never displayed signs of dysphagia. Consecutive sampling was conducted (Dec. 2014-Jul. 2016) to investigate an association between exposure profiles and health outcomes. Halter samplers applied to the dams, capturing individual exposure; and stationary well water and air samplers were used to identify potential routes of exposure associated with unconventional drilling. Analysis of well water samplers identified differences in polycyclic aromatic hydrocarbon (PAH) profiles between the two locations. PAHs with 3 or more rings were higher in the area with active drilling, and 2 ring PAHs were higher in the area not active in drilling (p<0.05). After the installation of a water treatment system at the active drilling location, a decrease in concentration of PAHs with 3 or more rings was reported. During this time, a significant decrease in incidence of dysphagia also occurred from 41% to 13% (p=0.04). Comprehensive foal health assessments identified duration of time the dam spent at the location near the unconventional drilling (odds ratio OR=1.41, 95% confidence interval CI 1.16, 1.71, p=0.0006 for each additional month of gestation spent at this location) and male gender (OR=5.47, 95% CI 1.22, 24.49, p=0.03) as risk factors for dysphagia. Future studies are needed to quantify PAHs and metabolites in biologic samples, identify a toxicopathological mechanism of dysphagia, and establish long term health risks for humans and animals living near active drilling.

**MP112 Developing AI forensics tools for chemical source tracking**

E. Dávila-Santiago, G.D. Jones, B.M. Medeghini, Oregon State University / Biological and Ecological Engineering

Water bodies are chemical data loggers that contain tens of thousands of chemicals that are derived throughout a watershed. While many compounds are widespread and are derived from multiple sources, we hypothesize the distribution of chemicals across the landscape is not random. Instead, different sources are expected to contain highly unique suites of chemicals or chemical ratios. Our aim is to extract non-polar organic compounds from both water samples at/near pollution sources, and then use high-resolution mass spectrometry (HRMS) data in conjunction with machine learning tools to identify the non-target chemicals that are diagnostic of each source. If these diagnostic chemicals, or chemical fingerprints, are detected in environmental samples, we can unequivocally identify their original sources. Grab samples were collected and analyzed in triplicate from different sources including headwater streams and run-off from urban, suburban, industrial surfaces, and agricultural sources. Preliminary data from artificial intelligence models indicate that each sample can be correctly identified with near perfect classification based on its chemical composition. These algorithms also show that highly similar water samples are readily distinguishable. In degraded ecosystems, where pollution sources are unknown or multiple sources exists for a given contaminant, this tool can help managers identify the most likely sources, which will help direct limited resources to projects that maximize water quality improvements.

**MP113 Developing and applying tools for high-throughput human health safety assessment**

J.A. Arnot, ARC Arnot Research & Consulting; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; F. Wanga, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; R. Becker, American Chemistry Council

Humans are exposed to chemicals from various use scenarios and often multiple exposure pathways including near-field (direct applications and indoor fate) and far-field (via multimedia including food and water). Ratios of exposure and hazard data are required to assess the safety and potential risks of chemicals used in society. The exposure and hazard values should be aligned such that the values being compared are relevant,
appropriate and in equivalent units. The Threshold of Toxicological Concern (TTC) is an approach that has been used for exposure-based waiving and chemical safety assessment in various regulatory agencies such as Health Canada and the European Food Safety Agency. Current TTC data are expressed as an oral intake rate (e.g., mg/kg/d) corresponding to external exposure. However, for many chemicals aggregate exposure can occur from multiple portals of entry to the body; therefore, using such an external exposure TTC may not always be appropriate. Here we outline a new tiered approach for developing internal TTC (iTTC; µmol/L-blood) values that can be applied more broadly in chemical hazard and safety assessment. We apply the first tier of this method as a case study for 95 organic chemicals. Parameterizing and applying a physiologically-based toxicokinetic model, we convert the traditional oral intake TTCs for Cramer Class I, II and III and for acetylcholinesterase inhibition to unique steady-state blood concentrations. These blood concentrations are unique iTTCs for the individual chemicals. We then use a new holistic modeling framework, comprising a substance flow model (a modified version of CIP-CAFE) and chemical exposure models (RAIDAR and RAIDAR-ICE) to simulate the steady-state human blood concentrations resulting from aggregate exposures. The exposure modelling framework predicts human blood concentrations from only two parameters: chemical structure and production volume. The model predicted blood concentrations are shown to be in reasonable agreement with inferred blood concentrations derived from the US population (R2 = 0.5; 66/95 chemicals predicted < 1 order of magnitude of inferred blood concentrations). The modelling framework estimates margin of safety as ratios of chemical-specific iTTCs and predicted steady-state blood concentrations. Margins of safety estimates for the 95 case study chemicals span approximately 8 orders of magnitude demonstrating the capacity of the system for screening and prioritizing large numbers of chemicals for human health assessment. Merits and limitations are outlined to provide a path forward for further developing and applying the tools and data for chemical hazard and safety assessment.

MP114 Distribution and concentrations of pharmaceutical and personal care products (PPCPs) within cattails (Typha latifolia) as function of exposure time

D.J. Perez, INTA / Agronomy; M. Menone, Universidad Nacional Mar del Plata / Lab de Ecotoxicologia; W.J. Doucette, Utah State University / Utah Water Research Laboratory

The passive uptake of organic contaminants such as PPCP by plants is well documented. Uptake is often quantified and reported as concentration ratios between whole plants or specific plant compartments (e.g. roots, shoots, leaves, fruit) and the exposure media (e.g. soil, air water). The ratios may also be normalized to the amount water transpired by the plant or to lipid content of the plant tissue. However, there have been relatively few studies that have investigated the changes in concentrations among the various plant tissue compartments over time. Using hydroponically grown cattails (Typha latifolia) exposed to four PPCPs (carbamazepine, fluoxetine, gemfibrozil, triclosan) at environmentally relevant concentrations near 20 µg/L, the uptake and distribution of these compounds within the plants were evaluated at several time periods over a 42 day growing period. Thirty-six plants of uniform size were selected, eighteen exposed to the target PPCPs and eighteen untreated. Two unplanted, unexposed controls were also used. A nutrient solution containing the target compounds was used to replenish water lost to transpiration and maintain a consistent exposure environment (static exposure bioassay). Root zone samples were collected over time to determine the average exposure concentration. Whole plants were harvested at days 7, 14, 21, 28, 35 and 42 days. Concentrations of PPCPs in the exposure solution and various plant tissues were determined by direct injection LC-MSMS or after extraction, concentration and cleanup. Carbamazepine, fluoxetine, gemfibrozil and triclosan were detected in all underwater tissues (roots, rhizome, etc.) and above water tissues, except gemfibrozil which was not detected in shoots. Carbamazepine concentrations were highest in the upper leaves in the plants exposed for the longest time. Concentrations in the below water tissues were 30-40 times lower than the upper leaves and did not vary significantly with time. Above water tissue concentrations for fluoxetine were highest in the lower leaves and similar to the concentrations in the below water tissues. Triclosan concentrations were greatest in the roots and were about 50 higher than those found in the leaves. Overall, the results show that the root uptake, translocation and distribution within the plant tissues varies with the physical chemical properties of PPCP and longer exposures result in higher leaf concentrations for those compounds that are translocated from root to shoot. For compounds that are readily translocated from roots to shoots, the large differences in tissue concentrations could have important implications in risk assessment and biomonitoring applications.

MP115 Evaluating the RAIDAR-ICE model with monitoring and biomonitoring data from Europe

J.A. Arnott, ARC Arnott Research & Consulting; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; K. De Brouwere, VITO NV / Health; L. Geerts, VITO NV; M. Lamoree, VU University, Department Environment & Health / Department Environment & Health

Humans are exposed to a wide variety of chemicals that originate in “near-field” environments (i.e., indoors) as a part of building materials, consumer goods and articles, and products used daily, e.g., household products, personal care products. Measured data are emerging through various monitoring and biomonitoring projects and programs. For example, the Cefic-LRI SHINE project is conducting targeted and non-targeted analyses of dust and air samples in indoor environments coupled with a literature review for biomonitoring data for the target chemicals (e.g., flame retardants, pesticides, plasticizers). Mechanistic, mass-balance, multi-media models serve as powerful tools to understand important exposure pathways and to predict exposures in the absence of measured data for human health assessment. Such models that link external exposures with internal exposures can also be used to integrate monitoring data (air, dust, surface concentrations) with biomonitoring data (blood, urine). There is a need to test (evaluate) exposure models to foster confidence in their application in regulatory programs in both data rich and data poor contexts. The Risk Assessment IDentification And Ranking - Indoor and Consumer Exposure (RAIDAR-ICE) model combines an indoor fate model with a toxicokinetic model to simulate chemical exposures from direct (e.g., personal care products) and indirect (e.g., vaporization of chemicals from building materials) sources of chemicals. It simulates human exposure from the near-field environment through inhalation of indoor air, dermal absorption, non-dietary object-hand-mouth contact. Here we evaluate RAIDAR-ICE with monitoring and biomonitoring datasets from Europe for a range of chemicals, including new data obtained in the SHINE project. The case study chemicals comprise a broad range of use categories, partitioning properties, and biotransformation half-lives.

MP116 Evaluation of Metastatic Pathway Inhibition by Novel Ruthenium -based Metallodrugs using the Zebrafish Model

B. Karas, Rutgers University / Toxicology; J. Hitz, D. Fitzgerald, Rutgers University / Microbiology and Biochemistry; L. Corte-Real, Universidad de Lisboa / Faculdade de Ciências / Centro de Química Estrutural; L.A. White, Rutgers University / Microbiology and Biochemistry; K. Cooper, Rutgers University School of Environmental and Biological Sciences / Microbiology and Biochemistry; A. Valente, Universidade de Lisboa / Faculdade de Ciências / Centro de Química Estrutural; B. Buckley, Rutgers University / Environmental and Occupational Health Science Institute

Cancer progression into metastasis is an incredibly complex, multi-step process that is the major cause of cancer-related deaths. Targeting this cancer phenotype would result in decreased mortality. However, therapeutic efficacy is difficult to evaluate in vitro due to the complex nature of metastasis. The widely accepted model of testing metastasis is immunosuppressed nude mice, but the field agrees there are limitations
MP117 Identification and Quantification of Chemical Constituent Losses during Fine Particulate Matter Filter Extraction for Toxicology Research

C. Roper, Oregon State University / Department of Environmental and Molecular Toxicology; E. Weeks, Oregon State University / L.S. Trine, Oregon State University / Chemistry / Environmental and Molecular Toxicology; D. Barrett, Oregon State University / Department of Environmental and Molecular Toxicology; S. Simonich, Oregon State University / Dept of Chemistry and Environmental Molecular Toxicology; R.L. Tanguay, Oregon State University / Sinnhuber Aquatic Research Laboratory and the Environmental Molecular Toxicology

Fine particulate matter (PM2.5) exposures are complex mixtures that vary in concentration and composition resulting in differential human health effects. To better understand the known adverse health associations, toxicology studies are frequently conducted using filter collected PM2.5. However, the methods of filter extraction have significant impacts on both the chemical composition and subsequent toxicity of PM2.5 samples. We set out to optimize a previously used filter extraction method for PM2.5 toxicology research by quantifying chemical constituent losses throughout the steps of sample processing, including filter extraction and preparation for toxicology studies. For PM2.5 collected from different sources (n=3), Four different points during the sample processing were analyzed for polycyclic aromatic hydrocarbons (n=18) and elements (n=75) via gas chromatography-mass spectrometry and inductively coupled plasma optimal emission spectrometry, respectively; the points during extraction were following: sonication, concentration, drying, and re-suspension in a media amenable to toxicity testing (DMSO). Concentrations of chemical constituents at the various points in the sample preparation process were compared to constituent concentrations using standard extraction methods for characterization of ambient PM2.5. Significant differences were observed between the preparation steps in concentrations of PAH classes, individual compounds, and spiked surrogate compounds. Elemental data and differences based on the sources of PM2.5 are currently being analyzed to ultimately optimize sample processing of filter collected PM2.5 for toxicology studies.

MP118 Introducing a Nested Exposure Model for organic contaminantants (NEM): Part 1. The physical environment

K. Breivik, S. Eckhardt, NILU - Norwegian Institute for Air Research / Atmospheric and Climate Change Department; I.S. Krogseth, Norwegian Institute for Air Research / Environmental Chemistry; M. MacLeod, Stockholm University / Department of Environmental Science and Analytical Chemistry; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

Persistent Organic Pollutants (POPs) and some other organic contaminantants have achieved global distribution. Yet, most empirical studies have a more restricted geographical scope (e.g. focus on a specific country or jurisdiction), and/or cover time-periods shorter than the contaminantants’ potential lifetime in the environment. This calls for regional modelling strategies that are global in context, yet dynamic, reflecting both the possible mobility and lifetime of relevant contaminantants in the physical environment. Our Nested Exposure Model (NEM) reflects the hypothesis that accurate predictions of organic contaminant exposure calls for increasing resolution with increasing proximity to a study region of interest. The description of contaminantate fate in the physical environment within NEM builds upon two existing dynamic (time-variant) fugacity-based multimedia models, BETR-Global and Co2Mo-POP 2, which describe organic contaminant fate in multiple compartments representing the physical environment. Unlike those models, NEM is a nested model. Through nesting up to five different model domains, NEM offers increasing resolution with increasing proximity (in space and time) to a study region of interest. Chemical transport between neighboring grid cells may occur by air, fresh water and seawater. Through sequential simulations, chemical inflow from the outside world into the next user-defined domain of NEM is based on model outputs stored from simulations of the preceding domain. We illustrate the utility of the model with a case study of the Nordic region, including remote Arctic areas such as Svalbard.

In order to expand the utility of the model beyond our study, the NEM model is developed such that any user-defined region may be targeted in a similar fashion. This is made possible as spatially and temporally variable environmental input data are derived from global data sets, processed and stored at a spatial resolution of 0.5°x0.5° (latitude/longitude). NEM thereby allows for the evaluation of the impact of variable spatial resolutions on predicted exposures in any region of interest across multiple scales. For example, NEM may offer insights on the merit and possible limitations of using regionalized models to simulate global organic contaminantants.

MP119 Introducing a Nested Exposure Model for organic contaminantants (NEM): Part 2. Bioaccumulation in Arctic Ecosystems

I. Krogseth, Norwegian Institute for Air Research / Environmental Chemistry Department; K. Breivik, NILU - Norwegian Institute for Air Research / Atmospheric and Climate Change Department; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

Persistent Organic Pollutants (POPs) and some other organic contaminantants have achieved global distribution. Yet, most empirical studies have a more restricted geographical scope (e.g. focus on a specific country or jurisdiction), and/or cover time-periods shorter than the contaminantants’ potential lifetime in the environment. This calls for regional modelling strategies that are global in context, yet dynamic, reflecting both the possible mobility and lifetime of relevant contaminantants in the physical environment. Our Nested Exposure Model (NEM) reflects the hypothesis that accurate predictions of organic contaminant exposure calls for increasing resolution with increasing proximity to a study region of interest. The description of contaminant fate in the physical environment within NEM builds upon two existing dynamic (time-variant) fugacity-based multimedia models, BETR-Global and Co2Mo-POP 2, which describe organic contaminant fate in multiple compartments representing the physical environment. Unlike those models, NEM is a nested model. Through nesting up to five different model domains, NEM offers increasing resolution with increasing proximity (in space and time) to a study region of interest. Chemical transport between neighboring grid cells may occur by air, fresh water and seawater. Through sequential simulations, chemical inflow from the outside world into the next user-defined domain of NEM is based on model outputs stored from simulations of the preceding domain. We illustrate the utility of the model with a case study of the Nordic region, including remote Arctic areas such as Svalbard.

In order to expand the utility of the model beyond our study, the NEM model is developed such that any user-defined region may be targeted in a similar fashion. This is made possible as spatially and temporally variable environmental input data are derived from global data sets, processed and stored at a spatial resolution of 0.5°x0.5° (latitude/longitude). NEM thereby allows for the evaluation of the impact of variable spatial resolutions on predicted exposures in any region of interest across multiple scales. For example, NEM may offer insights on the merit and possible limitations of using regionalized models to simulate global organic contaminantants.
and ringed seal, and is under development to be expanded to key seabird species. The bioaccumulation module was evaluated independently for predicted bioaccumulation of polychlorinated biphenyls (PCBs) across species and time by running the model based on measured or predicted PCB concentration in Arctic seawater and air. Predicted concentrations in biota were compared with available measurements in literature. The bioaccumulation module performed well in reproducing bioaccumulation of PCBs in a Svalbard food web. Predicted time-trends of ΣPCB6 and ΣPCB7 were also in good agreement with measurements from the Barents Sea for all fish species. The good model performance across trophic levels and time is promising for further expansion of the model to include (i) variation in space through connection with the physical module of NEM, and (ii) Arctic marine top-predators, the terrestrial environment, and human exposure. When finalized, we hope that the NEM model will be a useful tool for scientific and regulatory communities interested in understanding and protecting ecosystem and human health from legacy and emerging organic contaminants.

**MP120 Metabolic dysregulation by exposure of organochlorine pesticides mixture in obese zebrafish**

H. Lee, Gyeongsang National University / Marine Environmental Engineering; K. Kim, S. Lee, Seoul National University of Science and Technology / Environmental Engineering

Obesity and exposure to organochlorine pesticides (OCPs) are well-known physiological and chemical contributing factors of type 2 diabetes (T2D). Given that OCPs are lipophilic and well-accumulated in the adipose tissue, effect of exposure of OCPs on the incidence of T2D could be influenced by obesity. However, limited studies have been conducted to elucidate these trade-off roles. In this study, we investigated the different biological response related to T2D incidence on each condition of obesity and chemical exposure, and mixed scenarios in zebrafish. We exposed female zebrafish to 0 (solvent control, 0.1% DMSO) and 0.05 μg/L of OCPs mixture where non-monotonic dysregulation was observed at very low concentrations in our previous study, with dietary control. Obese zebrafish was provoked by feeding high-fat-diet (Gemma micro + chicken egg yolk) for energy imbalance and fat accumulation. After feeding amount and frequency were optimized, the experiment was lasted for 14 weeks in a flow-through system. After the exposure periods, zebrafish were sacrificed and body weight, length, blood glucose, fasting insulin, triglyceride and free fatty acid were measured. For identifying gene expression changes underlying molecular mechanism, the transcriptomic analysis (i.e., RNA-seq) was conducted in the liver tissue. Through this study, we demonstrate that metabolic dysregulation was caused by exposure of OCPs mixture in the obese condition, and we suggest the applicability of zebrafish model to study of metabolic diseases such as T2D or obesity under chemical exposure.

**MP121 Proteome-Wide Effects of Naphthalene-Derived Secondary Organic Aerosol Are Caused by Short-Lived Unsaturated Carbonyls**

J. Han, University of Toronto / Department of Chemistry; S. Wang, University of Toronto / Department of Chemical Engineering and Applied Chemistry; K. Yeung, University of Toronto / Chemistry; D. Yang, University of Toronto / School of the Environment; W. Gu, Chinese Center for Disease Control and Prevention; J. Sun, University of Toronto / Chemistry; A. Chan, University of Toronto / Department of Chemical Engineering and Applied Chemistry; H. Peng, University of Toronto / Department of Chemistry

It is widely recognized that naphthalene contributes largely to global organic aerosol (OA) burden, its adverse health effects is still poorly understood. Here we assessed the proteome effects of naphthalene derived secondary organic aerosol (NSOA) at 6 different aging stages on human airway epithelial cells (BEAS-2B) by quantitative proteomics. Compared with the precursor (C0), 125 proteins were significantly changed in C1 condition, whereas the number of proteins dramatically deceased along with aging (e.g., 12 changed proteins in C6 condition). This result indicated that proteome-wide effects of NSOA were caused by short-lived species produced during chamber reaction. While the majority of proteins were down-regulated by NSOA exposure (e.g., Rho pathways), two Nrf2-pathway proteins (i.e., Noq1, Txnrd1) were significantly upregulated in C1 condition, which was further confirmed by a Nrf2-ARE stably transfected reporter cell line. Consistent with quantitative proteomics results, Nrf2 responses induced by NSOA showed noteworthy elevation (6.38-fold) during the early atmospheric process, but subsequently decreased (66.51%) after a long term of aging. Pre-incubation of NSOA with cysteine significantly decreased the Nrf2 responses (49.98%), indicated that Michael addition to cysteinyi thiol is the major toxic pathway for NSOA. To further identify the exact chemicals responsible for the toxicities, non-targeted analysis was adopted to analyze the chemicals of NSOA lost and produced after incubations with cysteine. Among 151 detected chemical components, only 2 of them, including 1,2-naphthaquinone showed significant decrease. Consistent to this, 5 Michael addition adducts were detected and 4 of them were 1,2-naphthaquinone derived adducts. This study clearly indicated that short-lived unsaturated carbonyls are responsible for the proteome-wide effects of NSOA on BEAS-2B cells.

**MP122 Quantifying Polycyclic Aromatic Hydrocarbon (PAH) Losses During Sample Preparation Steps of Fine Particulate Matter (PM2.5) Filters**

E. Weeks, Oregon State University; C. Roper, Oregon State University / Department of Environmental and Molecular Toxicology; L. Trine, Oregon State University / Chemistry / Environmental and Molecular Toxicology; S. Simonich, Oregon State University / Depts of Chemistry and Environmental Molecular Toxicology

Fine particulate matter (PM2.5) has known adverse health effects in humans and is frequently comprised of compounds that are potential carcinogens, including polycyclic aromatic hydrocarbons (PAHs). Due to the known human health implications, toxicology research is routinely conducted on various types of PM2.5 to better understand the health impacts associated with these exposures. However, the actual chemical composition of PM2.5 in toxicology studies is rarely measured but there are known losses during filter extraction and preparation for toxicology research, resulting in samples not representative of the ambient exposures. Additionally, different research groups use differing methods for PM2.5 filter extraction, increasing the methods bias in this field. We set out to identify the steps during filter extraction that result in the highest losses of PAHs with a surrogate spike and recovery experiment on ambient collected PM2.5 filters. Surrogates represented five classes of PAHs including: Parent (n=7), Hydroxy (n=8), Oxy (n=2), Nitro (n=5), and High Molecular Weight (n=1) PAHs. Three different points in the sample preparation were tested: 1) Extraction - sonication of filter, 2) Concentration - fine blow down by N2 gas, and 3) Clean up - solid phase extraction of the sample prior to analysis using gas chromatography mass spectrometry (GC-MS). In this research the surrogate levels were compared between methods and between steps to target where the highest losses occurred. Preliminary results indicate that there is variability between PAHs and within classes of PAHs in surrogate recovery. Additionally, at all three points of sample preparation there were surrogate losses over 30% indicating the need for further investigation of these techniques. This research highlights the need for optimizing PM2.5 filter extraction methods to provide samples for toxicology research that are more representative of ambient exposures.

**MP123 Moving toward a spatially-resolved global surface water flow and aquatic exposure model for consumer-use down-the-drain ingredients: Japan case study**

S. A. Ciszar, Procter & Gamble Company / Global Product Stewardship; R. Yamshi, Waterborne Environmental, Inc.; M. Fan, K. McDonough, Procter & Gamble Company / Global Product Stewardship

Exposure assessment is a key factor in the environmental risk assessment (ERA) of consumer products that are disposed down-the-drain. The Procter & Gamble Company conducted research, resulting in samples not representative of the ambient exposures. Additionally, different research groups use differing methods for PM2.5 filter extraction, increasing the methods bias in this field. We set out to identify the steps during filter extraction that result in the highest losses of PAHs with a surrogate spike and recovery experiment on ambient collected PM2.5 filters. Surrogates represented five classes of PAHs including: Parent (n=7), Hydroxy (n=8), Oxy (n=2), Nitro (n=5), and High Molecular Weight (n=1) PAHs. Three different points in the sample preparation were tested: 1) Extraction - sonication of filter, 2) Concentration - fine blow down by N2 gas, and 3) Clean up - solid phase extraction of the sample prior to analysis using gas chromatography mass spectrometry (GC-MS). In this research the surrogate levels were compared between methods and between steps to target where the highest losses occurred. Preliminary results indicate that there is variability between PAHs and within classes of PAHs in surrogate recovery. Additionally, at all three points of sample preparation there were surrogate losses over 30% indicating the need for further investigation of these techniques. This research highlights the need for optimizing PM2.5 filter extraction methods to provide samples for toxicology research that are more representative of ambient exposures.

**SETAC North America 40th Annual Meeting | 259**
 explicit aquatic exposure model for down-the-drain ingredients by leveraging the growing availability of computational methods and large spatial datasets. Current models often assume average conditions across a country/region in a deterministic calculation, while, in reality, there can be substantial spatial variation in input parameters (e.g., emissions, per capita water use, and waste water treatment) across a region. While spatial variability has been addressed by some models, they have focused on a single country/region; and there is a need for a user-friendly, global aquatic exposure model on a single platform with a consistent approach, using best available data. The iSTREEm(R) model (American Cleaning Institute) is a spatially-explicit aquatic exposure model parameterized and evaluated primarily for the United States. The model has also been extended to China and evaluation has indicated excellent agreement between modeled and measured river flow data. There was also excellent agreement between case study modeled and monitored chemical concentrations. This platform was leveraged and extended to cover Japan and follows a framework that uses global datasets to estimate river flow on a catchment level, route chemicals between catchments, and estimate catchment-specific concentrations. Each catchment is parameterized with a specific population, per capita water use, and waste water treatment plant (WWTP) information; and allows for spatial variation in emissions. For Japan, spatial locations of WWTPs were incorporated into the model and the resulting population served by WWTP treatment corresponds well with published reports of treatment levels. Direct discharge of grey water was included to represent current practice in some areas of Japan. Measured river flow data and case study chemicals with available monitoring data were used to evaluate the flow predictions and concentration distribution estimates by the model. Thus, this model framework provides a promising platform for expansion as a global aquatic exposure model for down-the-drain ingredients.

Multi-Pathway Exposure to Neonicotinoids and the Implications to Ecological and Public Health

MP124 Toxicity of neonicotinoids to non-target soil invertebrates
K. Pearson, Pennsylvania State University / Entomology; J. Tooker, The Pennsylvania State University / Department of Entomology

In conventional field corn production, it is common practice to coat seeds with neonicotinoid insecticides. These seed coats are designed to target below-ground and early season pests, however, up to 90% of neonicotinoids applied to seeds end up contaminating field soil. Non-target soil invertebrates are likely to come into contact with high doses of these insecticides, yet the risk of neonicotinoids to non-target soil invertebrates is largely unknown. While toxicological assays have been performed for handful of standard test species (e.g. Eisenia earthworms and Folsomia springtails), these species are unlikely to represent the diversity of soil invertebrates. To explore the risk of neonicotinoids to non-target soil invertebrates, we paired field-based pesticide residue analyses with acute toxicity assays. Rather than running assays on standard test species, we ran assays on a suite of ecologically and taxonomically diverse soil invertebrates from the local agroecosystem; species represented non-target herbivores (slugs), saprophages (millipedes and isopods), weed-seed predators (carabid beetles), and invertebrate predators (carabid beetles and wolf spiders). While basic, the results of these assays can be used to explore possible mechanisms behind insecticide-induced shifts in soil invertebrate populations and soil-based functional endpoints.

MP125 Neonicotinoid insecticides in common milkweed and soil next to agricultural fields in Ontario: Potential harmful effects to Monarch butterfly larvae
L. Collins, Trent University / Institute for Watershed Science; T. Sultana, Trent University / Environmental and Resource Studies; C.D. Metcalfe, Trent University / Water Quality Centre

The monarch butterfly (Danaus plexippus) is a species of special concern due to the restricted range of its overwintering habitat, and the negative impacts on population numbers from habitat destruction, climate change and exposure to pesticides. Southern Ontario is one of the most important breeding areas in Canada for the eastern monarch butterfly. This is also an area of intensive agriculture, especially for corn and soybean production. Exposure to neonicotinoid insecticides (NNIs) in intensive agricultural landscapes may play a role in reducing monarch numbers through contamination of the plant species that is favored by the larvae for forage, the common milkweed (Asclepias syriaca). Recent laboratory and field studies show that exposures of monarch larvae to low concentrations of the NNI, chloothionidin reduces larval size and condition. In this study, we sampled milkweed and soils at four field sites in two separate watersheds in southwestern Ontario to assess contamination with NNIs. Samples were prepared for analysis by liquid chromatography with tandem mass spectrometry (LC-MS/MS). The levels of chloothionidin and thiamethoxam in soil samples adjacent to agricultural fields at all sites were very low or below detection limits. Clothianidin and thiamethoxam were detected in the leaves of milkweed collected from sites in southwestern Ontario, but the concentrations were highly variable. The highest concentration of chloothionidin detected in milkweed leaves was 23.9 ng/g dry weight, which is above the reported threshold for sublethal effects in larvae of the monarch butterfly. No NNIs were detected in milkweed leaves collected from a non-agricultural reference site. These data indicate that exposures of larvae of the eastern monarch butterfly to NNIs may play a role in the reduced numbers of this species of special concern.

MP126 Transcriptional responses of yellow perch (Perca flavescens) exposed in vivo to individual neonicotinoid and diamide pesticides, and mixtures
M. Giraudou, L. Mercier, A.D. Gendron, M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Neonicotinoid pesticides, including clothianidin, are widely used in agriculture to fight pest insects. Given the upcoming restrictions on neonicotinoid use in Canada, new replacement compounds have been developed and some of them, such as the diamide chlorantraniliprole, are already in use. Despite the efforts put into evaluating the effects of these compounds on the environment, toxicity data on non-target aquatic organisms such as fish are scarce. The yellow perch (Perca flavescens) is an indigenous species of the St. Lawrence River inhabiting macrophyte beds and floodplains and therefore prone to pesticide exposure in agricultural areas. Concentrations reaching up to 100-200 ng/L of clothianidin and chlorantraniliprole have been measured in surface water samples from Lake St. Pierre, Quebec, Canada, where pesticide-treated soy and corn cultures are predominant. Juvenile perch are particularly vulnerable in this area and their exposure to pesticides could partially explain the low recruitment observed in this fluvial lake of the St. Lawrence River where the perch population has collapsed, leading to a fishing moratorium. The goal of this study was to evaluate the effects and modes of action of clothianidin and chlorantraniliprole in juvenile yellow perch chronically exposed in vivo (28 days) to environmental concentrations (200 ng/L) of the two pesticides alone and in a mixture. Hepatic transcriptional responses were measured by RNA-sequencing. Results showed that clothianidin did not affect gene transcription, while chlorantraniliprole deregulated the transcription of 38 genes. When the two compounds were combined, 251 genes were deregulated, which suggest synergistic effects of these two pesticides at environmental concentrations. Impacted molecular pathways and associated cellular responses will be discussed. Results will help identify biological processes affected by these compounds in fish and better understand their effects on this vulnerable developmental stage of yellow perch.
Neonicotinoids are rapidly-acting neuroactive pesticides with biological activity reported across many taxa. As a result of their rapid action and excretion, current approaches to detect exposure and effect in wild birds are limited. In order to identify new approaches, it is important to understand the biological mechanisms linking exposure to apical outcomes.

Although it is understood that these compounds act as reversible nicotinic acetylcholine receptor agonists, the way in which they exert their diverse set of effects has not been catalogued. Therefore, we report the results from an experiment in which the whole-transcriptome of chickens (Gallus gallus) in response to imidacloprid exposure was documented in a set of lethally and non-lethally collected tissues (liver, brain, and peripheral blood mononuclear cells (PBMCs)). Chickens were exposed orally over seven days to three treatment levels, based on known effects concentrations, and one control group, and tissues were collected via venipuncture or serial sacrifice. Isolated mRNA was sequenced via Illumina HiSeq 2500v4 (50 bp paired-end reads) producing from 8.02M to 17.42M reads per library. Data were analyzed for differential gene expression using RNAseq and edgeR pipelines. We found that although genes isolated from liver and brain were not highly responsive to exposure, genes in PBMCs were affected in a time and dose-dependent manner, suggesting potential immunological effects. In PBMCs, 29 out of 151 genes were significantly expressed at a logFC>5 fold change compared to baseline) and occurred less than 5 times or were expressed at a logFC>5 and occurred more than 5 times in the treatment groups. Twenty-five genes were down-regulated and only four were up-regulated. Our data provide an initial step towards discovering a means to non-lethally detect biological activity in response to IMI exposure in gallinaceous birds.

**MP128 Neurotoxicity Induced by Thiamethoxam and Clothianidin in SK-N-SH Cells**

X. Lu, J. Li, Q. Zhang, Y. Huang, B. Yu, Peking University

Thiamethoxam (TMX) and clothianidin (CLO) are two widely used neonicotinoid insecticides generally considered to have low toxicity to mammals. However, in recent years, there is a growing number of studies showing that neonicotinoid insecticides have potential hepatotoxicity, neurotoxicity, reproductive toxicity and developmental toxicity to mammals. In this study, human neuroblastoma cells (SK-N-SH cells) were used as models to explore the neurotoxicity of TMX and CLO. For each neonicotinoid, exposure experiments were set up at three levels: 0.01 mM, 0.1 mM and 1 mM. After exposure for 24 h, the cells were analyzed for oxidative phosphorylation levels, oxidative stress effect, activity of acetylcholinesterase, gene expressions of various subunits of nicotinic acetylcholine receptors (nAChR) and protein expression of nAChR α7 subunit. To further reveal the mechanism of CLO neurotoxicity, multi-omics analyses were performed. The results showed that exposure to TMX and CLO for 24 h had no significant effect on energy metabolism, but caused significant oxidative stress at 1 mM. For TMX, exposure at all three levels did not significantly change the gene expressions of nAChR subunits, the protein expression of nAChR α7 subunit, and the activity of acetylcholinesterase. However, for CLO, exposure at all three levels significantly increased the gene expression and protein expression of nAChR α7 subunit, and the increase positively correlated with the concentration of clothianidin. Exposure to CLO at 1 mM also significantly increased the gene expression of nAChR α3 subunit and decreased the activity of acetylcholinesterase. Multi-omics analyses revealed multiple differential genes, proteins and metabolites due to CLO exposure (0.1 and 1 mM), and the associated functions and pathways included oxidative stress and synaptic function-related pathways, as well as amino acid metabolism and other metabolic related pathways. This research provides a rich list of biomarkers for the study of neurotoxicity of neonicotinoid insecticides to human.
Mercury Fate, Biogeochemistry and Risk in a Changing Environment

MP131 Mercury speciation in gull guano samples and changes over a summer season on Brier Island, Nova Scotia

H. Geizer, N.J. O’Driscoll, S. Klapstein, Acadia University / Earth & Environmental Science

Birds are vectors for nutrient and pollutant movement between ecosystems which may influence habitat. Big Meadow Bog on Brier Island, Nova Scotia is home to >6000 herring gulls (Larus argentatus) and a few black-backed gulls (Larus marinus) each year during their nesting season (May - June). Previous research in this bog has shown that methylmercury and phosphate (PO₄) concentrations in surface groundwater are highest in gull nesting areas. This correlative finding suggested significant inputs from these avian biovectors. However, the concentrations of mercury and phosphate in guano samples was unknown. To address this knowledge gap, we collected guano samples in the most populated areas of the bog. In 2018 guano samples were collected from the ground using plastic scoops. Those results of total mercury are presented below. Initial results in 2018 had a wide range of total mercury concentrations (1.7 - 458.8 ng/g) with a mean of 64.5 ± 81.1 ng/g (n=97). In 2019 four plastic posts were installed for birds to perch and excrete on and samples collected ~bi-weekly from May to August to establish temporal patterns in Hg content. Samples were dried, homogenized and analyzed for total mercury, methyl mercury, and total phosphorous. These data are key for modelling environmental exposure and movement of Hg in these habitats. This poster will overview the most recent data collected in 2019 and temporal trends in Hg speciation and P data relative to gull life histories and visual inspections of guano.

MP132 Human activities enhance mercury methylation in soils and sediments

H. Zhang, P. Lei, W. Tang, Nanjing University

Recently, there are increasing concerns about human activity-impacted methylmercury (MeHg) production and bioaccumulation in aquatic and terrestrial systems. For instance, new hotspots of Hg methylation were reported in paddy soils and sediments in eutrophic lakes. It is thus necessary to better understand the effects of human activities on mercury methylation and the underlying mechanisms. Our recent studies focus on investigating the impacts of human activities (e.g., farming activities and eutrophication) on Hg methylation in soils and sediments. By conducting a national-scale survey in China (~70 paddy soils and 10 major lakes) together with mechanistic studies, we demonstrate that: (1) Input of plant-derived organic matter due to human activities (rice cultivation, straw return, and eutrophication and algal bloom) could mobilize refractory Hg in soils/sediments (e.g., HgS), or provide electron donors to microbial methylators, thus facilitating Hg methylation in soils and sediments. These may partly explain the enhanced MeHg levels in paddy soils and sediments in eutrophic lakes. (2) Sulfur fertilization in Hg-mining areas could impact Hg speciation in soils, e.g., by releasing mobile Hg species from HgS minerals, leading to enhanced MeHg levels in soils and crop grains. These recent findings demonstrate that human activities could be important factors, contributing to elevated risk of MeHg in both aquatic and terrestrial systems.

MP133 Temporal changes in dissolved elemental mercury at a coastal aquaculture site in the Grado Lagoon, northern Italy

N.J. O’Driscoll, Acadia University / Department of Earth and Environmental Science; S. Covelli, Dipartimento di Matematica e Geoscienze; E. Petranich, F. Floreani, University of Trieste; S. Klapstein, Acadia University / Earth & Environmental Science; A. Acquavita, ARPA FVG

Mercury can be lost from ecosystems through the process of photoreduction to its volatile elemental form (Hg(0)) in natural waters which is primarily controlled by abiotic reactions with ultraviolet (UV) radiation. There is little mercury photoreduction research available for contaminated coastal marine systems. Grado lagoon, northern Italy, is an aquaculture area with high total mercury concentrations in sediment due to past cinnabar mining activities at Idrija (western Slovenia). Two sites (one highly Hg contaminated, VN1, and one with lower contamination, VN3) located within a lagoon fishfarm were analyzed for temporal changes in dissolved elemental mercury (Hg(0)aq) and its relationship with UV radiation in May of 2018. Solar radiation spectra were continuously quantified using an OceanOptics USB 4000 spectroradiometer and aqueous Hg(0) concentrations (Hg(0)aq) using a Lumex 915-RA with headspace analysis and an equilibrium partitioning model with temperature-corrected Henry’s law constant. It was found that the small pH changes observed were significantly correlated with Hg(0)aq concentrations at both sites however this was likely due to auto correlations with the daily cycle of microbial respiration and carboxylic acid concentrations. It was found that Hg(0)aq concentrations ranged between 237.6 - 401.5 pg L⁻¹ (mean = 331.4 pg L⁻¹; SD=42.94; n=13) at the more contaminated site, VN1, and showed a diurnal trend. Total dissolved mercury at this site ranged between 3.85 - 28.22 ng L⁻¹ (mean=7.7; SD=6.17 ng L⁻¹; n=13), which resulted in a % Hg(0) ranging between 0.84 - 8.24 %. At the lower mercury site, VN3, Hg(0)aq concentrations ranged between 200.3 - 321.52 pg L⁻¹ (mean=279.49 pg L⁻¹; SD=46.99; n=14). Total dissolved mercury at this site ranged between 2.86 - 9.13 ng L⁻¹ (mean=5.04; SD=2.06 ng L⁻¹; n=14), which resulted in a % Hg(0) ranging between 2.89 - 8.91 %. In both cases the Hg(0)aq concentrations in water were higher in the central part of the day and positively correlated with incoming UVB and UVA radiation measurements (Site VN1 Pearson r = 0.48, p=0.09, n=13; Site VN3 Pearson r=0.70, p=0.01 n=13). In conclusion, it was found that % Hg(0) relative to total mercury concentrations were similar at the contaminated coastal aquaculture site to other contaminated areas in previous work, but were substantially higher than those observed at other uncontaminated sites.

MP134 Water and sediment chemistry influences on mercury bioaccumulation in freshwater invertebrates from two lakes in Kejimkujik National Park, Nova Scotia

R. Clarke, Acadia University / Biology; S. Klapstein, Acadia University / Earth & Environmental Science; N.K. Hillier, Acadia University / Department of Biology; N.J. O’Driscoll, Acadia University / Department of Earth and Environmental Science

Mercury is a trace metal and a toxic environmental pollutant that can be deposited in remote ecosystems and result in adverse effects on the heath of organisms. Elevated mercury levels at the bottom of the food web have implications for significant mercury (in the form of methylmercury (MeHg)) transfer to higher trophic organisms. Kejimkujik National Park (KNP), Nova Scotia is an area with a high landscape sensitivity to interactions with mercury. MeHg bioaccumulation in KNP lakes is of high concern in the area because elevated MeHg near the bottom of the food chain, such as near-sediment invertebrates, has implications for significant mercury transfer to higher trophic levels. Therefore, analysis of MeHg concentration in aquatic invertebrates and the relationship with water and sediment characteristics is required to understand food web bioaccumulation and relative bioaccumulation between invertebrates. Mayfly naïads, caddisfly larvae, lake water, and benthic sediments were collected from two lakes and one wetland catchment in KNP. Methylmercury (MeHg) was analyzed in all samples using gas chromatography-atomic fluorescence spectroscopy (AFS). MeHg concentrations in mayflies and caddisflies ranged from 14.28–427.78 ng/g (N=58), 0.05–0.46 ng/L (N=45) in water, and 0.02–28.94 ng/g (N=22) in sediment. Results indicated that mayfly MeHg concentration was positively correlated with water MeHg concentration (Spearman Rank correlation coefficient (rs)=0.43; P-value=0.02). Caddisflies may be more associated with sediment MeHg concentration than water MeHg (rs=0.45;0.07, respectively), although correlations were not significant. Most sediment and invertebrate samples and all water samples from the wetland catchment were significantly higher in MeHg concentration than the lake locations because wetlands are areas of efficient MeHg production. In conclusion, no significant relationships
were observed between MeHg concentration in caddisfly and mayfly and sediment MeHg. However, our data suggest that mayfly MeHg concentration is influenced by water characteristics (MeHg, pH). Analysis of MeHg bioaccumulation in aquatic invertebrates and the relationships with water and sediment characteristics are key. More research into MeHg bioaccumulation is necessary to better understand food web transfer.

**MP135 Assessing the mobilization potential of mercury during bog restoration**

*S. Klapanstein, Acadia University / Earth & Environmental Science; R. Cameron, Nova Scotia Provincial Government / Department of Environment; A. Walker, Acadia University / Biology Department; J. Murimboh, Acadia University / Chemistry; C. Hallett Saunders, Acadia University / Biology Department; N. O’Driscoll, Acadia University / Earth & Environmental Science*

Restored peat bog ecosystems create favourable conditions for methylation and therefore the formation of neurotoxic mercury that can bioaccumulate and biomagnify through food webs. A restoration project in a historically disturbed (ditched, drained, and then colonized by approximately 8000 herring gulls) bog ecosystem has raised the water table to pre-disturbance levels. This shift in hydrology has inundated peat that has experienced decades of drying and wetting cycles and consequently reiterative oxidation-reduction. To assess the potential for mercury mobilization and the formation of bioavailable methylmercury under post-restoration bog conditions, we extracted 10 cm diameter surface cores (0 - 20 cm, 20 - 40 cm, and 40 - 60 cm depth) from 3 sites: 2 sites within the disturbed Big Meadow Bog in southwestern Nova Scotia and 1 control site with no known disturbance. Cores were frozen and divided into 2 cm increments. Each subsample was then dried for up to 3 weeks at 20°C under low humidity mimicking an induced disturbance such as water table drawdown. Subsamples were then submerged in deionized water for 1 hour to rehydrate, gravity-drained for 15 minutes, and then flooded and leached for 1 hour. Leachates were analyzed for organic carbon, total mercury, and methylmercury. Field moisture, initial water holding capacity, varied more greatly in the control site (14-41%) than the ditched and nutrient sites (13-26% and 16-25%, respectively). Organic carbon concentrations of solid peat were consistent with depth across all sites (94-100%) and dissolved organic carbon concentrations in leachate decreased minutely with depth at all 3 sites and were very low (< 0.3 ppm). Total mercury in the leachate represented about 0.005% of the mercury in the solid peat whereas methylmercury in the leachate represented about 0.01% of the methylmercury in the solid peat. The disturbed sites had similar total mercury depth profiles in leachates with depth with more total mercury near the surface (10-15 cm), whereas the control site peaked in higher total mercury concentrations in the leachates from at 20-30 cm depth. Methylmercury concentrations in leachates tended to be higher near the surface (0 - 10 cm) across all sites. This experiment was conducted pre-restoration and indicates the potential for mercury mobilization and specifically methylmercury mobilization in the wetland outflows.

**MP136 Delineating sources of mercury and trace metals using epiphytic lichens in Nova Scotia, Canada**

*S. Klapanstein, Acadia University / Earth & Environmental Science; R. Cameron, Nova Scotia Provincial Government / Department of Environment; A. Walker, Acadia University / Biology Department; J. Murimboh, Acadia University / Chemistry; C. Hallett Saunders, Acadia University / Biology Department; N. O’Driscoll, Acadia University / Earth & Environmental Science*

Mercury is a persistent pollutant present in all ecosystems. The prevalence and speciation of mercury will determine its movement in the atmosphere and potential to bioaccumulate and biomagnify through food webs. Monitoring of mercury and other trace metals can be costly, whereas the use of naturally occurring epiphytic lichens can be an effective tool for these types of studies. Nova Scotia, Canada is a hotspot for mercury and other trace metal accumulation in ecosystems, partially attributed to long-range transport of anthropogenic air pollution. The region also contains a number of historic gold mining sites that are known to have persistent high levels of mercury and arsenic in sediment. The relative contribution of local and national sources of mercury to local air is unknown. This work aimed to address which elements can be effectively monitored using lichens. Trace metals in lichens other than mercury may also help elucidate the potential sources of these elements: whether from geological, re-emission, or long-range transport. Almost 200 lichen (*Usnea spp.*) samples were collected across Nova Scotia and analyzed for total mercury (THg); a subset of these samples was analyzed for other trace metals, including arsenic, nickel, copper, cadmium, lead, and selenium (n=163). Significant variation in mercury content was observed across sampling sites and GIS analysis was used to display and model these regional trends. While broad spatial resolution was the initial focus for these collections, a few target areas (biological mercury hotspot Kejimkujik National Park and historic gold mining areas) were also sampled in more intensively to confirm spatial patterns and if these target areas deviated as expected from background concentrations of mercury and other trace metals. Similar to other monitoring studies of lichens and mosses as bioindicators of mercury deposition, this research provides an excellent baseline for a long-term monitoring program of mercury in Atlantic Canada with ongoing industrial activity and a changing climate.

**MP137 Assessment of the concentrations of mercury, selenium, and their molar ratios in traditional foods of the Bigstone Cree community in Alberta, Canada**

*N. Golzadeh, McGill University / Natural Resource Sciences; B. Barst, University of Alaska, Fairbanks / Water and Environmental Research Centre (WERC); N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; J.M. Baker, Athabasca University / Department of Anthropology; J. Auger, Bigstone Cree First Nation Community; M.A. McKinney, McGill University / Department of Natural Resource Sciences*

Traditional foods provide nutritional, social, and economic benefits for Indigenous communities; however, anthropogenic activities have led to increasing concerns over the levels of mercury (Hg), especially methylmercury (MeHg), in these foods. This issue may be of particular concern for communities adjacent to large industrial activities, such as the Bigstone Cree near the Athabasca oil sands region of Alberta, Canada. In this community-led study, our main objective was to assess variation in THg and MeHg concentrations among traditional food types (plants or animals), species, and tissues (muscles or organs). We also assessed variation in concentrations of the micronutrient selenium (Se)—thought to protect against Hg toxicity—and in Se:THg ratios. Thirteen species of plants and animals were collected in 2015 by members of the Bigstone Cree community. From this, we quantified THg, Se, and Se:THg ratios in 65 plant and 111 animal samples and MeHg in 106 animal samples. For plants, the lichen, old man’s beard (*Usnea spp.*), showed the highest concentrations of THg and Se (0.11 ± 0.02 µg g⁻¹, wet weight (w.w.) and 0.08 ± 0.01 µg g⁻¹, w.w., respectively) and also had a low Se:THg molar ratio. Concentrations of THg, MeHg, and Se significantly differed among animal samples (mixed model, P < 0.01), showing variation among species and among tissues/organisms. Generally, concentrations of THg and MeHg were highest in aquatic animals including whitefish (*Coregoninae clupeiformis*) and mallard duck (*Anas platyrhynchos*), which also had relatively low Se:THg molar ratios. Overall, our results revealed substantial variation in the patterns of THg, MeHg, Se and Se:THg ratios across this comprehensive basket of traditional foods. Thus, measuring concentrations of THg alone, without considering MeHg and potential associations with Se, may not adequately convey the exposure to Hg in assessment studies of traditional foods.
MP138 Nutrient Stoichiometry (C:N:P) and Methylmercury Bioaccumulation in Arctic Freshwater Zooplankton

G.A. MacMillan, McGill University / Natural Resource Sciences; J. Chéretel, Environment and Climate Change Canada / National Wildlife Research Centre; M. Richardson, Carleton University / Geography and Environmental Studies; M. Amiot, University of Montreal / Biological Sciences

To predict long-term shifts in mercury dynamics with climate change, we need to better understand how aquatic productivity influences methylmercury (MeHg) bioaccumulation in freshwater food webs. Although studies have shown strong interactions between nutrient stoichiometry (C:N:P) and metal accumulation in the laboratory, relationships between these two variables have not been adequately tested in northern lakes. In this study, we sampled a gradient in ecosystem productivity in the eastern Canadian Arctic and measured MeHg bioaccumulation and carbon:nutrient ratios in seston and zooplankton from 47 lakes. Observations spanning 20° of latitude were used to compare MeHg bioaccumulation with water chemistry, food resource quality, growth rates, and food web structure. Contrary to previous findings at temperate latitudes, seston biomass, chlorophyll concentrations and seston nutritional quality (seston %P, and C:N, C:P ratios) were not good predictors of either seston or zooplankton MeHg concentrations. Rather, bulk zooplankton (57 ± 45 ng g-1) and Daphnia MeHg concentrations (101 ± 86 ng g-1) were positively correlated with water MeHg concentrations and only weakly negatively correlated to water nutrient concentrations (TN, TP). The highest zooplankton MeHg concentrations were found in lakes with high MeHg and low TN in surface waters. Overall, we found that indicators of lake productivity, seston nutritional quality and organism growth rates did not explain MeHg bioaccumulation, as predicted by biodilution theory. We suggest that aqueous MeHg exposure is the dominant factor controlling MeHg uptake at the base of these freshwater food webs, and that seston biomass and nutritional quality are not key drivers of MeHg bioaccumulation in these northern systems.

MP139 Use of Neural Network Models to Predict Ecosystem Response to Remediation in the Mercury-Impacted South River System

S. Thakali, AECOM / Remediation/Risk; D. Baldwin, AECOM; J. Collins, AECOM / DCS Remediation; N.R. Grosso, Corteva / Environmental Remediation

Historical mercury releases occurred at a textile manufacturing facility on the South River, Virginia, which led to increased mercury concentrations in biotic (fish tissue) and abiotic media (sediment and surface water). The mercury concentrations were expected to decline over the past forty years but remain higher than expected in these media. The current concept is that MeHg bioaccumulation in freshwater food webs, the cumulative impacts of MeHg from upstream to downstream, if mercury levels are affected by different harvesting intensities. To answer these questions three watersheds in New Brunswick, Canada were selected with different intensities of forest management with six sites each, each at a different harvesting intensity. The samples taken in fall 2018 from each site included water, seston, three food sources, five aquatic invertebrates representing different functional feeding groups, and slimy sculpin (Cottus cognatus) (n=2-10/sample type). To assess mercury bioaccumulation in a food web the food sources and invertebrates are being analyzed for MeHg and fish for total mercury (THg) while stable isotopes of carbon, nitrogen and hydrogen will be used to determine the food web structure. Water and seston samples have been analyzed using inductively coupled plasma mass spectrometry (ICP-MS) and MeHg levels varied from 0.0005 to 0.150 ng/L for water and 0.200 to 11.0 ng/g for seston across all sites. The average MeHg levels in water and seston for each watershed from the most intensively harvested to least harvested were 0.039 ng/L and 4.10 ng/g, 0.095 ng/L and 4.19 ng/g, and 0.027 ng/L and 2.28 ng/g. These findings start to fill a knowledge gap by giving a holistic understanding of MeHg in stream systems by investigating how it bioaccumulates in foodwebs, culminates in space and if MeHg levels change with harvesting intensity. This type of information can be used to focus efforts when improving best management practices for forest harvesting.

MP140 Does forest harvesting change methylmercury levels in New Brunswick stream systems and in aquatic food webs?

L. Negrazis, McMaster University; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute

Forestry harvesting is one of the most important natural resource industries in Canada, yet it is also a major disturbance on forest ecosystems. Some of the impacts include increasing sediment loading, altering nutrient cycling and increasing mercury inputs into freshwater systems from run-off, and creating more aquatic environments that produce the neurotoxin, methylmercury (MeHg). Research on MeHg in fish, water, and zooplankton exists but mainly focuses on each component separately at a small scale within headwater streams and at high harvesting intensities. The objective of this thesis is to understand broader scale impacts of forestry on MeHg by looking at the bioaccumulation of MeHg in food webs, the cumulative impacts of MeHg from upstream to downstream, as well if mercury levels are affected by different harvesting intensities. To answer these questions three watersheds in New Brunswick, Canada were selected with different intensities of forest management with six sites each, each at a different harvesting intensity. The samples taken in fall 2018 from each site included water, seston, three food sources, five aquatic invertebrates representing different functional feeding groups, and slimy sculpin (Cottus cognatus) (n=2-10/sample type). To assess mercury bioaccumulation in a food web the food sources and invertebrates are being analyzed for MeHg and fish for total mercury (THg) while stable isotopes of carbon, nitrogen and hydrogen will be used to determine the food web structure. Water and seston samples have been analyzed using inductively coupled plasma mass spectrometry (ICP-MS) and MeHg levels varied from 0.0005 to 0.150 ng/L for water and 0.200 to 11.0 ng/g for seston across all sites. The average MeHg levels in water and seston for each watershed from the most intensively harvested to least harvested were 0.039 ng/L and 4.10 ng/g, 0.095 ng/L and 4.19 ng/g, and 0.027 ng/L and 2.28 ng/g. These findings start to fill a knowledge gap by giving a holistic understanding of MeHg in stream systems by investigating how it bioaccumulates in foodwebs, culminates in space and if MeHg levels change with harvesting intensity. This type of information can be used to focus efforts when improving best management practices for forest harvesting.

MP141 The influence of temperature on mercury methylation and demethylation potentials in high Arctic lake sediments

K. Hudelson, University of Windsor / Environmental Science; P. Drevnick, Alberta Environment and Parks / Environmental Monitoring and Science Division; F. Wang, D. Armstrong, University of Manitoba / Centre for Earth Observation Science, Department of Environment and Geography; A. Fisk, University of Windsor / Great Lakes Institute for Environmental Research

The fate of mercury (Hg) in Arctic environments is uncertain in the face of climate change disruptions to the cryosphere. Mercury methylation and demethylation are key factors that influence exposure and Hg concentrations in fish and humans, but these processes are poorly characterized in Arctic lakes. In lakes, most methylation occurs in the sediments, and the rate of the methylation reaction has been shown to be temperature dependent. We hypothesized that warmer lakes would exhibit higher methylation potential in the Arctic, and that warmer incubation temperatures would increase methylation potential in sediments. We also hypothesized that warming would have less of an effect on demethylation potential and that demethylation potential would not vary significantly among lakes. We collected littoral sediments from four well studied high Arctic lakes, to estimate methylation and demethylation potentials using
Hg stable isotope tracers at incubation temperatures of 4, 8, or 16 °C for 24 hrs. Overall, the magnitude of the methylation potential exceeded that of the demethylation potential, but this was not the case in all lakes. Methylation potential were greatest in sediments from the warmest lake and responded to increased temperatures in the warmest and in the coolest lakes. Demethylation potential was less affected by temperature but was more pronounced in sediments with greater [MeHg]. Overall, our results demonstrate significant lake-to-lake variation in methylation potential and evidence that both relatively warm and cold lakes can exhibit rapid increase in methylation potential due to warming.

**MP142 Trends in Atmospheric Mercury Fractions and Wet Mercury Deposition Across the United States**  
*C. Olson, Middle Tennessee State University / Civil and Environmental Engineering; H. Fakhraei, C.T. Driscoll, Syracuse University / Civil and Environmental Engineering*

The creation of long-term monitoring programs has proved invaluable in assessing the efficacy of environmental policies. Two such programs, the Atmospheric Mercury Network (AMNet) and the Mercury Deposition Network (MDN), have been used to characterize the magnitude and changes in concentrations of gaseous elemental mercury, particulate mercury and gaseous oxidized mercury, and wet mercury deposition across the United States. These networks provide information on the spatial and temporal responses of air quality management aimed at reducing mercury emissions. Recently, the United States Environmental Protection Agency (USEPA) has proposed to roll back Mercury Air Toxics Standards (MATS), raising questions about the effectiveness of such policies and how the environment will respond to their removal. Presented here is an analysis of the long-term trends in concentrations of atmospheric mercury fractions and mercury wet deposition across select MDN and AMNet sites, and their relationships to changes in mercury emissions. The results of these analyses show significant decreases in concentrations of all fractions of atmospheric mercury and wet mercury deposition across the United States, but particularly in the east, with only few sites showing significant increases. Also presented are short-term trends in mercury emissions from several states measured during the course of MATS’ enforcement. These results highlight the long-term effectiveness of air pollution control and underscore the importance of maintaining these policies and mercury monitoring programs.

**MP143 Total Mercury and Methylmercury Concentrations in Rice From Three Cities in Vietnam (Hanoi, Hue, and Ho Chi Minh City)**  
*V. Hoang, S. Rothenberg, Oregon State University / Environmental & Occupational Health*

Background: Vietnam is the third highest rice consuming country in the world (405 g rice/capita/day). However, there are no studies concerning total mercury (THg) and methylmercury (MeHg) in rice; yet, this is an important dietary source of mercury and other metals. The purpose of this study was to assess THg and MeHg levels in polished rice samples purchased in Vietnam. In addition, a comprehensive review of THg and MeHg concentrations in rice was completed for papers published since 2014, to update our previous review. Methods: In 2018, a convenience sample of 100 polished rice samples were purchased in three major cities in Vietnam, including Hanoi (n=46 rice samples, 9 stores), Hue (n=15 rice samples, 3 stores), and Ho Chi Minh City (n=39 rice samples, 3 store) (n=100 total, 15 stores). Rice THg and MeHg concentrations were determined using EPA 1631 and 1630, respectively. Using ISI Web of Science and U.S. National Institutes of Health PubMed, we searched papers in English using the terms “rice” and mercury,” which were published since 2014. Results: In Vietnam, the median values for THg and MeHg were 1.2 ng/g (range: 0.49-20 ng/g) and 0.41 ng/g (0.12-5.5 ng/g), respectively, and the median value for %MeHg (of THg) was 35% (range: 11-76%). There were no significant differences in THg, MeHg, and %MeHg (of THg) between the three Vietnamese cities (ANOVA, p-value range: 0.17-0.99). For the comprehensive review, 32 manuscripts reported rice THg and/or MeHg concentrations in nine countries since 2014. The median values for rice THg, MeHg and percent MeHg (of THg) for non-polluted sites were 4.7 ng/g, 2.4 ng/g, and 54%, respectively. For polluted sites, the median values for rice THg, MeHg and percent MeHg (of THg) were 69 ng/g, 14 ng/g, and 32%, respectively. All values for Vietnamese rice THg and MeHg concentrations fell within the ranges for non-polluted sites. Conclusions: In Vietnam, rice THg and MeHg levels were similar to rice cultivated in non-polluted areas, and were considered low-level. However, rice does not contain the same nutrients as fish, and thus the health impacts due to MeHg exposure are uncertain. Also, Vietnam has one of the highest rice ingestion rates globally, and thus MeHg exposure levels through rice ingestion may be elevated, and should be further investigated.

**MP144 Freshwater subsidies to insectivores: characterization of risks from methylmercury and benefits from omega-3 highly unsaturated fatty acids**  
*S.A. Dzielski, SUNY ESF / Department of Environmental and Forest Biology; C.W. Twining, University of Konstanz / Limnological Institute; L.B. Cleekner, Hobart and William Smith Colleges / Finger Lakes Institute; R. Rasuvi, SUNY ESF / Department of Environmental and Forest Biology*

Aquatic environments are sources of mercury (Hg) to insectivores such as birds. However, aquatic environments are also important sources of omega-3 highly unsaturated fatty acids (HUFAs), which are essential to meet nutritional requirements of nearly all organisms. HUFAs thus represent a benefit of consuming a dominantly aquatic diet while Hg represents a cost. Here we investigate aquatic subsidies of methylmercury (MeHg) and HUFAs to Eastern Phoebe (Sayornis phoebe) chicks. Stable isotopes of carbon, nitrogen and hydrogen were also used to estimate chick diet from aquatic versus terrestrial sources. We predicted that 1. Eastern Phoebe chicks whose diets contain more aquatic insects would have higher MeHg feather concentrations than chicks with more terrestrial diets and 2. aquatic insects contained more MeHg than terrestrial prey. Previous research showed that that aquatic insects were nearly as high in the HUFA eicosapentaenoic acid (EPA) compared to terrestrial prey, demonstrating the benefits of consuming emergent aquatic insects, and that Eastern Phoebe chick EPA d13C values were similar to those of aquatic insects, confirming that the source of their HUFA was from aquatic insects. Significant differences were found across sites in chick feather MeHg concentrations, and feather MeHg concentrations increased linearly with d13C. Preliminary data did not show a linear increase in Hg concentration with increasing proportion of aquatic diet. Further analyses of diet items will provide an assessment of the risks and benefits to wildlife of relying upon aquatic food sources contaminated by anthropogenic activities.

**Stockholm Convention on POPs: Progress in Monitoring, Research and Risk Assessment of Legacy and Emerging Chemicals**

**MP145 New measurements and consistency tests for physicochemical properties of phosphate flame retardants**  
*S. Endo, National Institute for Environmental Studies (NIES) / Center for Health and Environmental Risk Research; H. Karamochi, National Institute for Environmental Studies, Japan / Center for Material Cycles and Waste Management Research*

Phosphate flame retardants (PFRs) have increasingly been used as a result of restrictions of existing flame retardants. According to preliminary evaluations, some PFRs are suspected to have partitioning properties that are similar to those of existing POPs. Because of the absence of experimental data, such early evaluation typically uses predicted property values. Predictions tools could, however, generate errors by many orders of magnitude and thus need to be calibrated or validated.
against reliable experimental data, leading to a tautology problem. Hence, there is a steady need for accurate experimental property values with high accuracy for chemicals with diverse structures. In this presentation, we report new measurements of vapor pressure (P), aqueous solubility (Sw), and octanol-water partition coefficients (Kow) of triphenyl phosphate (TPHP), tri-m-cresyl phosphate (TmCP), and tri-p-cresyl phosphate (TpCP). P was measured with a gas saturation method, using PFR-coated beads packed in a stainless-steel column. P measurements around ambient temperature were conducted for the first time with these chemicals. Sw was measured with the conventional shake-flask method as well as an indirect method using the measured silicone/water partition coefficient and the solubility in silicone, and consistency of the results was evaluated. Kow was determined from the measured Sw and solubility in octanol as well as the measured silicone/water and silicone/octanol partition coefficients. Consistency was evaluated together with literature Kow measured by the established slow-stirring and generator column methods. All property values were compared to the existing values measured or predicted in the literature. We also predicted the values based on the COSMO-RS theory using COSMOtherm software. The first results indicate that P values measured around 25°C were much lower than previously reported estimations, while existing values for Kow and Sw are relatively accurate, suggesting that evaporation properties of PFRs need more intense experimental investigations.

**MP147 The concentration distribution and source of dioxin-like PCBs in air and soil in Republic of Korea**

D. Oh, Korea Environment Corporation

IntroductionPolychlorinated Biphenyls were used for transformers, capacitors’ insulating oils, lubricants, and plasticizers because of their excellent electrical insulation and thermal stability. PCBs are representative POPs along with dioxin and listed in annex A and C in the Stockholm Convention. Especially, among PCBs, dioxin-like PCBs (dl-PCBs) have a similar toxicity to dioxin. dl-PCBs which have a lot of chlorine is more easily adsorbed by airborne suspended dust or strongly adsorbed to soil. In addition, PCBs stay stable for longer periods of time in soil than other environmental media. This study was performed to see the differences how PFOA is distributed over in rivers and lakes in the Republic of Korea. This study describes PFCs are soluble in water, unlike general persistent organic pollutants, and drinking water has been pointed out as important human intake sources. PFOA has been listed as a persistent organic pollutant (Annex A) in the 2019 Stockholm Convention and is the only PFOA designated as a carcinogen by IARC under WHO. This study describes opportunities for inter-comparison modeling collaborations to possibly include but not be limited to: 1. Process oriented studies of POP/EC LRAT including joint analysis of modelling results and monitoring data (e.g. gas-particle partitioning, degradation, etc.) 2. Iterative integrated modeling (forward and inverse) to evaluate and assess qualified emission databases and uncertainties. 3. Modelling of Arctic pollution (and/or other regions/receptors) using emission scenarios and projections (e.g. thermal, shipping, waste combustion, etc.). 4. Model evaluation of trends in POP/EC deposition to the Arctic (and ecosystem receptors) including estimates of contribution of major groups of emission sources (e.g. based on HTAP, EDGAR, Stockholm Convention). 5. Sensitivity model simulations to evaluate effects of changes in meteorological conditions and atmospheric composition related to climate change. 6. Modeling with alternative parameterization the LRAT for SVOCs with high octanol-air partition coefficient. 7. Modelling how climate change influences the first and secondary emissions of POPs/ECs. 8. Understand the first and secondary fractionations under climate change conditions. Discussion at the conference will help refine and propose a concrete agenda for international collaboration serving the Stockholm Convention, LRTAP (e.g. HTAP) and AMAP and invite additional participants.

**MP148 POPS/EC Long Range Transport & Emission Uncertainties: Opportunities for Inter-comparison Modeling Collaborations**

P.W. Bartlett, Saint Peters University / Social Justice / Education; Y. Li, Harbin Institute of Technology; A. Gusev, Meteorological Synthesising Centre East; J. Ma, Peking University / College of Urban and Environmental Science; S. Tao, Peking University / Laboratory for Earth Surface Processes College of Urban and Environmental Sciences; C. Friedman, Maine Maritime Academy / Ocean Studies; R. Guardians, MARM; M. Muntean, European Commission Joint Research Centre / Energy, Transport and Climate Directorate; J. Kelly, Massachusetts Institute of Technology / Institute of Data, Systems, and Society; N.E. Selin, Massachusetts Institute of Technology / IDSS/EAES

There are many uncertainties of global emissions, Long Range Transport (LRT) and exposure of Persistent Organic Pollutants (POPs) and persistent Emerging Contaminants (ECs) for which modeling can be an effective tool to improve our understanding. This poster proposes and invites international research collaborations of inter-comparison modeling to better understand LRT from observations and incomplete emission estimates. Assessments by the Stockholm Convention, the Convention of Long Range Transport of Air Pollutants (e.g. Task Force on Hemispheric Transport of Air Pollutants, HTAP) and the Arctic Monitoring Assessment Programme (AMAP) identify key uncertainties and areas for which modeling can potentially be of great value. The global nature of the problem and extent of uncertainties call for an international collaborative modeling initiative. We focus on the Arctic since the unexpected discovery of many ECs in the Arctic call for a greater understanding of emissions and LRT. Specific ecosystem (e.g. biological effects), and food web receptors are also important to investigate. We suggest inter-comparison modeling collaborations to possibly include but not be limited to: 1. Process oriented studies of POP/EC LRAT including joint analysis of modelling results and monitoring data (e.g. gas-particle partitioning, degradation, etc.) 2. Iterative integrated modeling (forward and inverse) to evaluate and assess qualified emission databases and uncertainties. 3. Modelling of Arctic pollution (and/or other regions/receptors) using emission scenarios and projections (e.g. thermal, shipping, waste combustion, etc.). 4. Model evaluation of trends in POP/EC deposition to the Arctic (and ecosystem receptors) including estimates of contribution of major groups of emission sources (e.g. based on HTAP, EDGAR, Stockholm Convention). 5. Sensitivity model simulations to evaluate effects of changes in meteorological conditions and atmospheric composition related to climate change. 6. Modeling with alternative parameterization the LRAT for SVOCs with high octanol-air partition coefficient. 7. Modelling how climate change influences the first and secondary emissions of POPs/ECs. 8. Understand the first and secondary fractionations under climate change conditions. Discussion at the conference will help refine and propose a concrete agenda for international collaboration serving the Stockholm Convention, LRTAP (e.g. HTAP) and AMAP and invite additional participants.

**MP149 Distribution concentration for PFOA in water in Republic of Korea**

K. Son, S. Han, Korea Environment Corporation

IntroductionPFCs (perfluorinated compounds) is the fluorine-substituted structure of the basic skeleton of hydrocarbons and is used in the industry as a surfactant. PFCs are soluble in water, unlike general persistent organic pollutants, and drinking water has been pointed out as important human intake sources. PFOA has been listed as a persistent organic pollutant (Annex A) in the 2019 Stockholm Convention and is the only PFOA designated as a carcinogen by IARC under WHO. This study describes how PFOA is distributed over in rivers and lakes in the Republic of Korea.

Materials and methodsThe water samples were collected from Han River (8), Nak-Dong river (9), Geum river (5), Young-San river (4) and the others stream (10) from 2015 to 2016 (spring and autumn in each year) at a total of 36 sites. The water samples were taken using 500 mL polypropylene disposable screw-cap containers. The samples were purified by solid phase extraction (SPE) after removing the suspended material. The.
procedure is as follows. Activated the cartridge with 4 mL methanol and 4 mL distilled water and passed the sample. After the cartridge was washed with 20% methanol-distilled water, the remaining water was completely removed from the cartridge in the vacuum state and 5 mL of 0.1% ammonia-methanol solution was passed through the cartridge twice. The final samples were concentrated and analyzed using LC/MS/MS. Results and discussion POFA is detected at a relatively high concentration than PFOS. Some POFA was detected in the Nak-Dong River, Geum River, and other streams, but the Han River and Young-San River were below detection limits. Go-Ryung Bridge in the Nak-Dong River (123.615 ng/L in 2015, 16.056 ng/L in 2016) and the Geum-Gang Bridge (161.610 ng/L in 2015, 83.609 ng/L in 2016) and Geum-Gang estuary (201.876 ng/L in 2015, 152.012 ng/L in 2016) in the Geum River were relatively high. It is possible to affected by effluent which contains. There was no correlation between the concentrations in the season (spring and autumn), but all the annual mean concentrations of POFA in 2015 were decreased in 2016.

MP150 Nitrosamines analysis in drinking water using GC/MS/MS at ultra-trace levels

Nitrosamines, particularly NDMA, are a group of disinfection byproducts frequently detected in finished drinking water and of concern to environmental agencies. The USEPA Office of Groundwater and Drinking Water (OGWDW) developed Method 521 in 2004 to provide a procedure for trace level analysis of seven nitrosamines in finished drinking water by solid-phase extraction and chemical ionization tandem mass spectrometry (MS/MS). Ion Trap GC/MS is the approved technology, but the system is being obsoleted. Through an interlaboratory study, we show that migration to GC/MS/MS systems provided significant improvements in speed and sensitivity. This work demonstrates a GC/MS/MS method to allow for monitoring at levels below the current LCML (lowest concentration minimum reporting level) and detection limit set in Method 521. The GC/MS/MS method included the optimization of an additional nitrosamine, N-Nitrosomorpholine (NMOR). Three different laboratories collaborated to produce the LCML and performance data required for an Alternate Test Procedure method update. Results from these laboratories are compared to evaluate method feasibility and reproducibility. The method was validated by the three laboratories and written up for submission to the EPA for review. In 2008, the EPA issued a letter of equivalency deeming EEA-Agilent 521.1 for the analysis of nitrosamines in drinking water by GC/MS/MS as a method that provided equivalent performance to Method 521.

MP151 Assessment of steroid hormones and pharmaceuticals in South Florida surface waters by Liquid Chromatography-High Resolution Mass Spectrometry

N. Quinet, NC State University/Florida International University/SERC; K. Lugo, Florida International University; S. Maldonado, University of Puerto Rico; P.R. Gardinali, Florida International University/Chemistry & Biochemistry and SERC

Environmental exposure risk to different xenobiotics, which can alter the function of the endocrine system, remains a great threat to the health and safety of humans and aquatic species. Steroid hormones, pharmaceuticals, and personal care products (PCPs) have become recognized as relevant aquatic contaminants due to their widespread occurrence in surface waters and endocrine disrupting properties. Endocrine disruptors compounds (EDCs) are chemicals known to cause interferences in the reproduction system, developmental malformations, increased cancer risk, disturbances in the immune and nervous system at very low concentrations. Most previous studies in South Florida has been largely concentrated on assessing the relevance of the fate and transport of inorganic nutrients, heavy metals, and pesticides. Therefore, a significant gap exists in the occurrence and biological significance of human-related organic contaminants in surface waters. In this study, we have developed a fast and sensitive online solid phase extraction followed by liquid chromatography-high resolution mass spectrometry (SPE-LC-HRMS) method using a Q-Exactive for the determination of selected wastewater tracers, recalcitrant pharmaceuticals, PCPs, and steroid hormones in coastal ecosystems in South Florida in order to assess the water quality and potential health impacts to the aquatic system and humans. Seasonal and spatial variations of these contaminants have been monitored from 2017 to 2019. The presence of total coliforms and e-coli were also evaluated. Correlations between hormones and anthropogenic tracers will be explored to better elucidate the sources, pathways and exposure risks to these contaminants. Caffeine, sucralose, DEET and carbamazepine were frequently detected in the water samples, which is indicative of wastewater intrusion sources impacting the surface water. Estrone, estriol, β-estradiol, 17α-ethinylestradiol and diclofenac levels found in surface water raises concern of potential endocrine disruption effects in human and aquatic microbiomes.

MP152 Analysis of legacy & emerging per- and polyfluoroalkyl substances in water: Evaluation of current regulatory methods

T. Anumol, E. Parry, Agilent Technologies Inc.; H. Zhao, Agilent

Per and polyfluoroalkyl substances (PFAS) are chemicals widely used in consumer products and industry due to the unique and desirable chemical properties. Due to widespread usage and environmental persistence, legacy PFAS are ubiquitous in the environment and new fluoro-chemicals are being found in the environment frequently. Public interest has increased pressure to develop comprehensive methods for sensitive analysis in different types of water. EPA has released a revised drinking water analysis method (EPA 537.1) that includes new fluorochemicals and ASTM 7979 (draft SW-846 Method 8327 has the same sample prep procedure) can be employed for non-drinking water samples. We present data collected with these two methods with optimized analytical procedures that include all analytes listed in the methods plus several new emerging fluorochemicals. Method robustness, range, and detection levels will be presented. As the state and federal regulations continue to evolve in this field, robust analytical methods that can be adjusted to encompass new analytes will be important for confidence the public water supply.

MP153 Emissions of Fluorotelomer Alcohols from Municipal Sewage Treatment Plants: Is volatilization or effluent discharge a more relevant pathway?

C. Chen, Peking University/College of Environmental Sciences and Engineering; J. Wang, Peking University; L. Li, University of Toronto, Scarborough/Department of Environmental Sciences; W. Xu, J. Liu, Peking University

Municipal sewage treatment plants (STPs) are an important source to fluorotelomer alcohols (FTOHs), from which FTOHs can enter the aquatic environment through effluent discharge, the agricultural environment through sludge application, the atmosphere through diffusive volatilization. While several earlier studies have attempted to gauge the emissions of FTOHs from STPs, it remains unknown the emission strength per capita and the dominant portal of entry, and by extension, their seasonal variations. The lack of this information hinders our comprehensive understanding of the environmental risk of FTOHs. To this end, we conducted an on-site investigation on the multimedia emission of FTOHs from a typical STP in Beijing throughout a year. We derived the fluxes of FTOHs volatilizing to the atmosphere through measuring the gradient in air concentration above the STP, and those discharged into receiving water bodies through measuring concentrations in effluents and corresponding volumes. Our results indicate that effluent discharge is more relevant than diffusive volatilization to determine the total FTOH emissions in winter, because of the minimal volatilization at a low temperature, whereas their relative importance is reverse in other seasons. The long-chain 8.2 FTOH is still the major component, although the short-chain 6.2 FTOH becomes abundant due to the ongoing substitution of long-chain FTOH products. We extrapolated the results and concluded that ~7 kg FTOHs annually migrate from STPs to the air and aquatic environments in...
Beijing, equivalent to 0.32 mg/cap/year. Our results indicate that, to better understand the contribution of FTOH emission from STPs to environmental burdens, we should take into account the multimedia emissions through both volatilization and effluent discharge. This presentation fills in the knowledge gap of FTOH emission level via STPs for Beijing-like cities and highlights a method to improve future monitoring research for FTOHs in STPs.

**Recent Advances on the Analytical Chemistry, Fate and Mitigation of PFAS from Aqueous Film-Forming Foam (AFFF) Contamination**

**MP156 Evaluation of Current Use C6 AFFF: What do they really contain?**

R. Singh, Clarkson University / Department of Chemical and Biomolecular Engineering; T.M. Holsen, Clarkson University / Civil and Environmental Engineering; S. Mededovic Thagard, Clarkson University / Department of Chemical and Biomolecular Engineering

Aqueous film forming foam (AFFF) is a highly efficient fire suppressant agent used to extinguish flammable liquids that has been widely used at industrial and military sites. AFFF contains large concentrations of fluorinated surfactants including per- and polyfluoroalkyl substances (PFAS) which are persistent in the environment and associated with adverse health effects. In an effort to decrease their persistence and toxicity, current AFFF formulations are being advertised as containing only C6 and smaller perfluorinated surfactants and low molecular weight polymers. To evaluate this claim and better characterize currently available AFFF solutions, several AFFF samples were obtained and analyzed using mass spectroscopy before and after oxidation using the total oxidizable precursor assay (TOP). Measurable concentrations of >C6 acids were found including PFHpA, PFOA, PFNA, PFOS, PFDA, and PFDS. The TOP assay was only partially effective at oxidizing the precursors so increased doses and reaction times were needed. Even after doses of up to 240 mM persulfate and reaction times of 6 hours concentrations of PFAs and 6:2 FTS continued to increase indicating that higher doses and longer reaction times are needed to completely oxidize the precursors present. We are continuing these experiments and exploring other oxidation techniques and plasma destruction technologies for AFFF treatment.

**MP155 Estimating Total Concentrations of Polychlorinated Biphenyls in Fish Tissue using Congener Subsets**

G. Young, Advisian WorleyParsons Group / Aquatic Sciences; G. Ramesh, WorleyParsons Advisian

Polychlorinated biphenyls (PCB) are listed under the Stockholm convention, and signatories are obliged to phase out equipment containing PCBs and remediate contaminated materials by 2025. Meeting this target requires characterizing PCB concentrations in various environmental media, and developing clean disposal/destruction methods. Fish fillets from lakes near one of two facilities in Canada capable of incinerating PCB-contaminated material are sampled annually, and PCB content is analyzed according to EPA Method 1668C to assess potential human health risks. This analytical method measures concentrations of individual PCB congeners to provide accurate toxicity estimates for comparison with Canadian guidelines. However, analysis is costly and labour intensive, and the cost efficiency of environmental monitoring is an important consideration. The number of annual samples in the current monitoring program is limited and this also limits the power of statistical analyses used to track long-term trends in PCB concentrations and accumulation rates in fish from the lakes. Other monitoring programs throughout the world that collect many samples have used subsets of PCB congeners to estimate cost effectively the toxicity and total PCB concentration in biological tissue. This depends on close correlation between subset results and those for analysis of all congeners. Five PCB congener subsets were used to estimate total PCB concentrations in samples from 2013 to 2017. Estimated total PCB concentrations based on these subsets were compared with measured PCB concentrations based on all congeners using relative percent difference (RPD). The resulting RPD values were similar to those for duplicate analyses during the same time period suggesting that the accuracy of total PCB concentrations based on PCB congener subsets are within the analytical uncertainty of the more costly approach. It is crucial to maintain the reliability of analyses for health risk assessment, but our results indicate that analysis of PCB congener subsets could be a useful tool for characterizing total PCB concentrations in a greater number of samples thus improving program effectiveness.

**Recent Advances on the Analytical Chemistry, Fate and Mitigation of PFAS from Aqueous Film-Forming Foam (AFFF) Contamination**

**MP156 Evaluation of Current Use C6 AFFF: What do they really contain?**

R. Singh, Clarkson University / Department of Chemical and Biomolecular Engineering; T.M. Holsen, Clarkson University / Civil and Environmental Engineering; S. Mededovic Thagard, Clarkson University / Department of Chemical and Biomolecular Engineering

Aqueous film forming foam (AFFF) is a highly efficient fire suppressant agent used to extinguish flammable liquids that has been widely used at industrial and military sites. AFFF contains large concentrations of fluorinated surfactants including per- and polyfluoroalkyl substances (PFAS) which are persistent in the environment and associated with adverse health effects. Measurable concentrations of >C6 acids were found including PFHpA, PFOA, PFNA, PFOS, PFDA, and PFDS. The TOP assay was only partially effective at oxidizing the precursors so increased doses and reaction times were needed. Even after doses of up to 240 mM persulfate and reaction times of 6 hours concentrations of PFAs and 6:2 FTS continued to increase indicating that higher doses and longer reaction times are needed to completely oxidize the precursors present. We are continuing these experiments and exploring other oxidation techniques and plasma destruction technologies for AFFF treatment.

**MP155 Estimating Total Concentrations of Polychlorinated Biphenyls in Fish Tissue using Congener Subsets**

G. Young, Advisian WorleyParsons Group / Aquatic Sciences; G. Ramesh, WorleyParsons Advisian

Polychlorinated biphenyls (PCB) are listed under the Stockholm convention, and signatories are obliged to phase out equipment containing PCBs and remediate contaminated materials by 2025. Meeting this target requires characterizing PCB concentrations in various environmental media, and developing clean disposal/destruction methods. Fish fillets from lakes near one of two facilities in Canada capable of incinerating PCB-contaminated material are sampled annually, and PCB content is analyzed according to EPA Method 1668C to assess potential human health risks. This analytical method measures concentrations of individual PCB congeners to provide accurate toxicity estimates for comparison with Canadian guidelines. However, analysis is costly and labour intensive, and the cost efficiency of environmental monitoring is an important consideration. The number of annual samples in the current monitoring program is limited and this also limits the power of statistical analyses used to track long-term trends in PCB concentrations and accumulation rates in fish from the lakes. Other monitoring programs throughout the world that collect many samples have used subsets of PCB congeners to estimate cost effectively the toxicity and total PCB concentration in biological tissue. This depends on close correlation between subset results and those for analysis of all congeners. Five PCB congener subsets were used to estimate total PCB concentrations in samples from 2013 to 2017. Estimated total PCB concentrations based on these subsets were compared with measured PCB concentrations based on all congeners using relative percent difference (RPD). The resulting RPD values were similar to those for duplicate analyses during the same time period suggesting that the accuracy of total PCB concentrations based on PCB congener subsets are within the analytical uncertainty of the more costly approach. It is crucial to maintain the reliability of analyses for health risk assessment, but our results indicate that analysis of PCB congener subsets could be a useful tool for characterizing total PCB concentrations in a greater number of samples thus improving program effectiveness.
MP158 Identification and quantification of perfluorooctane sulfonamide isomers by liquid chromatography-tandem mass spectrometry in biological samples
G. Shan, L. Zhu, Nankai University

Characterization of perfluorooctane sulfonamide (PFOSA) isomers, a key intermediate of precursor transformation into perfluorooctane sulfonate (PFOS), is a prerequisite to understand the contribution of precursors to PFOS in the environment. However, the lack of commercial standards makes PFOSA isomers quantification in complex matrices a big challenge. For the first time, a liquid chromatography-tandem mass spectrometry (LC-MS/MS) method was established to identify and quantify PFOSA isomers. Improvement on chromatographic separation with monitoring by selective fragments allowed full resolution of six mono-, di-, and tri-methyl branched isomers of PFOSA. The isomers were identified using a series of characteristic daughter ions and the specific ions were assigned to quantify isomers: m/z 78 (n-), m/z 169 (iso-), m/z 419 (1m-), m/z 164 (2m-), m/z 259 (3m-), m/z 269 (4m-) and m/z 219 (5m-PFOSA). With the aid of 31P isotope, a stepwise tandem mass spectrometry technique, one technical product served as standard, and was used to quantify PFOSA isomers in other technical products and fish blood samples. The results indicated that the developed method displayed strong application prospect for measuring trace level of PFOSA isomers in environmental samples. The method detection limits for all isomers were in the range of 0.1 to 0.6 pg/g ww for blood samples.

MP159 Use of high-resolution mass spectrometry to assess phytoremediation of PFAS at the former Loring Air Force Base
S.L. Nason, Connecticut Agricultural Experiment Station / Environmental Science; C. Stanley, Unaffiliated; N. Zuverza-Mena, Connecticut Agricultural Experiment Station / Analytical Chemistry

The use of Aqueous Film-Forming Foams (AFFFs) has caused widespread contamination with per- and polyfluoroalkyl substances (PFAS) in areas that have been used for fire-fighter training. Such is the case at the Burn House site of the former Loring Airforce Base in northern Maine, USA, where the land now belongs to the Aroostook band of the Micmac nation. A group of concerned citizens is growing industrial hemp on the land in an attempt to reduce the contamination levels, and scientists at the Connecticut Agricultural Experiment Station (CAES) are assisting them with assessing the effectiveness of their efforts. At CAES, we are developing methods to evaluate levels of AFFF related PFAS in soil and hemp tissue using liquid chromatography coupled with quadrupole-orbitrap mass spectrometry. This tandem, high resolution mass spectrometry method has the advantage that we can both screen for a wide range of compounds and develop sensitive quantification methods for a more limited number of contaminants. Our preliminary results tentatively identified 41 PFAS in soil from the Burn House site, including both cationic and anionic compounds. Hemp will be grown on the site for the first time in summer 2019, and we will use our analysis methods to compare the amounts and distribution of PFAS in the soil and plant tissue. Our presentation will focus on the design of this collaborative project, as well as on our initial results.

MP160 Creation of an AFFF Reference Material
J. Reiner, B. Place, National Institute of Standards and Technology / Chemical Sciences Division

The National Institute of Standards and Technology (NIST) provides a wide range of reference materials for the quality assurance and quality control (QA/QC) of chemical measurements. NIST reference materials are produced to be homogenous and stable with SI-traceable, qualitative values for individual compounds or mixtures. As a unique class of organic contaminants, per- and polyfluoroalkyl substances (PFAS) present measurement challenges to the environmental analytical community that can affect the accuracy and precision of quantitative measurements. Currently, NIST has ten different reference materials with concentration values of PFAS on them; however, there are relevant gaps in the NIST library of reference materials. A major gap is a reference material of technical mixtures, specifically an aqueous film-forming foam (AFFF) material. NIST currently has four AFFF materials in-house and has botiled these materials for an interlaboratory study to determine the usability of the materials. This presentation will discuss the current efforts at NIST to produce an AFFF reference material.

MP161 Occurrence of AFFF-derived perfluoroalkyl and polyfluoroalkyl substances in the Bohai Bay, China
H. Chen, Nankai University / College of Environmental Science and Engineering; G. Munoz, S. Yo Duy, University of Montreal / Chemistry; L. Zhang, Y. Yao, L. Yi, Nankai University / College of Environmental Science and Engineering; M. Liu, McGill University / Civil Engineering; H. Sun, Nankai University / College of Environmental Science and Engineering; J. Liu, McGill University / Civil Engineering; S. Sauvé, University of Montreal / Chemistry

Limited data are available regarding the occurrence and distribution of aqueous film-forming foam (AFFF) related PFASs in urban environments in China. In the present study, 53 PFASs were quantitatively monitored in surface river water, groundwater, seawater, and sediment samples collected around the Bohai Bay, China. Perfluorooctanoic acid, perfluorooctane sulfonic acid, and 6:2 chlorinated fluoropolyfluorinated ether sulfonic acid (6:2 CF-PFESA) were the predominant PFASs in all environmental matrices. AFFF-related PFASs such as 6:2 fluorotelomer sulfonamide alkylbetaine (6:2 FTAB) and perfluorooctane sulfonamidoal kyl amine (PFOSA) were also widely detected. To our knowledge, this constitutes the first report of zwitterionic and cationic PFASs in coastal seawater and sediment. Field-derived sediment-water partitioning coefficients confirm that cationic and zwitterionic PFASs tend to be strongly associated with the sediment. Fifteen classes of infrequently reported PFASs were qualitatively identified through suspect screening using high-resolution Orbitrap mass spectrometry. In particular, n,2 CF-PFESA, hydrogen-substituted fluorokelyther homologs, and p-perfluorooctane nonoxynbenzensulfonate (OBS) were identified across all environmental matrices. Fluorotelomer-based PFASs, including n,2 FTAB and n,2 fluorotelomer sulfonamide amine homologs, were present in the water and sediment samples. Most of these emerging PFASs were reported at high concentration levels. Monitoring efforts were initiated to document the spatial distribution of perfluoroalkyl acids (PFAs) in urban areas.
in samples collected near the south and central portions of the river, compared to those collected near the north shore. The marked spatial trends of PFECHS within the different water masses could indicate the prevalence of upstream sources (e.g., Laurentian Great Lakes), as was observed for some other pollutants targeted in this survey.

**MP163 Spatial trends of legacy and novel perfluoroalkyl substances in tap water in Québec, Canada**

S. Vo Duy, G. Munoz, University of Montreal / Chemistry; J. Liu, McGill University / Civil Engineering; S. Sauvé, University of Montreal / Chemistry

Perfluoroalkyl and polyfluoroalkyl substances (PFASs) have been reported in the St. Lawrence watershed, but limited monitoring data are available regarding their occurrence in drinking water produced from the river, tributaries, and groundwater. The present survey set out to investigate the occurrence of perfluoroalkyl acids, some of their anionic, cationic, and zwitterionic precursors, and ether-PFASs in drinking water. The analytical procedure involved off-line solid-phase extraction and UHPLC-HRMS analysis with new mobile phase modifiers to improve retention and sensitivity of short-chain PFASs. Method quantification limits in the sub-part-per-trillion range were obtained for all compounds with accuracy and precision compliant with acceptability criteria. The method was applied to drinking water samples collected in 2018 at a large spatial scale from public tap water supplies in Quebec, Canada. Overall, 99% of the tap water samples were positive to at least one PFAS. Perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) were the most recurrently detected (88% and 80%, respectively). Regardless of the particular treatment technology, PFOS levels were generally higher in tap water produced from the St. Lawrence River compared to other sources (other rivers or groundwater). The 6:2 fluorotelomer sulfonate (6:2 FTSA) was detected in 21% of samples, while 8:2 FTSA and 6:2 fluorotelomer sulfonamidoalkyl betaine (6:2 FTAB) were less frequent. Our study also confirms results from an earlier survey indicating the potential widespread exposure to short-chain perfluoroalkyl sulfonamides, especially the C4 and C6 homologs, while a cyclic perfluoroalkyl acid was also recurrently detected in tap water.

**MP164 Bioaccumulation potential of novel fluoroalkyl substances in soil to earthworm microcosms**

G. Munoz, University of Montreal / Chemistry; M. Desroisiers, Center of Expertise in Environmental Analysis of Quebec; S. Vo Duy, University of Montreal / Chemistry; J. Jarjour, J. Liu, McGill University / Civil Engineering; S. Sauvé, University of Montreal / Chemistry

Various classes of per- and polyfluoroalkyl substances (PFASs) were recently discovered in aqueous film-forming foams (AFFFs) and environmental samples impacted by AFFF activities. However, critical knowledge gaps remain regarding their environmental fate and effects, including assessment of their bioaccumulation potential. Here, we performed a comprehensive assessment of the bioaccumulation of legacy and newly-identified PFASs, using earthworms (Eisenia fetida) as model organisms. Extraction procedures were first validated for improved recoveries of fluorotelomer sulfonamidoalkyl betaines (FTAB) and fluorotelomer betaines (FtB) from soil and earthworm matrix. This allowed a more accurate assessment of bioaccumulation factors (BSAF) for compounds without authentic standards. In the first step of this study, earthworms were exposed to soils amended with AFFFs (Ansol, Arctic Foam) or pure standards, as well as to a field-collected soil impacted by fire-equipment testing activities. The 6:2 FTAB bioaccumulated in earthworms but showed a substantially lower BSAF compared to that of perfluorooctane sulfonate. In earthworms exposed to Ansolite amended soil, the BSAF exhibited certain chain length dependence for n:3 FtB and n:1.2 FtB. In the second step of this study, earthworms were collected in situ from an active firefighting training area and submitted to UHPLC-HRMS analysis. Fluorotelomer sulfonates were detected at elevated levels in field-collected earthworms, especially the 6:2 and 8:2 homologs. Several major PFAS classes are also reported for the first time in terrestrial organisms, including FTAB, FtB, fluorotelomer thioether amidosulfonates, and presumed biotransformation intermediates.

**MP165 In situ and laboratory assessment of PFAS effects using the in situ Toxicity Diagnostic System (iToDS)**

E.C. Cervi, University of Michigan / SEAS; G.A. Burton, University of Michigan / School for Environment and Sustainability; E. Verhamme, T. Dekker, J. Daley, LimnoTech; C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering; N. Fitzgerald, University of Minnesota

An in situ Toxicity Diagnostic System (iToDS) was developed to better establish stressor exposure-causality. Recently, we evaluated its use for detecting per- and polyfluoroalkyl substances (PFASs) exposures and adverse biological effects. ToDS deployment was conducted in the Clinton River, Michigan; previously identified as a PFAS hotspot. The iToDS units were acid cleaned (12% hydrochloric acid) prior to deployment. Each unit was connected to a 500 mL polypropylene collection bottle via silicone tubing with an additional check valve to prevent backflow into the bottles. Commercially available resins were preweighed (3-5 g each, dry) and preconditioned with deionized water or methanol. Resins chosen for deployment included activated carbon (AC), Oasis HLB, Oasis WAX, and glass wool. AC, HLB, and WAX were chosen as active resins while glass wool represented a control (no chemical removal). Daphnia magna were placed in exposure chambers to assess acute (in situ) and chronic toxicity (post-exposure reproduction) of water processed by each resin chamber. The iToDS units pumped at 25 mL h⁻¹ for a 24 h exposure. PFAS concentrations were analyzed by ultra-performance liquid chromatography - tandem mass spectrometry (UPLC-MS/MS). Concurrent comparisons in the laboratory consisted of a chemtainer (50 L) containing site water and using similar sorption and exposure conditions. The comparisons showed each approach provided different outcomes with different advantages and limitations. PFOS concentrations of over 600 ng L⁻¹ in situ failed to produce toxicity. Spiking studies in the laboratory confirmed D. magna was not sensitive at environmentally-relevant concentrations. The iToDS technology required half the resource time as the lab TIE, and again proved to be robust, reliable, and easy to use in the field. It also has shown to be more sensitive at detecting ambient toxicity than the traditional lab-based protocols. A primary limitation of the iToDS is also its strength - it must be deployed in situ which increases accuracy and realism; but, can present logistical challenges. This innovative system is providing benefits by allowing for more accurate assessments of ecological risk at PFAS contaminated sites.

**MP166 Estimating Human Accumulation Potential of Per- and Polyfluoralkyl Substances: A Novel Density Functional Theory Approach**

B. Yan, J. Liu, McGill University / Civil Engineering

The extremely stable carbon-fluorine bonds make per- and polyfluoroalkyl substances (PFASs) ideal for widespread industrial uses, but also result in highly persistent and globally distributed contaminants. Humans are exposed to PFAS via ingesting contaminated food, dust or drinking water, while PFAS exposure has been reported to associate with series human diseases such as bladder cancer and prostate cancer. Close to 97% population in North America has detectable levels of PFASs, particularly, perfluorooctanoic carboxylate (PFOA) and sulfonate (PFOS). Binding to proteins is one of the routes by which PFASs accumulate in the human body; PFASs are mainly distributed in serum, kidney, and liver, with liver concentrations being several times higher than serum concentrations. However, the binding of protein and PFAS is not fully understood. A novel Density Functional Theory (DFT) based approach that combines molecular docking, molecular dynamics simulation, and quantum calculation was developed to estimate the binding affinity of three human proteins (i.e., serum protein, -lipoprotein, and liver-type fatty acid binding protein) with PFASs commonly detected in soil, groundwater and drinking water. The PFASs under examination include PFOA, PFOS,
florotolomer sulfonates, 6:2 florotolomer sulfonamidoalkyl betaine, perfluorohexanoic sulfonate and sulfonamide, and perfluoro-4-ethylcyclohexanesulfonate. The estimated values of binding energy demonstrated a good correlation with the experimental data obtained from three different studies. The strong binding affinity was primarily contributed by hydrogen-bonding, electrostatic attraction, and hydrophobic interaction. The strength of binding was enhanced with the increase in the perfluoroalkyl chain length. The DFT based computational method shows a great promise to allow estimating and evaluating the human accumulation potential of PFASs in organisms.

**MP167 The bioaccumulation of polyfluoroalkyl and perfluoroalkyl substances (PFASs) in earthworms (Eisenia fetida) from sorbent amended soil**

J. Jarjour, McGill University; G. Munoz, University of Montreal / Chemistry; M. Desrosiers, Center of Expertise in Environmental Analysis of Quebec; S. Sauvé, University of Montreal / Chemistry; J. Liu, McGill University / Civil Engineering

The use of aqueous film forming foams (AFFFs) for putting out flammable liquid fires has introduced polyfluoroalkyl and perfluoroalkyl substances (PFASs) into different environmental media, including soil. In situ soil stabilization using sorbent amendment has demonstrated potential in reducing PFAS leaching from contaminated soil and bioavailability. However, the behaviors of PFASs following the amendments have to be further evaluated to validate this approach. The uptake by earthworms (Eisenia fetida) following amendment will be studied as it is a widely used means to assess bioavailability in soil. Two different amendments will be used for this study: coal based activated carbon (F-400) and a new clay-based adsorbent (Fluorosorb® 100). A surface soil was collected in Montreal to which the sorbents will be amended at different concentrations (0-4%). A mixture of representative PFASs including 4 perfluorokyl sulfonates (PFsAs), 6 perfluorocarboxylates (PFCAs), 3 (n:2) florotelomer sulfonic acids, and 6:2 florotelomer sulfonamidoalkyl betaine (6:2 FTAB) will be used to spike the soils at relevant concentrations. Spiked soils will be amended with the sorbents to which the earthworms will be exposed to for an uptake phase test until steady-state is reached. This study will examine and discuss the relationship between the different factors that contribute to the reduction of bioaccumulation of PFASs. The reduction in bioaccumulation will be compared with the data generated using the USEPA Method 1311 (TCLP test) to allow the determination of appropriate amendments for different soil types and PFAS, and establish cost-effective materials for stabilizing PFAS in the soil.

**MP168 The relationship between PFAS and microbial communities at a legacy firefighting training area**

D. O’Carroll, M. Lee, S. Le, A. Yeung, M. Manefield, University of New South Wales / Civil and Environmental Engineering; S.J. Wallace, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; N. Battye, Royal Military College of Canada / Chemistry and Chemical Engineering; K.P. Weber, Royal Military College / Chemistry and Chemical Engineering

We evaluated the relationship between microbial communities and PFAS distributions in the subsurface at a firefighting training area (FFTA). Aqueous film forming foam (AFFF) was applied to the FFTA for over 50 years, a time period which spans many different AFFF manufacturer formulations. A suite of PFAS encompassing those with Canadian guidance values (C4-C12, carboxylates, sulfonates) and those found in newer formulations (8:2 and 6:2 telomers) were profiled in 40+ wells over a two year period yielding over 80 samples total. Microbial communities from these same samples were also characterized using next generation sequencing and this data analyzed in conjunction with PFAS profiles, available site data (e.g., subsurface stratigraphy), monitoring well data (e.g., pH, ORP, inorganic species) and soil data (e.g., soil type, organic carbon). Our data indicates and supports current hypotheses that PFAS telomer transformations occur onsite. Additionally, we found several correlations indicating positive, negative, and sometimes threshold inhibition relationships between certain PFAS and specific microbial genera.

**MP169 Sorption of PFAS to Rock**

S. Saucé, University of Montreal / Chemistry; J. Liu, McGill University / Civil Engineering

Despite the widespread occurrence of PFAS contamination in bedrock formations, the fate and transport of these contaminants in fractured bedrock remains unexplored. Fractured bedrock formations are complex, dominated by flow through fractures and exhibit much different characteristics than soils and sediments. It is currently unclear whether distribution coefficients, retardation factors and sorption mechanisms of PFAS to soils and sediments are applicable to fractured bedrock formations. To address this knowledge gap, a series of laboratory experiments was conducted to study the sorption of a suite of PFAS to rock. Crushed and re-wetted Lockport Dolostone was used to evaluate sorption kinetics, mechanisms, and competition for a suite of 13 PFAS (C4-C12) with varying functional head groups (carboxylates, sulfonates and sulfonamide). For long chain PFAS (C8-C12 for carboxylated or C6-C12 for sulfonated) sorption increased with increasing chain length, suggesting hydrophobic-like interactions to be the predominant sorption mechanism. For short chain PFAS (C4-C7 for carboxylated or C4-C5 for sulfonated) sorption was not correlated to chain length, potentially due to competition between short and long chain compounds for available sites. This phenomenon has not been observed in previous sorption studies conducted using soils and sediments, suggesting that PFAS fate and transport in fractured bedrock formations is likely different than in soils and sediments. Additionally, sorption of long chain length compounds exhibited two different behaviors depending on chain length, suggesting that long chain length compounds should be subdivided into intermediate chain length compounds and long chain length compounds (C10-C12). Sorption of sulfonated PFAS was found to be greater than sorption of carboxylate or sulfonamide analogs with the same carbon chain length, suggesting that electrostatic forces also play a role in sorption to these rock samples. This is the first data for sorption of PFAS to rock and thus represent the first step towards evaluating PFAS fate and transport in fractured bedrock aquifers.

**MP170 Degradation of PFAS in a nuclear reactor: Determining an underlying and universal degradation mechanism**

J. Rook, Department of National Defence; E. Corcoran, Royal Military College of Canada / Chemistry and Chemical Engineering; K.P. Weber, Royal Military College / Chemistry and Chemical Engineering

Degradation of PFAS is challenging by any means. We put a selection of 13 PFAS (C4-C12) with varying functional head groups (sulfonates, carboxylates, sulfonamide), in various water chemistries, inside a nuclear reactor core for over 1 hour. We did not see complete degradation of any of the PFAS (3-90% over the range of conditions). We were however able to see varying degradation efficiencies based on PFAS length, functional head group, and water chemistry. Through a rigorous, numerical model assisted, dose and fluence characterization we were able to discern the likely degradation mechanism involved in a reasonably realistic ground-water scenario. Reduction, specifically and solely based on aqueous electrons, was shown to be effective and therefore holds promise as a universal degradation mechanism. The information learned here can be universally applied to the development of remediation technologies for both water and soil.
MP171 Development of an experimental and modeling framework to evaluate the remediation of PFAS by colloidal activated carbon
S. Gilak Hakimabadi, University of Waterloo / Civil and Environmental Engineering; G. Carey, Porewater Solutions; A. Pham, University of Waterloo / Civil and Environmental Engineering

The remediation of sites contaminated with poly- and perfluoroalkyl substances (PFAS) using colloidal activated carbon (CAC) was investigated in this study. CAC are micron-sized particles that can readily migrate through pore spaces in transmissive sand zones. Following injection into the subsurface, CAC will attach to soil grains, creating a stationary barrier zone that will adsorb PFAS compounds in situ and substantially reduce contaminant transport downstream of the barrier. As with any sorption-based technology, the sorption sites on CAC will eventually become saturated, resulting in a breakthrough of PFAS. The overall objective of this research was to gain insights into the factors influencing the adsorption of PFAS by CAC, the knowledge of which will allow the development of a reactive transport model capable of predicting the longevity of CAC barriers. To this end, a series of batch adsorption experiments were conducted to investigate how the solution composition as well as various water chemistry parameters affected the adsorption of 15 perfluoroalkyl acids and 3 PFAS precursors on CAC. The adsorption isotherm parameters obtained from these experiments were then employed in a reactive transport model to predict the concentrations of PFAS in the CAC barrier and downgradient under various scenarios of source zone PFAS mass discharge, and the concentration of CAC in the barrier. Modeling of a conceptual aqueous film-forming foam (AFFF)-impacted site indicated that the longevity of CAC barriers could be on order of decades for longer-chain compounds such as PFOA, PFOS and PFHxS, because these compounds have a high affinity to CAC. Shorter chain compounds (e.g., PFBS and PFBA) generally had lower adsorption affinity, especially in the presence of longer-chain compounds that competed with the shorter-chain ones for the CAC surface. Although the breakthrough of the shorter-chain compounds may occur within a shorter timeframe, these compounds are less toxic and have higher groundwater action levels if they are regulated in a jurisdiction. Further research will focus on evaluating the efficacy of this technology for shorter-chain PFAS and designing of more robust modeling tools to support remedial predictions.

MP172 PFAS Destruction in Soil through Smouldering Combustion (STAR)
A. Duchesne, Western University / Civil and Environmental Engineering; D. Patch, Royal Military College of Canada / Chemistry and Chemical Engineering; J. Gerhard, J. Brown, Western University / Civil and Environmental Engineering; G. Grant, Savron Solutions; K.P. Weber, Royal Military College / Chemistry and Chemical Engineering; D. Major, Savron Solutions

Smouldering is a flameless, exothermic oxidation reaction; charcoal in a BBQ is a typical example. Once initiated the smouldering reaction is self-sustaining and will propagate through the contaminated porous media without any additional external energy input. This makes smouldering a less costly and more cost-effective process than other thermal treatments. STAR can destroy a variety of recalcitrant organic compounds with removal efficiencies typically in excess of 99%. The tests used either GAC loaded with PFAS combined with sand to produce a smoulderable mixture, or a soil contaminated with PFAS and mixed with uncontaminated GAC to create a smoulderable mixture. In all tests, the PFAS-contaminated mixtures were subject to smouldering (STAR) tests in 60 cm high, 16 cm diameter steel columns instrumented with thermocouples. Results reveal that the smouldering front propagated in a self-sustained manner through the PFAS-impacted mixtures, destroying all the GAC and organic carbon and generating temperatures in excess of 900°C, which is expected to be sufficient to thermally destroy PFAS compounds. Post-treatment concentrations of PFAS in the remaining sand, soil, and ash were below detection limits (0.05 µg/kg). Initial emission analysis indicated that over 82% of the available fluorine was captured as HF with only small amounts of PFAS emitted which could be subsequently captured by activated carbon and treated. Results to date are promising, suggesting STAR may provide an effective remediation technique for PFAS-impacted soils.

MP173 Scale-up and destruction of per- and polyfluoroalkyl substances in soil via ball milling
N. Battye, Royal Military College of Canada / Chemistry and Chemical Engineering; L. Turner, Queen’s University / Department of Civil Engineering; O. El-Sharnouby, GeoSyntec Consultants, Inc.; D. Patch, Royal Military College of Canada / Chemistry and Chemical Engineering; K. Juansalu, NATO; B. Kueper, Queen’s University / Department of Civil Engineering; K.P. Weber, Royal Military College / Chemistry and Chemical Engineering

We have demonstrated that ball milling can destroy per- and polyfluoroalkyl substances (PFAS) in contaminated soil. PFAS impacted soil from a 50+ year old firefighting training area (FFTA), as well as PFAS-spiked Ottawa sand, were used in all trials. Three different sized ball mills were used to evaluate and demonstrate scalability. A suite of 13 PFAS compounds spanning and extending beyond those with Canadian guidance values were tracked in all cases. Our results demonstrate up to 97% of the PFAS is destroyed within minutes in two types of soil, sand, and clay, and that no identifiable PFAS products are produced. Conventional remediation technologies are not effective for the destruction of PFAS; this methodology of onsite PFAS-contaminated soil remediation is cost-effective and will be scaled on-site to develop detailed operational requirements.

Environmental Occurrence, Bioaccumulation, Fate and Transport of Poly- and Perfluoroalkyl Substances (PFAS)

MP174 Environmental Degradation of a Novel Polyfluorinated Surfactant: Aerobic Biodegradation and Atmospheric Oxidation
S. Jouad, University of Toronto / Chemistry; J.J. Orlando, G.S. Tyndall, National Center for Atmospheric Research / Atmospheric Chemistry, Observations & Modeling; T.C. Furlani, York University / Chemistry; C. Young, York University / Department of Chemistry; S. Mabury, University of Toronto / Chemistry

As many per- and polyfluoroalkyl substances have been legislated or phased-out, newer chemistries are being developed. Ideally, the replacement chemicals will be intelligently designed to degrade to non-bioaccumulative components under ambient environmental conditions. One new commercially available fluorinated surfactant has an active ingredient with the chemical structure \([R_2-O-CHF-CF_2-S-CH_2-O-C=O]_2\). To investigate if this surfactant will in fact degrade, we incubated it with wastewater treatment plant sludge under aerobic conditions. Preliminary experiments with 0.5%, 2% and 10% sludge resulted in the degradation of about 70%, 84% and 92% of the surfactant over eight days. Using positive chemical ionization GC-MS, we observed the formation of an alcohol, \(R_2-O-CHF-CF_2-S-CH_2-OH\), and using negative electrospray ionization UPLC-MS/MS, we observed the formation of a carboxylic acid \(R_2-O-CHF-CF_2-S-CH_2-C(=O)OH\). Further degradation products are being investigated using a longer biodegradation experiment with 0.5% sludge, which will be completed in time for this meeting. The alcohol is a starting material for the synthesis of the surfactant, and we have shown that it also forms as a degradation product. Since it is semi-volatile, we investigated its atmospheric fate via laboratory oxidation experiments with Cl and OH radicals. Preliminary results report reaction kinetics faster than the fluorotelomer alcohols (FTOHs) which are synthetic intermediates and degradation products of many phased out or current use products. The atmospheric lifetime of this alcohol is about 1-3 days with respect to reaction with OH.
including COF₂, SO₂ and a prominent acyl fluoride (R₁-O-CH₂C(=O)F). Offline product experiments were also performed under various atmospheric conditions, and offline samples were collected in a bubbler and analyzed for acid degradation products. Two larger acids were identified as primary degradation products [R₁-O-CHF-CF₂-S-CH₂CH₂-C(=O)OH; R₁-O-CHF-CF₂-SO₂H], and two smaller acids that appear to be terminal degradation products, one of which is perfluoropropanoic acid. These two studies will assess the formation of degradation products under various environmental conditions to determine if this replacement surfactant is less persistent than other fluorinated surfactants.

**MP175 Waste Incineration of Polytetrafluoroethylene (PTFE) to Evaluate Potential Formation of Per- and Poly-fluorinated Substances (PFAS) in Flue Gas**

D. Pigeon, W.L. Gore & Associates; H. Gehrmann, Karlsruhe Institute of Technology KIT / Institut für Technische Chemie (ITC); K. Aleksandrov, Karlsruhe Institute of Technology KIT; M. Wexler, H. Mätzinger, Karlsruher Institut für Technologie; M. Hauser, Karlsruher Institut für Technologie (KIT); D. Staff, Karlsruher Institut für Technologie

In recent years, concerns over some per- and polyfluorinated alkyl substances (PFAS) have grown steadily. PFAS are a large group of chemical substances with widely differing properties. While one class of PFAS, fluoro polymers, have been demonstrated to meet the OECD criteria for polymers of low concern during the in-use phase of their lifecycle, questions remain regarding waste handling at the end of useful life for products containing fluoro polymers. To show that polytetrafluoroethylene (PTFE) can be almost fully transformed into fluorne (F) (as hydrofluoric acid (HF)) and to study the possible generation of low molecular weight per- and polyfluorinated alkyl substances (PFAS), PTFE combustion under typical waste incineration conditions at the BREnda (German acronym for "Brennkammer mit Dampfkessel") pilot plant at Karlsruhe Institute of Technology (KIT) was investigated. Results indicate that, within procedural quantitation limits, no statistically significant evidence was found that the PFAS studied were created during the incineration of PTFE. Therefore, municipal incineration of PTFE using best available waste treatment technologies (BAT) is not a significant source of the studied PFAS and should be considered an acceptable form of waste treatment.

**MP176 Heterogeneous reaction of perfluoropropanoic acid (PFPrA) with aerosol proxies: Implications for aerosol-mediated long-range transport**

E. Gaona Colmán, Universidad Nacional de Córdoba / Chemistry; T. Vandendoor, York University / Department of Chemistry; J. Wentzell, J. Liggio, Environment and Climate Change Canada / Air Quality Research Division; C. Young, York University / Department of Chemistry

Perfluoropropanoic acid (PFPrA) is a short chain aliphatic carboxylic acid part of the poly- and perfluoralkyl substances (PFASs) family. PFASs are highly demanded substances due to their stability and properties surfactant properties leading to industrial applications such as textiles, cookware, and firefighting foams. Therefore, due to their extensive industrial use and their high persistence, these substances are ubiquitously distributed in the environment even in remote locations such as the Arctic. In the atmosphere, short chain PFASs can be emitted directly from sources or formed from reactions of longer chain precursors (e.g. fluorotelomers) with atmospheric oxidants (e.g. hydroxyl radicals). Despite the well-known atmospheric formation of short chain fluorinated acids, there is still a gap of knowledge regarding their transport to remote locations, where aerosols could contribute to this transport. In this study we present the uptake of gas phase PFPrA onto aerosol proxies, including carbonate salts as proxies of inorganic mineral dust. The experiments were performed in a flow tube reactor at 298 K and atmospheric pressure in zero air carrier gas coupled to a chemical ionization mass spectrometer (CIMS) detection system using acetate reagent ion. Gas phase PFPrA was obtained from the acid displacement reaction of HCl(g) over a salt bed of sodium perfluoropropanoate. The monitored ions were acetate (m/z=59), acetate dimer (m/z=119), PFPrA ion (m/z=163), nitrate (m/z=62) and chloride (m/z=35). To our knowledge, this work is the first determination of the reactive uptake coefficients of gas phase PFAS onto aerosol proxies. Reactive uptake coefficients will be presented and the implications for PFAS long-range transport will be discussed.

**MP177 Precipitation Dominates Atmospheric Deposition of PFASs to the Great Lakes**

Y. Wu, Indiana University, Bloomington / O’Neill School of Public and Environmental Affairs; A. Salamova, Indiana University / SPEA; R.A. Hites, Indiana University / School of Public Environmental Affairs; M. Venier, Indiana University / SPEA

In this study, we collected vapor and particle phase samples as well as precipitation in Bloomington, Indiana (n = 10 each) with the goal of determining which phase contributed the most to atmospheric deposition. We also compared two sampling methods for precipitation, one employing a stainless steel funnel and one a polypropylene funnel. Our results clearly indicate that polypropylene should be used for PFASs precipitation sampling due to sorption of ionic PFASs to stainless steel. In Bloomington, ΣPFAS median concentrations were 99.6 pg/m³ in the vapor phase, 4.02 pg/m³ in the particle phase, and 2000 pg/L in precipitation. We also collected precipitation samples at two sites (n = 3 each) located in the Great Lakes basin, which are part of the Integrated Deposition Atmospheric Network (IADN), one urban (Cleveland, Ohio) and one remote (Sleeping Bear Dunes, Michigan). Median ΣPFAS concentrations were 9000 and 817 pg/L at Cleveland and Sleeping Bear Dunes, respectively. Median wet deposition fluxes for ΣPFASs in Cleveland were 7810 ng y⁻¹ m⁻², significantly higher than in Bloomington at 1730 ng y⁻¹ m⁻². Wet deposition fluxes for PFASs were also about 15 times higher than those for total PCBs and total organochlorine pesticides at about 500 ng y⁻¹ m⁻². Based on the relatively low vapor and dry deposition fluxes (2.39 and 254 ng y⁻¹ m⁻², respectively) measured in Bloomington, we suggest that precipitation is the most important atmospheric phase to monitor.

**MP178 Air concentrations of per- and polyfluoroalkyl substances (PFAS) in North Carolina**

J. Zhou, K. Baumann, J.D. Surratt, University of North Carolina at Chapel Hill / Department of Environmental Science and Engineering; R. Mead, S. Skrabal, R.J. Kieber, G.B. Avery, J.D. Willey, M. Shimizu, University of North Carolina at Wilmington / Department of Chemistry and Biochemistry; W. Bodnar, Z. Zhang, University of North Carolina at Chapel Hill / Department of Environmental Science and Engineering; J.C. DeWitt, East Carolina University / Pharmacology and Toxicology; M. Sun, University of North Carolina at Charlotte / Civil and Environmental Engineering; L.B. Collins, University of North Carolina at Chapel Hill / Department of Environmental Sciences and Engineering; B.J. Turpin, University of North Carolina at Chapel Hill / Department of Environmental Science and Engineering

While per- and polyfluoroalkyl substances (PFAS), especially legacy compounds, have been measured in ambient air in urban and rural areas in several locations around the world, concentrations, source contributions and atmospheric transformations of legacy and emerging PFAS remain poorly characterized. North Carolina (NC) is a logical place to study these, given the existence of a PFAS manufacturing plant (Chemours), military bases and other users of fire-fighting foams, and urban waste streams, all of which are sources. The potential for human exposure to these compounds (directly through inhalation and indirectly as a result of atmospheric deposition) is a source of concern for stakeholders in NC and beyond. For these reasons, we initiated an on-going sampling campaign that includes 6-day integrated sampling of particle and gas-phase PFAS using quartz filters and polyurethane foam (PUF) plugs, respectively. Samples are being collected weekly for one year at 5 locations: Fayetteville, Wilmington, Research Triangle Park, Charlotte, and Greenville, NC. Seasonally-compomised samples are analyzed using an optimized (targeted) method via AB SCIEX Triple Quad(TM) 6500 LC/MS/MS. Detection limits for targeted PFAS are 0.05-1 ppb in
Poly- and perfluoroalkyl substances (PFAS) and volatile methyl siloxanes (VMS) are high production volume chemicals and are persistent, hence show long-range transport in the environment. Among PFAS, perfluorooctane sulfonate (PFOS), its salts and precursor compound (perfluorooctane sulfonyl fluoride), were added to the Stockholm Convention (SC) on persistent organic pollutants (POPs) in 2009. Very recently in 2019, perfluorooctanoic acid (PFOA), its salts and related compounds have also been listed in SC, given their potential toxic effects of human health and environment. As such, their continuous monitoring is required to assess the effectiveness of these regulations. PFAS and VMS are globally being monitored at 20 sites under Global Atmospheric Passive Sampling (GAPS) Network for the past decade. In 2017, GAPS expanded the monitoring of these chemicals at over 40 sites across the globe including polar, background, agricultural and urban sites. Sorbent impregnated polyurethane foam disks (SIPs) were deployed at ~45 GAPS sites in double-dome sampling chambers. Sampling was conducted from April to June 2017 and samples were stored below -10°C until analysis. Samples are being analysed for 18 perfluoroalkyl acids, 7 neutral-PFAS (nPFAS) and 7 linear and cyclic VMS. Preliminary results are presented here for n-PFAS at 8 sites in the United Nations region of ‘Western Europe and Others Group’ (WEOG) monitored under GAPS network. These include 2 polar, 5 background and 1 urban sites. Levels of Σ7nPFAS were 2.4-12, 0.2-16 and 50 pg/m³ at polar, background and urban sites, respectively. Among nPFAS, 8:2TOT, 10:2 FTOH and Me-FOSA were most widely detected at these sites. Upcoming analysis will report new information on levels of all PFAS and VMS on larger spatial scale across the globe.

MP182 Multimedia fate modelling of per- and polyfluoroalkyl substances near industrial point sources

A.M. Lampic, J. Parnis, D. Mackay, Trent University / Chemistry

Per- and polyfluoroalkyl substances (PFASs) are man-made chemicals widely used in a variety of industries. Once introduced to the environment, PFASs are resistant to degradation which increases their bioaccumulation potential and exposure to the surrounding environment. Fluorochemical manufacturing parks (FMPs) are important point sources of PFASs into surrounding environments. Understanding the environmental fate of emitted PFASs from FMPs is important to mitigate exposure and aid in environmental remediation. We will report on the status and progress in the creation of a fugacity-based multimedia model to accurately describe the fate and transport of 25 PFASs in urban and agricultural environments that surround FMPs. We will report and critically review predictions of physicochemical properties of PFASs made by application of property estimation programs. Fugacity-based multimedia
models will be created using a similar theoretical framework as described in Mackay (2001). Three fugacity-based multimedia models with increasing complexity will be created (Mackay Level I, Level II, and Level III). The quality of the models will be assessed by the degree of agreement between the predicted and experimentally measured PFAS levels in the various environmental compartments of the system, with the experimental data coming from the work by Chen et al. (2018) in Fuxin, China. This research will shed light on the important processes that control the fate and distribution of these compounds and will provide a supportive framework for regulatory control and environmental remediation. The developed models will also provide insight and understanding into the processes and important factors that govern PFAS fate in the environment. The primary sinks for PFAS will also be highlighted under the defined environmental conditions.

MP183 PFAS Fate and Transport During Wastewater and Indirect Potable Reuse Treatment: A Utility’s Perspective on the Importance of Source Control

D. Gonzalez, Hampton Roads Sanitation District; J. Heisig-Mitchell, Hampton Roads Sanitation District / Water Technology and Research

While there are several potential sources of PFAS in wastewater influent, one of the most concentrated sources can be aqueous film forming foam (AFFF) when it is accepted by treatment plants in industrial waste streams. Research going back to the 1970s using different versions of AFFF has indicated that fluxes of these chemicals into treatment plants in southeastern Virginia has the potential to inhibit effective treatment of wastewater. While initial source control implementation at the utility stemmed from potential impacts to wastewater treatment, recent source control efforts also consider limiting PFAS content for indirect potable reuse and advanced water treatment. In this talk we will review impacts of various types of AFFF using a holistic view of both wastewater and drinking water quality at a utility in southeastern Virginia. Impacts on biological nutrient removal (BNR) using sequencing batch reactor (SBR) studies will be presented. In this work, three different wastewater treatment configurations (fully nitrifying, Modified Ludzack-Ettinger (MLE), and 5-stage Bardenpho) were considered to investigate impacts on nitrification, denitrification, and biological phosphorus removal. In addition, the fate and transport of AFFF-associated PFAS during wastewater treatment will be discussed. The importance of source control in minimizing pass-through to water reuse activities cannot be understated. Here, we will present results from an indirect potable reuse project that employs an advanced treatment train using coagulation, flocculation, sedimentation, ozonation, biofiltration, granular activated carbon (GAC), and UV disinfection. The main mode of PFAS removal in this train is via adsorption on GAC. Large swings in influent PFAS content to this carbon-based train are avoided primarily by a comprehensive pretreatment program that does not allow AFFF into the waste stream. We will present data showing that finished indirect potable reuse water has low PFAS levels when the lowest possible quantitation limits are employed.

MP184 Per- and Polyfluoroalkyl Substances (PFAS) in Landfill Leachate, Municipal Wastewater and Occurrence in Drinking Water Sources

J. Thelusmond, M. Barlaz, North Carolina State University / Civil Constr and Env Eng

Per- and polyfluoroalkyl substances (PFASs) are used in a variety of consumer products which, at the end of their life cycle, are disposed in landfills. It is not surprising that PFASs have been detected in leachate percolating from landfills that receive municipal solid waste (MSW). This is cause for concern because leachate from MSW is generally treated together with domestic wastewater in publicly owned wastewater treatment plants (POTWs) which were not originally designed to remove such contaminants. Therefore, POTWs have the potential to act as point sources for PFAS surface water contamination. Other potential water contamination sources include construction and demolition landfills, which are typically unlined, and therefore release their leachate untreated to both groundwater and surface water. The aim of this research is to estimate the mass of PFASs released from North Carolina (NC) domestic wastewater and landfill leachate to POTWs, and in turn, from POTWs to surface water. We collected leachate samples from 13 MSW landfills and 4 construction and demolition sites. We also collected flow-proportional, 24 h composite samples of raw influent and final effluent from 24 POTWs throughout NC. To account for PFAS temporal variability, two of the 24 POTWs were sampled weekly for 4 weeks. All samples were kept on ice until their arrival in the laboratory where they were frozen until PFAS extraction by solid phase extraction. The samples have been extracted and their analysis by liquid chromatography high-resolution mass spectrometry is in progress. PFAS concentrations will be quantified or estimated depending on whether adequate standards are available. PFAS concentration data will be used to estimate the mass of individual PFAS as well as total PFAS entering POTWs. We will also estimate the mass of PFASs discharged from NC POTWs.

MP185 Occurrence of per- and polyfluoroalkyl substances (PFAS) in North Carolina drinking water sources

N. DeStefano, North Carolina State University; Z. Hopkins, NC State University / Department of Civil, Construction, and Environmental Engineering; A. Joyce, Duke University / Civil and Environmental Engineering; Y. Han, M. Sun, University of North Carolina at Charlotte / Civil and Environmental Engineering; L. Ferguson, Duke University / Civil and Environmental Engineering; D. Knappe, North Carolina State University / Civil, Construction and Environmental Engineering

Per- and polyfluoroalkyl substances (PFAS) are a group of man-made compounds produced and used commercially for their nonstick and heat resistant properties. They are commonly used in food containers, house- hold products, electronics manufacturing, and firefighting foam. Several PFAS, such as perfluorooctanoic acid (PFOA), are ubiquitous globally and can harm human health through commercial and environmental exposure. In addition to the suite of known compounds, thousands of new PFAS are being produced and released into environmental matrices, limiting our ability to reliably assess true human exposure potential. For example, the compound known as “GenX” was recently discovered in high concentrations in the Cape Fear River in North Carolina (NC) downstream of a fluorochemical manufacturing plant. GenX and related compounds passed through drinking water treatment plants unaffected into finished water taps, and the resulting impacts on human health are largely unknown. As a result of the discovery of GenX and related fluoroethers, residents in other NC communities are wondering whether poorly understood PFAS are present in their drinking water. Therefore, the overarching aim of this study is to gain a better understanding of PFAS occurrence in North Carolina drinking water sources. A combination of targeted and non-targeted workflows is being performed to comprehensively identify PFAS in raw drinking water from public water systems throughout NC. Also, adsorbable organic fluorine (AOF) is being quantified in each water sample by combustion ion chromatography to understand the total burden of fluorinated compounds. Known PFAS compounds are quantified using available authentic standards and compared to AOF data to determine the proportion of PFAS that remains uncharacterized. Non-targeted PFAS identification is being performed by spectral library interrogation, isotope rationalization, in situ fragmentation, generation of fragmentation trees, and comprehensive literature and patent review.

MP186 Monitoring of perfluorinated compounds (PFCs) in private drinking well water in the Tama area of Tokyo, Japan

T. Yamazaki, T. Kinoshita, Tokyo Metropolitan Institute of Public Health; T. Suzuki, Tokyo Metropolitan Institute of Public Health; T. Suzuki, Tokyo Metropolitan Institute of Public Health; T. Nishimura, Teikyo Heisei University / Faculty of Pharmaceutical Sciences

Perfluorinated compounds (PFCs) are used widely as a water repellent, fire extinguishing agent, coating agent, etc. PFCs have many kinds of
congeners, and their properties differ depending on their carbon chain length. In particular, perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), both having a straight chain composed of 8 carbon atoms (C8), are well known. They are persistent in the environment and bioaccumulative in wildlife and humans. Therefore, they have been internationally regulated. PFOS has been listed in Annex B (Restriction) of the Stockholm Convention on Persistent Organic Pollutants, which restricts its production, use, import, and export, since 2009. On the other hand, PFOA was recently recommended for listing in Annex A (Elimination) of the convention in the 14th meeting of the Persistent Organic Pollutants Review Committee. In Japan, as well, manufacture and importation of PFOA have basically been prohibited, and production and import results for PFOA must be reported. In this study, we investigated the contamination levels of PFCs in well waters in the year 2018 and compared these results to the monitoring results in 2007-2011. The monitored PFCs were PFPeA(C5), PFHxS(C6), PFHpA(C7), PFOA, PFNA(C9), PFDA(C10), PFUdA(C11), PFDoA(C12), PTrA(C13), PFtA(C14), PFBS(C4), PFHxS(C6), PFHpS(C7), PFOS, and PFDS(C10). A 500 mL water sample was concentrated to 0.5 mL by a solid-phase extraction method (OASIS HLB, elution with methanol) and the resulting sample was analyzed by ultra-high performance liquid chromatography-tandem mass spectrometry. In 2007-2011 (n = 276), the average of the detected concentration (maximum) was 42.6 (1118.3) ng/L for PFOS and 9.6 (199.7) ng/L for PFOA. On the other hand, in 2018 (n = 58), the average (maximum) of the detected concentration was 34.3 (776.1) ng/L for PFOA and 8.3 (83.7) ng/L for PFOA. Comparing the average values in 2007-2011 with those in 2018, it is apparent that both concentrations of PFOS and PFOA have decreased. In addition, we performed a cluster analysis of all the PFCs detected in 2007-2011 and 2018. In both monitoring periods, a correlation was found between PFOS and PFHxS, and this correlation was more pronounced in 2018. Furthermore, the average concentration of PFHxS in 2018 (39.3 ng/L) was larger than that in 2007-2011 (25.5 ng/L). It is suggested that the use of PFHxS may have increased because of its use as an alternative to PFOS.

**MP187 Tissue-specific distribution of emerging per- and polyfluoroalkyl substances (PFASs) in Atlantic seabirds**

A. Robuck, University of Rhode Island / Graduate School of Oceanography; J. McCord, US Environmental Protection Agency / ORD; M.J. Strynar, US Environmental Protection Agency / ORD/ NERL/EMMD; R. Lohmann, University of Rhode Island / Graduate School of Oceanography

Long-chain per- and polyfluoroalkyl substances (PFASs) demonstrate remarkable environmental persistence, bioaccumulative capacity, and have been found globally in surface water and biota, including birds from diverse habitats. Public health concerns and regulatory attention have caused a shift in PFAS production, causing industry to move away from longer-chain perfluorinated structures towards short-chain analogues or structurally diverse compounds with variable functional groups or fluorination patterns. Seabirds are ideal sentinels to assess the occurrence of both legacy and emerging PFASs in food webs, as their upper trophic level position allows them to assimilate resources and related biological, physical, and chemical conditions across multiple ecosystems and temporal scales. Here, PFASs were measured in multiple tissues from juvenile Atlantic seabirds collected in 2017 and 2018. Species sampled included deceased immature or juvenile herring gulls, great shearwaters, terns, and pelicans from Narragansett Bay in Rhode Island, Massachusetts Bay off the coast of Massachusetts, and the Cape Fear River Estuary (CFRE) in southeastern North Carolina. Samples were analyzed for legacy and emerging PFASs using liquid chromatography/high resolution mass spectrometry, employing both targeted and suspect screening methods. Tissues screened included heart, brain, kidney, lungs, uropygial gland, adipose fat, liver, muscle, blood, and feces. PFOS dominated all liver samples across all individuals and habitats. Emerging compounds previously found in the CFRE system were variably detected in tissues from CFRE chicks, with high inter-individual variability. Emerging compound Nafion byproduct-2 was detected at concentrations similar to or exceeding legacy PFOS in brain and muscular tissues, driven largely by low PFOS concentrations in these matrices in conjunction with significant Nafion byproduct-2 concentrations. Concentrations of emerging compounds decreased significantly in chicks collected from the CFRE system in 2018, suggesting a rapid food web response to cessation of upstream sources.

**MP188 Uptake and effects of per- and polyfluoroalkyl substances in fish exposed to contaminated environments**

Exposure to per- and polyfluoroalkyl substances (PFASs) has been associated with many negative human health effects including immunotoxicity and metabolic disruption. Aqueous film-forming foams (AFFFs) containing PFASs are effective at extinguishing hydrocarbon fires but can be a large source of contamination to the surrounding environment. To date, there is still limited knowledge of risks posed by AFFF-impacted ecosystems to humans and wildlife, including toxicological data for exposed aquatic organisms. This project aims to fill some of these gaps by investigating whether PFAS exposures are associated with bio-uptake and expression of metagenomic indicators of adverse effects in exposed fish. We experimentally measured PFAS accumulation in model freshwater fish exposed to groundwater pumped from a contaminant plume on Cape Cod, Massachusetts, that was formed by historical use of AFFF. Near the source, the groundwater contains up to 17 individual PFAS compounds, with perfluorooctanesulfonic acid (PFOS) and perfluorohexanesulfonic acid (PFHxS) being the most abundant. We used a mobile laboratory to control chronic exposure scenarios. Fathead minnows were exposed on-site over a 21-day period under flow-through conditions to both groundwater from a reference area (minimally impacted by PFAS contamination) and groundwater from the vicinity of a historical fire-training area with known high concentrations of PFAS. PFAS uptake and whole-body burden were evaluated using an ion-pairing extraction and liquid chromatography tandem mass spectrometry method. Preliminary results show that PFASs with longer carbon chain length and sulfonate head groups preferentially accumulate in fish, with increases in body burden over the 21-day period. The most abundant PFASs detected in the fish include PFHxS and PFOS, with significant contributions from the branched isomers, and perfluorohexane sulfonamide (FHxSA). We find significant variability in PFAS concentrations between individuals. Female and male fathead minnows differ in the temporal patterns of PFAS accumulation, and some evidence of PFAS elimination was noted for female fish after the first week of exposure. We will present results of our analysis assessing differential uptake of aqueous PFASs by fish.

**MP189 Health Goals for Perfluoroalkyl Substances (PFAS)—Phase I**

K. Schulz, M. Silva, University of Wisconsin, Milwaukee; R. Klapaer, University of Wisconsin, Milwaukee / School of Freshwater Sciences

Perfluoroalkyl substances, or PFAS, are a class of persistent organic pollutants that have become a major concern in recent years due to their associated health effects and near-ubiquitous presence in the environment and biota, including humans. Recent attention has led to a call for regulation and a quickly widening body of research relating to PFAS, especially the two most prominent compounds, perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). This project seeks to summarize available information about the health effects, environmental transport, contamination sources, and available detection and remediation technologies for this class of chemicals using Wisconsin as a case study. In order to achieve this goal, the project consists of five main steps: (1) a review of available literature on PFAS, focusing on transport, exposure, and health effects; (2) identification of known and unknown but likely sources and areas of contamination in Wisconsin; (3) contact and survey of companies...
MP190 First Report on in vivo Pharmacokinetics and Biotransformation of Novel Chlorinated Polyfluoroalkyl Substances in Rainbow Trout
S. Yi, Nankai University / Environmental Science and Engineering
Juvenile rainbow trout received 30-day dietary exposure to perfluorooctane sulfonate (PFOS), chlorinated perfluorooctane sulfonate (CI-PFOS), and 6:2 and 8:2 chlorinated polyfluoralkyl ether sulfonates (CI-PFESAs), respectively, followed by a 34-day depuration phase fed with clean food. Qualification and quantification of target compounds in fish tissues were achieved via UPLC-MS/MS analysis. The four test chemicals shared certain similarities in bioaccumulation potential and partitioning preference among tissues, but differences exhibited dependent on their structural rigidity and molecular size. To be specific, PFOS and CI-PFOS displayed comparable bioaccumulative potencies and similar distribution patterns in the tissues (blood > liver > kidneys), regardless of a terminal chlorine in CI-PFOS molecule. The CI-PFESAs, especially 8:2 CI-PFESA, were predominantly assimilated by liver and kidneys from the bloodstream and resisted elimination. The longer half-lives in liver and kidneys of CI-PFESAs stressed their heavier biological burdens and posed risks as alternatives to legacy PFOS. For the first time, in vivo transformation of 6:2 and 8:2 CI-PFESAs was reported, with 6:2 and 8:2 H-PFESA identified as the sole metabolites, respectively, providing the first line of evidence on the transformation susceptibility of CI-PFESAs distinct from their environmental persistence. In contrast to the liver-mediated oxidation of legacy per- and polyfluoralkyl precursors in biota, dechlorination of CI-PFESAs implies the involvement of reductases in catalyzing this process.

MP191 Metabolism of fluorotelomer alcohols (FTOHs) to perfluorocarboxylic acids (PFCAs) in rat microsomes
D. Daramola, Carleton University / Chemistry
Fluorotelomer alcohols (FTOHs) are a group of flame resistant and lipophobic compounds that consist of a long non-polar fluorinated tail attached to an ethanol head group. They are denoted by the nomenclature x-y FTOH, with “x” and “y” representing the number of fluorinated and hydrogenated carbons, respectively. Several studies on the widely used 8:2 FTOH congener have shown significant metabolism, in humans and animals, to the environmentally persistent perfluorooctanoic acid (PFOA). However, there are limited investigations on the metabolism and enzymology of the shorter chain length FTOHs like the 6:2 and 4:2 analogues. This research aims to understand the metabolism of 6:2 FTOH to the respective C6 PFOA analogue, perfluorohexanoic acid (PFHxA), in a biotic environment. In vitro enzymatic assays, performed with rat and human liver microsomes, seek to identify the primary enzyme responsible for the metabolism of the 6:2 FTOH. We hypothesize that the conversion of 6:2 FTOH to PFHxA starts with the phase I metabolism by a cytochrome P450 (CYP) to a fluorinated aldehyde. The aldehyde is further metabolised through oxidative reactions to form PFHx A. Given the enzymes responsible for metabolizing 8:2 FTOH, CYP 2E1 and CYP 2C19 are currently hypothesized as the CYPs responsible for the phase I metabolism. Enzyme kinetic constants were obtained by monitoring decreases in the 6:2 FTOH levels in active microsomes using GC-MS. A series of inhibition assays were then performed using selective CYP 2E1 and CYP 2C19 inhibitors to determine the CYP responsible for 6:2 FTOH metabolism. Further enzymatic trials will be performed to quantify the difference in the metabolic kinetic constants between human and rat in vitro assays. The environmental regulation of PFOA precursors such as 8:2 FTOH in consumer products was achieved through several investigative analyses of the metabolic pathways. A similar series of analysis for its shorter chain industrial replacements, 6:2 and 4:2, is of utmost importance to determine their significance in the production of the persistent and potentially toxic C-6 and C-4 PFOA analogues and other bioactive fluorinated metabolites.

MP192 Body distribution and placental transfer of per- and polyfluorinated substances (PFASs) in marine mammals
Y. Jeong, Hanyang University / Marine Sciences and Convergence Engineering; S. Mok, Hanyang University / Marine Sciences and Convergence Technology; Y. An, Cetacea Research Institute (CRI), NFRDI; H. Moon, Hanyang University / Marine Sciences and Convergence Engineering
Limited studies have conducted on placental transfer of per- and polyfluorinated substances (PFASs) in marine mammals. In this study, a total of 62 samples were collected including blubber, kidney, stomach, liver, ovary, heart, lung, intestine, and brain, and umbilical cord from mothers and/or their fetuses, to assess the placental transfer of PFASs using the mother-fetus pair samples of finless porpoises. For mothers, the PFOS concentration was the highest in all tissues, ranging from 3.7 to 648 ng/g, followed by PFUnDA (0.44-54 ng/g) and PFTDA (0.35-31 ng/g). The concentrations of F-53B ranged from 0.14 to 48 ng/g, which has a similar range with long-chained carboxylates. Among the maternal organs, the liver (413 ng/g) showed the highest concentration, followed by kidney (122 ng/g), pancreas (99 ng/g), ovary (92 ng/g), and heart (79 ng/g). FOSA and F-53B are also found as higher concentration in liver, pancreas, heart, and kidney than other tissues. Similar to mothers, the fetal concentration of PFOS (28.3-470 ng/g) was the highest, followed by PFUnDA (11-69 ng/g) and PFTDA (7.3-55 ng/g). In fetuses, the concentrations of PFASs increased with gestational age and the PFAS concentrations in older fetuses were higher than those measured for their mothers. Body distribution of PFASs in fetus was homogenous among organs. A high umbilical cord to placenta ratio was found for longer-chained carboxylates, suggesting the compound-specific placental transfer. Placental transfer rate was estimated using the body burden of mother-fetus pairs. The estimated placental transfer rate of PFASs, FOSA, and F-53B was 58%, 2.7%, and 74%, respectively, which were higher than those reported for lipophilic compounds (0.7-5.5%). This is the first study on placental transfer of precursors and alternatives of PFASs in marine mammals.

MP193 Biotransformation of 8:2 monosubstituted polyfluoralkyl phosphate in rat liver and intestinal S9 fractions
S. Fok, T. Harris, A.A. Rand, Carleton University / Chemistry
Polyfluoralkyl phosphates have been used in a variety of commercial and industrial applications owing to their thermal stability and surfactant properties. However, these chemicals are precursors to metabolically labile fluorotelomer alcohols and bioaccumulative and persistent perfluoralkyl carboxylic acids, making them a concern to humans and the environment. A previous study investigated 8:2 monosubstituted polyfluoralkyl phosphate (8:2 monoPAP) transformation in rats, observing an absence of 8:2 monoPAPs in blood. This suggested the monoPAPs are hydrolyzed in the gut, followed by the sorption of fluorotelomer alcohols into the blood stream. To further establish the mechanistic fate of polyfluoralkyl phosphates, this present work focuses on the biotransformation of 8:2 monoPAPs in rat via in vitro incubations with liver and intestinal S9 fractions. The hydrolysis product of 8:2 monoPAP, the 8:2 fluorotelomer alcohol, was monitored by GC-MS in EI mode. The maximum velocity (Vmax) for 8:2 monoPAP was 1.1×10-1 ± 2.1×10-2 nmol/min/mg, and the Michaelis constant (Km) was 4.0×103 ± 1.5×103 nM. The calculated intrinsic clearance rate (Clint) was determined to be 2.8±10-2 mL/min/mg protein. These results show that esterase activity in the liver is minimal. We hypothesize that the phosphate ester hydrolysis activity towards 8:2 monoPAPs is greater in the intestine compared to the liver due to the intestine being the first site of 8:2 monoPAP biotransformation before uptake into various parts of the body. Work to characterize esterase
activity in the gut is ongoing. The current study attempts to demonstrate the gut intestine as a major contributor for environmental toxicant metabolism via phosphate ester hydrolysis activity.

**MP194 In Vivo Biotransformation of a New Commercial Polyfluorinated Surfactant**

A. Folkerson, S. Joudan, S. Mabury, J.C. D’eon, University of Toronto / Chemistry

Fluorinated surfactants are a class of widely used compounds that are found in a range of products ranging from wetting and leveling agents in coating industries to window cleaning formulations. These fluorinated compounds are especially proficient at reducing the surface tension between two interfaces, however tend to also be more persistent than other surfactants. A new commercially available fluorosurfactant, whose active ingredient has the general structure of [R₂-O-CHF-CF₂-S-CH₂CH₂-O-(C=O)]₂C₆H₅SO₃⁻, has been designed with environmental degradation in mind. This study looks to characterize the fate of the surfactant in biological systems using both in vitro and in vivo experiments. We have shown that the ester linkages within the compound undergo hydrolysis and further oxidation to a carboxylic acid (R₂-O-CHF-CF₂-S-CH₂-COOH). In vitro assays using rat liver S9 fractions demonstrated this expected biological transformation; however in small quantities. In vivo studies in Sprague-Dawley rats dosed by oral gavage showed a lack of bioavailability of the fluorinated surfactant but significant biotransformation suggesting significant first pass metabolism. Additionally, the parent surfactant and its acid metabolite could not be detected by 3 days post-dose. Tissue distribution and a comprehensive degradation pathway will be discussed.

**MP195 In situ determination of cross-species protein binding affinities with chemical proteomics: FABP-PFCs as a case study**

J. Fu, Queens University / Department of Chemistry

Experimental determinations of protein binding affinities across species are challenging for current methodologies. In this study, we proposed a chemical proteomics platform for in situ determination of cross-species protein binding affinities without the need for laborious biochemical methods. The interactions between perfluorinated compounds (PFCs) and fatty acid-binding proteins (FABPs) are used as a case study since the FABP proteins are one of the primary factors to account for bioaccumulation of PFCs in organisms. The chemical proteomics method, Target-Identification by Ligand Stabilization (TILS) is tested for this project. Human FABP1 protein was purified in E. coli and optimized for TILS. A large melting temperature shift was observed when FABP1 was complexed with perfluorooctanesulfonic acid (PFOS), the most abundant PFC detected in organisms. The melting temperature of FABP1 shifted from ~65 °C to ~75 °C with good reproducibility. The method was further validated by crude E. coli lysates containing polyhistidine-tagged FABP1 proteins, and a clear melting temperature shift was observed by western blotting. This indicated that the interaction between PFOS and FABP1 could be determined by TILS even with complex lysate samples containing thousands of proteins. The method was further applied to human HepG2 cell line and rat liver samples and a shift of FABP1 was observed when the samples were spiked with PFOS. The chemical proteomics methods developed in this study will provide an effective opportunity to investigate inter-species protein binding affinities for PFCs, as well as other pollutants of concern.

**MP196 USEPA CompTox Chemicals Dashboard - a web-based database and information hub for over five thousand per- and polyfluoroalkyl chemical substances**

A.J. Williams, C. Grulke, G. Patlewicz, A. Richard, US Environmental Protection Agency / National Center for Computational Toxicology

The USEPA's CompTox Chemicals Dashboard (https://comptox.epa.gov/dashboard) is a publicly accessible website providing access to data for ~875,000 chemical substances, the majority of these represented as chemical structures. The web application delivers a wide array of computed and measured physicochemical properties, in vitro high-throughput screening data and in vivo toxicity data, product use information extracted from safety data sheets, and integrated chemical linkages to a growing list of literature, toxicology, and analytical chemistry websites. The application provides access to segregated lists of chemicals that are of specific interest to relevant stakeholders, including per- and polyfluoroalkyl substances (PFAS) containing thousands of chemicals. A procured testing library of hundreds of PFAS chemicals annotated into chemical categories has also been integrated into the dashboard with a number of resulting benefits: a searchable database of chemical properties, with hazard and exposure predictions, and links to the open literature. Several specific search types have been developed to directly support the mass spectrometry non-targeted screening community, enabling cohesive workflows to support data generation for the detection and assessment of environmental exposures to chemicals contained within the database. This presentation will provide an overview of the dashboard, the ongoing expansion of the PFAS chemical library, with associated categorization, and new physicochemical property and environmental fate and transport QSAR prediction models developed for these chemicals. This abstract does not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

**MP197 Moving beyond monitoring legacy per and polyfluoroalkyl substances (PFAS): Screening strategies for the growing list**

Per/Polyfluoroalkyl substances (PFAS), are compounds that have uniquely desirable properties for use in various industries. However, their wide-ranging use leads to emission into the environment, and as PFAS are persistent and bioaccumulate in the environment and wildlife, they are contaminants of concern. Monitoring PFAS precursors present in an environmental sample may impact decisions in treatment processes at remediation sites and help deduce possible degradation products that could exist in the environment. Consequently, scientists are contributing newly identified PFAS structures and spectra to various publicly available databases: growing the list of precursors and degradation by-products, some listing thousands of PFAS. Traditionally, methods such as USEPA 537 and ASTM 7979 and other self-tested targeted methods are designed to monitor a small and discrete number of PFAS compounds, thought to be end-products of degradation processes occurring in environmental systems. LC-MS/MS technology is usually employed to quantify commonly monitored PFAS end-products. Without standards, adding target compounds to an LC-MS/MS method is restrictive and it would be logistically difficult to monitor all possible PFAS without knowing them and having standards. LC-QTOF technology allows the simultaneous quantification of commonly monitored PFAS whilst acquiring untargeted data that can be screened for suspected PFAS precursors. The non-target nature of the data acquired also allows for retrospective detection of new PFAS as the scientific community learns more about these emerging contaminants. The total fluorinated compounds in a sample may be underestimated by not monitoring the precursor compounds of which these compounds are formed from. Sample preparation techniques such as the Total Oxidizable Precursor (TOP) Assay attempt to measure the total fluorinated compounds by forcing degradation of precursors into measurable end-products. This technique is time consuming and may not degrade all precursors into measurable end-products. Additionally, some countries decided to phase out specific classes of PFAS manufacturing and use, which has led manufactures to find alternative classes of PFAS, leading to new precursors and degradation products being found in environmental samples. This study uses a simple dilution (with MeOH) and acidification extraction of non-potable water samples to quantify ~20 commonly monitored PFAS and determines the accuracy, recovery and estimated limits of detection on an LC-QTOF. Further, the ability to collect non-targeted data
allowed us to screen against a user-created database of PFAS compounds to identify additional PFAS that were not in our original target list without the need for standards or re-injection of the sample.

MP198 Toward Comprehensive PFAS Annotation using a Novel Software FluoroMatch for LC-HRMS/MS Data
J.A. Bowden, University of Florida; J. Koelmel, Yale University / School of Public Health Environmental Health Sciences YSPH Global Health Concentration; E.Z. Lin, Yale University / Environmental Health Sciences; K.J. Jobst, McMaster University / Department of Chemistry and Chemical Biology; N. DeStefano, North Carolina State University; K. Pollitt, Yale University / Environmental Health Sciences

Per- and polyfluoroalkyl substances (PFAS) are a growing class of chemicals of increasing concern. Despite the reduction of use for the more commonly known PFAS, a new generation of replacement PFAS have now been introduced, with a limited understanding of how these chemicals impact both environmental and human health. Over 5000 PFAS chemicals are compiled in the USEPA’s CompTox Chemistry Dashboard (“The PFAS Master List”), and yet most analyses only cover a select few PFAS. One major bottleneck in the expansion of PFAS analyses is the lack of tools to adequately characterize unknown or lesser known PFAS species. Liquid chromatography (LC) high-resolution tandem mass spectrometry (HRMS/MS) is an effective approach for non-targeted analyses, which is well-suited for the comprehensive characterization PFAS content, and yet, to date, no software exists to effectively mine the wealth of information provided by this technique. For the first time, we present FluoroMatch for annotation of PFAS in LC-HRMS/MS experiments. Our expertise in developing informatics tools for lipodics (e.g., LipidMatch, IE-Omics, LipidPioneer) will be directly applied to the development of this PFAS annotation software, as lipids and PFAS, from an informatics standpoint, are similar (both contain differing “head groups” which can be combined with various carbon chains, resulting in predicted structures with predictable MS/MS spectra based on head group and carbon chain characteristics). We have generated in-silico PFAS libraries by combining various fluorinated carbon chains and functional groups and then searched against experimental data. We also applied iterative exclusion and intelligent data-acquisition algorithms developed in our laboratory to increase MS/MS coverage and hence the annotation of less abundant and intelligent data-acquisition algorithms developed in our laboratory to increase MS/MS coverage and hence the annotation of less abundant data. FluoroMatch was constructed and validated using a large set of perfluorinated standards and mixtures directly from companies. We have applied FluoroMatch to the LC-HRMS/MS analyses of various PFAS-containing products. We have determined tentative novel PFAS species, as well as major differences in the diversity of PFAS depending on the PFAS-containing product analyzed.

MP199 New Mass Spectrometry Analysis for short chain perfluorocarboxylic acids
J. Clouthier, C. Young, York University / Department of Chemistry

Perfluoroalkyl substances (PFAS) are widely used in many consumer and industrial products including stain repellents, non-stick food paper or pans, and fire fighting foams. Perfluoroalkyl carboxylic acids (PFCAs) are resistant to degradation and have adverse effects to the environment and human health. The long lifetimes of these compounds in the environment is due to the chemical and thermal stability of the carbon-fluorine bond. Long chain PFCAs are known to be toxic in the environment, bioaccumulate, and magnify in the food chain. Short-chain PFCAs (scPFCAs) are PFCAs with four or fewer carbons and are less studied with their toxicity poorly known; they have been observed to accumulate in different plant tissues, including crops. While the toxicity of scPFCAs are not well known, their long lifetimes and persistence in the environment indicate a risk to long term exposure that would adversely affect environmental and human health. PFASs have been observed in the High Arctic indicating that they participate in long-range atmospheric transportation. An additional major source for PFCAs is from the Montreal Protocol-mandated chlorofluorocarbon (CFC) replacements that have known degradation pathways to scPFCAs. Atmospheric scPFCAs have not been widely measured and is an area of research that is lacking; they are difficult to retain on analytical columns and there are currently no real time or quasi-real time measurements of scPFCAs. Therefore, I am developing new analytical methods to measure scPFCAs using ion chromatography mass spectrometry (IC-MS) and a new derivatization method to improve scPFC retention using gas chromatography mass spectrometry (GC-MS).

MP200 Untargeted Annotation of PFAS using a novel software for gas chromatography positive chemical ionization high resolution tandem mass spectrometry
J. Koelmel, Yale University / School of Public Health Environmental Health Sciences YSPH Global Health Concentration; J.A. Bowden, University of Florida / Department of Physiological Sciences; E.Z. Lin, Yale University / Environmental Health Sciences; K. Jobst, Ontario Ministry of the Environment; N. DeStefano, North Carolina State University; G. Charkoftaki, V. Vasiliou, K. Pollitt, Yale University / Environmental Health Sciences

Poly- and Perfluoroalkyl Substances (PFAS) have a diverse range of structures due to impurities, the production of highly complex technical mixtures, and degradation and transformation in the environment. For example, the Simons Electrochemical Fluorination process has been the major manufacturing process in China of PFAS compounds, yielding highly isomerically impure PFAS mixtures. International regulation of long chain PFAS has led to thousands of replacement compounds. The environmental and health impacts of these alternatives are not well understood. This is in part attributable to challenges in characterizing unknown PFAS species; unidentified organofluorine chemicals account for 50 to 99% of organofluorine content in environmental samples. While gas chromatography (GC) high-resolution tandem mass spectrometry can provide a wealth of data revealing PFAS structural information, software to mine this data and automate the compound annotation process is needed. We present a novel untargeted PFAS annotation software for GC-MS data, FluoroMatch GC. It has been shown that positive chemical ionization (PCI) gives high quality data for certain volatile perfluorinated compounds, including perfluoro- ethanol, ethyl acrylate, and ethylene species with varying degrees of fluorination and carbon chain lengths without the need for derivatization. FluoroMatch GC in-silico PCI high resolution tandem mass spectrometry (HRMS/MS) libraries are generated by combining various functional groups with carbon chains differing in length, branching, degrees of unsaturation, and degrees of fluorination. The resulting PCI HRMS/MS spectra is predicted for each generated PFAS structure. GC-PCI-HRMS/MS data was obtained on a GC Q-Exactive mass spectrometer acquiring high resolution MS/MS via HCD for more accurate annotation using both targeted and data-dependent acquisition. GC-EL data was also acquired for targeted search against experimental and predicted PFAS data. FluoroMatch algorithms were validated using over 40 internal standards and various standard reference materials. We applied FluoroMatch to GC-PCI-HRMS/MS analysis of various PFAS products. Demonstration of this software in environmental and biological samples will also be presented.

MP201 Sorption of per- and polyfluoroalkyl substances onto anion exchange passive samplers
K. He, University of Maryland, Baltimore County / Chemical, Biochemical & Environmental Engineering; A. Feerick, L. Blaney, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering

Per- and polyfluoroalkyl substances (PFASs) have been widely used in diverse products, including fire-fighting foams, insecticides, stain-resistant fabric, and food contact paper and packaging for several decades. Due to the chemical and thermal stability of the C-F bond, PFASs have been frequently detected in different environmental compartments, aquatic organisms, and even humans after using. The distinctive environmental behavior and subsequently potential health impacts have raised increased attentions on effective management of these special chemicals. To date, research in the temporal and spatial concentration...
distribution of a wide range of PFASs in the environment is still limited, which is partially due to the lack of effective passive samplers. Although sorption of some PFAS onto different anion exchange materials has been observed in previous studies, the application of anion exchange materials as potential passive samplers has not been carefully explored yet. In this study, we investigated the sorption of 12 chemically-diverse PFASs (e.g., perfluorooalkyl carboxylates, perfluorooalkyl sulfonates, fluorotelomer sulfonates, and perfluorooctane sulfonamides) into three different anion exchange materials (i.e., FAP-450 and FAS-50 anion exchange membranes (Fumatech) and the Mion AK-22 anion exchange fibers (Imatek&K)). The batch sorption tests were conducted in both clean (e.g., 10 mM NaCl) and real water (e.g., groundwater) matrices and the aqueous- and sampler-phase PFAS concentrations at equilibrium was assessed by multiple isotherms (e.g., Langmuir isoherm and Freundlich isotherm) to determine the selectivity coefficient for a PFAS anion over typical environmental anion (e.g., Cl\(^-\)). The concentrations of PFAS and inorganic anions were measured by liquid chromatography tandem mass spectrometry and ion chromatography, respectively. The deployment time required for ion exchange-based samplers to achieve equilibrium with PFAS-contaminated water was identified (e.g., 70 h in an ultrapure water matrix) and the relative trends in PFAS update by molecular properties was further investigated. Overall, our results highlighted the possibility of using the anion exchange membranes and fibers as passive samplers for the chemically diverse PFASs.

Great Expectations: Recovery after Remediation at Contaminated Sediment Sites

MP202 Baseline sampling at the Portland Harbor Superfund Site: How much natural recovery is occurring?

K.E. Vickstrom, CDM Smith / Environmental and Technology Group; J. Kern, Kern Statistical Services Inc; S. Sheldrake, USEPA

The Portland Harbor Superfund Site is a 10-mile reach of the lower Willamette River in Portland, Oregon that has contaminated sediment, water, and biota for which a Record of Decision (ROP) was signed in 2017. Patterns of deposition, erosion, and contaminant distributions are heterogeneous leading to complexities in understanding spatial and temporal change at various scales. Baseline sampling in 2018 and 2019 collected an unbiased dataset of 483 surface sediment grab samples in the site and upstream along with 7 surface water transects, 135 smallmouth bass specimens, and a bathymetry survey. These data were collected to assess pre-construction conditions and serve as a benchmark for post-remediation monitoring. Additionally, temporal change between the baseline and previous Remedial Investigation samples can be approximated with statistical methods that de-bias the different study designs. These data and analyses suggest that the areas selected in the ROD for monitored natural recovery, which comprise just over 80% of the total site area, are predominantly depositional over time and drive site-wide decreases in the different media. However, at smaller spatial scales, the areas of elevated sediment contamination (approximately 20% of total site area) are majority dynamic, have not experienced decreases in sediment concentrations, and continue to serve as sources to surface water and biota. Natural recovery is occurring at Portland Harbor but is limited to less dynamic areas where contaminant concentrations are already lower. Active remediation is therefore needed to accelerate this process and should result in more rapid declines across multiple spatial scales. Before, during and following construction, future unbiased sampling efforts are expected to give a more precise estimate of MNR rates which will help determine timeframes for achievement of cleanup levels post-construction.

MP203 Design, Installation and Quality Control for Organoclay-based Contaminated Sediment Cap at the East Branch of the Grand Calumet River

Background. The East Branch of the Grand Calumet River (EBGCR) is a heavily impacted section of river that enters the southern end of Lake Michigan via the Indiana Harbor Ship Channel. The river has been impacted by legacy industrial activity and primary contaminants consist of PAHs and metals. The east branch project segment consisted of an approximately 1.8 mile long reach just east of the confluence of the east and west branches of the river. The design for the project called for an active cap consisting of organoclay materials having certain minimum sorptive properties (partition coefficients - K\(_\text{d}\) values) for two target dissolved phase PAH contaminants. Based on modeling and design performed by Tetra Tech, organoclay was selected as the reactive/adsorptive material for the cap. J.F. Brennan placed the materials with their proprietary broadcast spreader system. Natural Resource Technology (NRT) performed monitoring and quality control during subaqueous installation of the cap materials in accordance with project specifications. After installation of the active layer, NRT collected additional samples of as-placed cap materials. SAO Environmental Consulting was engaged to oversee laboratory sorption testing to evaluate the relative sorption characteristics of both manufactured and as-placed product samples. Approach/Objectives. This presentation will provide an overview of placement and on-site quality control activities surrounding placement of the EBGCR active cap. In addition, the approach, methodology, and results for laboratory sorption testing of the active capping product will also be provided. The objective of the additional laboratory-based work in this study was to determine possible detrimental impacts that either the manufacturing process (incorporating CETCO’s organoclay powder material into a coated particle) or the act of placing the product in the river may have had on the organoclay sorption capability. Results/Summary. Data demonstrates that the project approach for delivering active-treatment materials to the sediments provided a result that supports the modeling assumptions which were incorporated into the EBGCR remedial design and enables full-scale application of active capping materials in a manner that allows verification of both the quantity and post-placement material properties.

MP204 Historical synthesis and evaluation of long-term recovery of pulpmill-impacted sediments in Alberni Inlet, British Columbia

R. Stevenson, M. Davies, C. Sanchez, R. Philibert, Hatfield Consultants

The pulp and paper mill at Port Alberni, BC has produced a variety of pulp and paper products since 1947. Historically, mill effluent was a significant source of biological oxygen demand (BOD) and suspended organic matter to Alberni Inlet, which led to localized severe sediment anoxia and a thick fibre mat on the sea floor near the mill, with significant associated impacts on the benthic invertebrate community. Substantial improvements in effluent quality in the early 1990s created conditions for natural sediment recovery including long-term burial and microbial degradation of the fibre mat. The study presented here involved a synthesis and evaluation of Federal Environmental Effects Monitoring (EEM) studies conducted since 1994 (immediately following effluent improvements) to examine long-term recovery and to attribute any persisting sediment effects and biological responses to current effluent discharges or legacy sediment conditions (related to historical effluent discharges). The evaluation applied trend analyses for stressors and biological responses, biological effect-size modelling, and community structure assessments to determine support for these alternative impact hypotheses (i.e., current effluent vs. legacy impacts). Sediment conditions near the mill have improved considerably with corresponding improvements in benthic invertebrate density and richness; invertebrate community structure also has transitioned from dominance by opportunistic, pollution-tolerant species to a structure more representative of reference conditions, with numerous taxa and feeding guilds represented. Ongoing benthic
invertebrate community impairment immediately adjacent to the effluent outfall appears to be associated with legacy impacts, requiring a longer recovery period than other stations due to more severe historical impacts. The correspondence between sediment improvements and benthic recovery implicated legacy sediment conditions (which are recovering) as opposed to current effluent discharge as the main mill-related stressor in the marine receiving environment. The length of this study (>25 years) informs the timeframe over which natural recovery occurs in a severely impacted marine environment.

**MP205 Long-term monitoring of a thin-layer sand cap in Peninsula Harbour Area of Concern**

T. George, L. Richman, Ministry of the Environment, Conservation and Parks / Environmental Monitoring and Reporting Branch; B. Rao, Texas Tech University / Department of Civil, Environmental and Construction Engineering; H. Schneider, Texas Tech University; U. Garza-Rubalcava, Texas Tech University / Department of Civil, Environmental, & Construction Engineering; D.D. Reible, Texas Tech University / Civil and Environmental Engineering; A. Jackson, Texas Tech University / Department of Civil, Environmental, & Construction Engineering; H. Biberhofer, Environment and Climate Change Canada / National Water Research Institute, AEMR, WSTD; M. Graham, Environment and Climate Change Canada; K. Kim, Environment and Climate Change Canada / Environment; R. Santiago, Environment and Climate Change Canada; R. Foster, B. Ratcliff, Northern Bioscience

Peninsula Harbour is located in Lake Superior and is identified as an Area of Concern due to historical inputs from the pulp mill and chlor-alkali plant, and historical log booming. Over time these activities resulted in impaired fish and benthic communities, as well as elevated levels of contaminants in sediment and biota - specifically mercury (Hg), methylmercury (MeHg), and polychlorinated biphenyls (PCBs). To reduce the risks posed by the contaminants, thin-layer capping was the selected sediment management option for the contaminant hot spot located adjacent to the mill. In 2012, a 15-20 cm sand cap was placed over sediment exceeding the remedial target of 3 µg/g total Hg. In 2017, five-years post-cap, the first long-term monitoring assessment was completed with the goals of assessing progress towards targets for cap stability, cap effectiveness, and ecological recovery. The large grain size of the sand cap presented some challenges, requiring divers and the use of novel technologies to collect samples. Cap stability was monitored through sediment grab samples and underwater video. The effectiveness of the cap in meeting the remedial target was assessed with surficial sediment data and porewater data from passive samplers inserted in the cap to measure movement of Hg through the cap. Ecological recovery was assessed by the collection of benthic invertebrates, measurements of submerged aquatic vegetation coverage, and the collection of sport fish tissue. Results showed that the cap is stable and has essentially eliminated the vertical transport of Hg from the native sediment to the water-sediment interface. Natural sedimentation on the cap has occurred since cap construction, and the spatially weighted area average concentration of Hg in the overlying sediment was 0.37 µg/g, almost ten times less than the remedial target. As expected, concentrations of PCBs and MeHg also decreased in the sediment. Biological surveys indicated that the cap has been colonized with benthic invertebrates and submerged aquatic vegetation; abundance is low but is expected to increase over time. Concentrations of Hg and PCBs in fish tissue have declined since cap placement. Overall the cap is functioning as intended and is accelerating the recovery of the Area of Concern.

**MP206 Long-term performance of in situ treatment of sediment with AC at Grasse River, NY**

U. Ghosh, T. Needham, H. Xia, University of Maryland, Baltimore County / Chemical, Biochemical and Environmental Engineering; B. Beckingham, College of Charleston / Environmental Geosciences; S. Newell, USACE; A. Harmon, US Army Engineer Research and Development Center; A.J. Kennedy, U.S. Army Corps of Engineers / ERDC; T.S. Bridges, US Army Corps of Engineers / Research and Development Center

We present here the first long-term (10-year) monitoring data from a pilot-study conducted in a river to demonstrate the feasibility of in situ remediation with the amendment of activated carbon (AC) into sediments. In 2006 the first pilot-scale demonstration of PCB bioavailability reduction in sediments with AC amendment was implemented in Grasse River, NY. The study initially documented the performance of the AC amendment over the first three years and showed that AC was stable in the river sediments. AC applied at a dose similar to the native organic carbon of sediment reduced PCB bioaccumulation in worms by 69-99% and porewater concentrations by more than 93% for three years after treatment. In 2016, we performed a 10-year post remedy assessment of the pilot study to evaluate the long-term stability of AC and performance of the treatment. Sediment core samples were collected form the AC-treated and background sites in Grasse River. The core samples were sectioned to determine the present location of AC and the persistence of the AC in the field. AC was stable in the sediments after 10 years and was buried under nearly 20 cm of new sediments confirming a sediment deposition rate of about 2 cm/year. AC recovery was at or above the target dose in the two treatment sites: one where the AC was applied as a thin layer on sediments, and the other where the AC was mechanically mixed into the top layer of sediments. Natural attenuation due to clean sediment deposition is high at Grasse River that has resulted in a nearly one order of magnitude reduction in surface sediment PCB concentration over 10 years. The porewater concentration in the two AC-treated sites has remained reduced by nearly 2-orders of magnitude over the 10 year period post treatment. AC amended to sediments continue to reduce bioaccumulation in worms within the zone of application. Initial mechanical mixing in one plot resulted in a more diffuse layer of AC with time as additional natural mixing spread out the AC through the depth. This finding suggests that the initial mechanical mixing is not necessary for sites where natural mixing can be anticipated. The long-term efficacy and permanence of remedies is one of the nine National Contingency Plan criteria that are used in evaluating and selecting remedies. We show here that in situ treatment with AC is effective in reducing PCB bioavailability in sediments for the long-term.

**MP207 Long-Term Sediment PCB Monitoring Data Influence Reassessment of Remedial Action Decisions**

L. Richman, Ministry of the Environment, Conservation and Parks / Environmental Monitoring and Reporting Branch; D.J. Milani, L.C. Grapentine, Environment and Climate Change Canada / Water Science and Technology Directorate

Monitored Natural Recovery (MoNR) was the management option for PCB contaminated sediment in Lyons Creek East (ON, Canada). The Remedial Action Objective was to reduce PCB exposure to biota (e.g., eastern belted kingfisher and mink) by achieving target concentrations of PCB in sediment that were based on an ERA from 2005. As deposition rates were low, recovery was expected to be slow. Sediment total PCB concentration protective of the kingfisher and mink were estimated at 3.4 µg/g and 1.0 µg/g respectively. The creek was sub-divided into seven Zones based on historical PCB contamination, habitat types, and the home ranges of the receptors. The upstream area, Zones 1-3, was the only identified source of PCBs to the downstream areas. To assess recovery in a step-wise fashion, short and long-term targets for surface sediment (top 0-3 cm and 0-10 cm segments) PCB concentrations were identified. Ninety-six cores were collected from the creek. Samples were analysed for PCB congeners, total organic carbon and particle size. Young of the
Contaminated sediment has been identified as one of the major impediments to remediation in many Great Lakes Areas of Concern (AOCs), including the Toronto and Region AOC. Designated in 1986, a formal Remedial Action Plan (RAP) was established in 1994 to implement numerous restoration actions aimed at the original 11 Beneficial Use Impairments (BUIs) identified. This led to significant improvements in sediment quality, and re-designation of the Degradation of Benthos Beneficial Use Impairment (BUI) as “not impaired” in 2013. The current study applied a sediment quality tetrad (SQtet) in a weight-of-evidence assessment to evaluate current sediment condition within the AOC after the re-designation of the Benthos BUI. The SQtet includes assessment of four lines of evidence (LOE): sediment chemistry, bioaccumulation, toxicity, and benthic community structure. Samples were collected in 2015 from 5 stations within the AOC and compared to 7 nearshore reference stations historically monitored by the Ontario Ministry of Environment, Conservation and Parks. Sediment chemistry indicated no beneficial use impairment.
MP211 Remediation and Restoration of Great Lakes Areas of Concern via Maintenance Dredging of Navigable Waterways and Beneficial Use of Dredged Material

The U.S. Army Corps of Engineers’ dredging program has contributed to the restoration of Great Lakes Areas of Concern (AOCs) in two main ways--historically through the removal of legacy contamination, and more recently through the beneficial use of dredged material. The Corps of Engineers operates and maintains the U.S. portion of the Great Lakes Navigation System, consisting of 140 harbors, 3 lock complexes, 104 miles of navigation structures, and over 600 miles of navigation channels stretching through all 5 Great Lakes and connecting channels. This navigation system supports recreational navigation and waterborne commerce—the most energy efficient and safest form of transportation of bulk commodities. Each year, the Corps of Engineers dredges 3 to 5 million cubic yards of sediment from 20 to 40 harbors in the Great Lakes. This includes federally-maintained navigation channels present in 29 of the Great Lakes’ 43 AOCs. Before the 1970s, virtually all dredged material from the Great Lakes was placed in established open-lake placement areas. In 1970, Section 123 of the Rivers and Harbors Act authorized construction of confined disposal facilities (CDFs) in the Great Lakes. In 2003 it was estimated that the 45 CDFs constructed by the Corps of Engineers had facilitated the removal of over 70 million cubic yards of contaminated sediments from AOCs. More recently, CDFs have served as economical and safe disposal facilities for contaminated sediments removed from outside of navigation channels under the auspices of the Great Lakes Legacy Act as part of active AOC remediation. Additional strategic navigation dredging contributes to remediation within federal channels that otherwise are not currently maintained. The removal of sediment contaminants provided by the CDF program represents a substantial contribution to the goals of Remedial Action Plans and Lakewide Management Plans. Material dredged from many federal navigation channels now contains sufficiently low concentrations of legacy contaminants such that it is suitable for use as fill material in habitat restoration and brownfield remediation projects. These projects include beach nourishment, storm protection, improvements to benthic, fish, and wildlife habitat, remediation of contaminated sediment, and reduction in bioaccumulation of PCBs and other contaminants. Beneficial use of dredged material has thereby further contributed to AOC restoration and removal of beneficial use impairments at some harbors.

MP212 Remedy effectiveness following early actions at the Lower Duwamish Waterway Superfund Site: Implications to long-term effectiveness

K.L. Godfredsen, Windward Environmental, LLC; J. Stern, D. Williston, King County / Department of Natural Resources and Parks; D. Schuchardt, Seattle Public Utilities; A. Crowley, City of Seattle; J. Florer, Port of Seattle; J. Flattery, The Boeing Company; P. Rude, City of Seattle

Early remedial actions have been completed in the Lower Duwamish Waterway (LDW) Superfund site in Seattle, Washington, and remedial design has started for the full sediment remedy. Baseline sampling occurred in 2017-18 to serve as a foundation for assessing trends from before the early actions, and future trends as the full sediment remedy is implemented. This talk presents the site-wide baseline water, sediment, and tissue sampling results for the four human health risk drivers—polychlorinated biphenyls (PCBs), cariocgenic polycyclic aromatic hydrocarbons (pPAHs), dioxins/furans, and arsenic—relative to Remedial Investigation/Feasibility Study (RI/FS) data, predicted concentrations, ARARs, sediment cleanup levels, and tissue target levels. Baseline results are generally consistent with FS modeling predictions following early remedial actions. Post-remedy predictions are discussed relative to site-wide cleanup levels that are not predicted to be met in this complex urban waterway. Predicted outcomes and implications are discussed.

MP213 Remedy Effectiveness: Lessons Learned from 12 Case Studies

J. Stern, King County / Department of Natural Resources and Parks; M. Mills, US Environmental Protection Agency / National Risk Management Research Laboratory; R. Johnston, Applied Ecological Solutions / Marine Environmental Support Office NW; S. Nadeau, Sediment Management Work Group; C. Patmont, B. Henry, Anchor QEA

In a recent collaborative workshop, we reviewed case studies of 12 large contaminated sediment sites to ascertain lessons learned regarding remedy effectiveness. The sites were located in the Pacific Northwest, Upper Midwest, and Northeast regions of the United States. Remedies were completed between 3 and 30 years ago and remedial approaches included dredging, capping, cover, and monitored natural recovery. Common contaminants of concern included PCBs, PAHs (including NAPL), mercury, and creosote constituents. Post-remediation monitoring generally focused on chemical concentrations in sediment, surface water, fish, and shellfish as well as porewater and cap integrity in the case of capping remedies. Each site was reviewed with respect to remedial objectives and risk drivers, a summary of early or completed remedy, significant remedy scope or schedule deviations, timing and effectiveness of source control, primary pre- and post-remedy monitoring elements, achievement of short- and long-term remediation objectives for surface sediment, if the remedy is on track to achieve long-term remediation objectives for water and/or biota, and key take home messages. Several themes were apparent. Source control was of primary importance and early or interim actions often resulted in significant progress toward meeting remedial objectives. At several sites, adaptive management in various forms was an effective way to deal with an evolving conceptual site model or changing site conditions. Remediation was found to be, in large part, effective at reducing contaminant concentrations in sediment. Remedy effectiveness with respect to reductions in contaminant concentrations in biota was mixed with some sites showing reductions consistent with expectations while others did not. The latter was generally attributed to an incomplete understanding of what controls contaminant concentrations in biota, particularly the link between sediment and tissue concentrations. In some cases, ongoing sources to surface water (e.g., stormwater runoff transporting PCBs derived from old building materials in areas subject to redevelopment) were considered responsible for maintaining tissue concentrations above remedial goals. This in-depth evaluation of remedy effectiveness is the first in a series of retrospective reviews and provides important information for site managers seeking to optimize the success of sediment remediation.
MP214 Toxicity evaluations of sediments in coastal area closing to a million cities in Japan using fish embryos

S. Uno, Kagoshima University / Faculty of Fisheries; M. Hashimoto, Kagoshima University; E. Kokushi, Kagoshima University / Faculty of Fisheries

Fukuoka and Kitakyushu cities, where are a million cities, locating on the north part of Kyushu Island, Japan. In Kitakyushu, a large industrial area spreads around the Dokai Bay. Because the sewage had been discharged and the industrial soot had been deposited, the bay is one of most seriously polluted coastal area in Japan, even though the regulations such as the effluent standard was established until now. The Dokai Bay is closed, long narrow terrain, and low frequency of water exchange, and, therefore, the improvement from pollutions progress slowly. The Hakata Bay has been thriving as an international port, and many vessels pass frequently. Additionally, because the bay is closed to Fukuoka, whose population is increasing yearly, the pollutants continue. On the other hand, a large number of species of biota inhabit in the bay, because that has geographical features such as the intertidal flats, seaweed beds, and neritic provinces. A part of pollutants has been possibly residue even in sediments, and expect to affect aquatic biota such as benthic organisms. However, the effects of sediments on the aquatic biota in the aquatic environment are not known well. We have been continuously evaluating the toxicities of sediment, collected from the coastal area in Japan, using the fish embryos, and can find that sediments collected even from the rural coastal area possibly affect the biota. In the present study, we evaluated the toxicities of sediments collected from 11 sites closed to Fukuoka and Kitakyushu cities using the embryos of Java medaka (Oryzias javanicus), which inhabits in the sea water area. Ten embryos were embedded in half of them on each sediments including the slight pore water, which is laid at a glass petri dish, and were developed on the sediment for 12 days post-fertilization.

In the period, the rearing water was not added on the sediments. An embryo was then individually transferred in a hole of 48-well microplates containing sea water, and kept until 3 days after hatching. The mortalities of embryos exposed to sediments collected from 3 sites of the Hakata Bay were from 46.7 to 93.3%. Additionally, 20 to 63% of those exposed to sediments of 4 sites in the Dokai Bay were killed. We could also observe to hatch larvae with some malformations of up to 27% after the exposures of sediments collected from the Hakata and Dokai Bays. These results suggest that both bays polluted as possibly affecting the aquatic biota.

MP215 Utility of conductive soil particles in enhanced direct interspecies electron transfer (DIET) for methanogenic organic acid degradation

T.P. Ezerhba, Department of Biochemistry; C.O. Onwosi, University of Nigeria, Nsukka / Department of Microbiology; E.J. Nweze, I.N. Onwurah, University of Nigeria / Department of Biochemistry

Anaerobic digestion (AD) is an attractive bioprocess for organic waste treatment as it proffers a clean source for energy generation and environmental remediation. However, the process over the years has suffered from limited applicability due to the prolonged lag phase, high susceptibility to environmental changes and substrate-induced inhibition. Several studies are ongoing for AD process optimization. Direct interspecies electron transfer (DIET) is a syntrophic association characterised by electron transfer between two microbial species in contact with each other. Enhancing DIET efficiency between acetogens and methanogens invariably enhances methane generation and the overall process efficiency of AD. Several conductive particles such as graphite, activated charcoal and haematite have been used in the past with great success to “hardwire” microbes for DIET. However, there are no reports on the use of soil particles for DIET, being that they are ubiquitous, cheap and silicon (semiconductor) derivatives. To this end, this study aimed at investigating the potentials of using soil particles for enhancing DIET. Out of 5 different soil types studied, clay soil with conductive clayey particles (CCP) having a conductivity of 77.33 ± 1.12 uS/m was chosen for DIET enhancing ability. Experimental setups with activated charcoal and without any additive were the positive and negative controls respectively. The setup (40 g/l of clay soil) with CCP of 77.33 ± 1.12 uS/m gave the highest methane yield (3496.60 ± 105.10 ml/g) with a production rate of 223.11 ± 7.00 ml/g/d and this corresponds to an enhancement of 44.7% and 38.5% respectively when compared to the negative control. The linear regression equation for production using 40 g/l clayey particle was modelled to y = 0.0325x + 232.45, while the negative control was y = -3.3859x + 188.18. Comparing their gradients suggests a sustained stability and delayed decline in production rate of the clayey setup. Hence, CCP, a representative of clayey soil, has the potential to enhance DIET for anaerobic digestion. The hypothesis is that this soil particle size was just adequate for attachment of the micro-organisms which resulted in sustained or enhanced production. There is a need for further studies to substantiate the actual mechanism of DIET enhancement by CCP.

MP216 Evaluation of Mercury Leaching From the Bank and Ability of the Stabilization Efforts on Mercury Fate and Transport

H. Ziaei Jam, Texas Tech University / Department of Civil, Environmental, & Construction Engineering; T. Vrtlar, CDM Smith / Civil and Environmental Engineering; B. Rao, U. Garza-Rubalcava, Texas Tech University / Department of Civil, Environmental, & Construction Engineering; H. Zhou, Texas Tech University; A. Jackson, Texas Tech University / Department of Civil, Environmental, & Construction Engineering; D.D. Reible, Texas Tech University / Civil and Environmental Engineering; N. Grosso, DuPont

The effectiveness of bank stabilization using biochar on controlling pore water mercury concentration was studied in the South River Waynesboro VA. Historical releases from a textile manufacturing facility resulted in increased mercury concentrations in biota and in sediment and surface water. In 2015, a sampling event was conducted to evaluate pore water total mercury and methylmercury concentration at baseline flow and during drainage conditions after flooding events. The results showed that significant amount of mercury could be releasing from the bank area during drainage conditions. Mercury measurements were conducted using diffusion gradient in thin film devices (DGTs). Bank stabilization efforts were conducted in 2016 and a cap layer of biochar was placed on a contaminated area as part of the mercury remedial action. The stabilization efforts were primarily designed to eliminate any erosion of the mercury contaminated bank soils but, with the biochar, offered control for the leaching of mercury to porewaters. After the bank stabilization, sampling results in August 2017 during baseline conditions showed significant decreases in pore water total mercury concentration; Additionally, sampling was conducted during drainage conditions after a flood event in October 2018 and showed modest increases in pore water mercury but still well below concentrations that were observed prior to bank management. High resolution passive profilers (HRPP) were also used to assess seepage velocities and fluxes of mercury from the bank. The work demonstrated the effective use of DGTs and HRPP to evaluate the impact of flooding and drainage cycles on contaminant release from contaminated banks as well as the effectiveness of bank stabilization and capping efforts in controlling the release.

MP217 In Situ Passive Sampling to Measure Remedial Effectiveness at the Pacific Sound Resources Superfund Site

A.F. Smith, D.D. Reible, Texas Tech University / Civil and Environmental Engineering; J. Williams, W. Gardiner, US Army Corps of Engineers / Environmental Engineering and Technology

During the 1998 remedial investigation for the Pacific Sound Resources (PSR) Superfund Site, dissolved-phase groundwater contamination and “fingers” of creosote-related Dense Non-Aqueous Phase Liquid (DNAPL) was observed to extend from the upland containment wall area towards the Marine Sediments Unit (MSU) within PSR. Following the investigation sub-tidal sediments were capped with borrow materials at depths of 7 feet (near shore) to 3.5 feet (offshore). In 2018, sampling was conducted to evaluate whether the cap contains polyaromatic hydrocarbon (PAH) contaminants that might suggest migration of the underlying cap materials. In 2011 in situ passive sampling for 16 PAHs and Dibenzofuran (DBF)
was deployed at 24 locations, at a depth of up to 34 inches below the cap surface in locations most likely influenced by contaminated groundwater discharge. PAHs were detected in nearly all depth intervals, but no clear vertical concentration gradients could be linked to the underlying contaminants. In 2018, Texas Tech University performed identical in situ passive sampling with the addition of a 25th location for the same 16 priority PAHs and DBF at the PSR site. Porewater concentrations remained low throughout the site (total PAHs < 1 μg/L). ΣPAH concentrations to the northwest portion of the site decreased to 100-200 ng/L in 2018 compared to 500-800 ng/L found in the 2011 sampling. Porewater ΣPAH concentrations in the NE sampling location exhibited a range of 32 ng/L to 879 ng/L with a majority of the observed porewater concentrations in the 500-600 ng/L range. Within the NE locations 11 out of 12 sampling sites showed modest increases in porewater concentrations from the 2011 analysis but no suggestion of substantial PAH penetration of the cap materials or breakthrough of underlying contaminants. Summed porewater concentrations of total PAHs are compared to the higher molecular weight PAHs (3+ ring PAHs) to identify mechanisms and the influence of hydrophobicity of the contaminants on mobility and cap integrity. There were limited effects of hydrophobicity indicating the limited sorption within the cap.

MP218 Sources of Polychlorinated Biphenyls to Upper Hudson River Sediment Post-Dredging

M. Chitsaz, D. Fennell, Rutgers University / Department of Environmental Sciences; S. Litten, Simon Litten, Consultant; L.A. Rodenburg, Rutgers University / Environmental Sciences

The Upper Hudson River (UHR) has been contaminated with polychlorinated biphenyls (PCBs) since the 1940s due to the manufacture of capacitors at two plants near Hudson Falls and Fort Edward, NY by General Electric (GE). Dredging of portions of the UHR was conducted from 2009-2015 as a partial remedy for this contamination. In 2017, the New York State Department of Environmental Conservation undertook a comprehensive post-dredging survey of sediment contamination in the UHR. Thousands of samples were collected, and 130 of these were analyzed for PCBs using EPA method 1668A, allowing a fingerprinting analysis to determine the main sources of PCBs to the UHR sediment post-dredging. This data set was analyzed using Positive Matrix Factorization. Six factors were observed. One resembled the original Aroclors 1016 and 1242 used by GE. Dredging of portions of the UHR was conducted from 2009-2015 as a partial remedy for this contamination. In 2017, the New York State Department of Environmental Conservation undertook a comprehensive post-dredging survey of sediment contamination in the UHR. Thousands of samples were collected, and 130 of these were analyzed for PCBs using EPA method 1668A, allowing a fingerprinting analysis to determine the main sources of PCBs to the UHR sediment post-dredging. This data set was analyzed using Positive Matrix Factorization. Six factors were observed. One resembled the original Aroclors 1016 and 1242 used by GE. Three represented different pathways and/or extents of microbial dechlorination. One factor resembled a dechlorinated version of Aroclor 1254, which was also used by GE. There was another factor that can be described as a mixture of four different Aroclors and its spatial distribution suggests that it is not directly attributable to the GE activities at the Fort Edward and Hudson Falls plants. It explains about 2% of the PCB mass in the sediment of the UHR.

Soil Contaminants: Fate, Bioavailability, Environmental Toxicology in Ecological and Human Health Risk Assessment

MP219 Assessment Of Bacterial Isolates Of Soil From Houston Area Watersheds

F. Adebowale, Texas Southern University / Environmental Toxicology

Assessing the Houston area watershed soil for bacterial levels is essential since some water bodies are prone to bacterial contamination from wastewater treatment plants, industrial facilities, and feces from animals. Houston has a complex watershed, which makes the city prone to flooding like the 2017 Hurricane Harvey. As a result, a comparative study between soil samples collected during the 2018 summer (July) and 2018 winter (November) was carried out. The Houston area bayous characterized for bacterial burden were: Dickinson, Horsepen, Mustang, Cypress Spring, and Clear Lake. Quantification of bacterial loads was done using selective and differential media as well as a broad-based medium for enteric and total counts, respectively. Biolog identification System was used to confirm the biochemical tests of the isolated colonies. It was observed that bayous closer to the densely populated urban center, such as Dickinson and Horsepen, had significantly higher enteric and total bacterial loads during the winter when compared to summer samples, perhaps due to their closeness to wastewater treatment plants, recreational activities, temperature change inhibiting the growth of some bacteria and also due to the redistribution of flow of water from upstream to downstream. Future studies will aim to identify isolated colonies (using biochemical and DNA sequencing approaches) and evaluate their growth kinetics, biofilm formation, and responses to oxidative stress.

MP220 The change of microbial diversity and community composition in the process of pig feces returning to the field in Jiuzhou River Basin, GuangXi

W. Shen, Y. Yu, Y. Jin, R. Zhou, Nanjing Institute of Environmental Science / Ministry of Ecology and Environment; G. Wang, Nanjing Institute of Environmental Science; Y. Zhang, Nanjing Institute of Environmental Science / Ministry of Ecology and Environment; Y. Bu, Nanjing Institute of Environmental Sciences

In recent years, breeding industry has development in China following the rise of the economy. The development of breeding industry brings not only economic development but also huge environmental problems. Fecal contamination is a major concern because of its direct pathogenesis. Feces can be used in fertilizer to return the soil after treatment, and now, many farms used fermentation to treat feces before using. But lots of microorganisms remained in the treated feces and they may cause harm to people’s health. In this study, we used MiSeq sequencing to explain the change of composition of microorganisms in the feces return to soil. We chose feces (MA), waster water (WA), farmland soil (FS), yard soil (YS), and sewage sludge (SS) as our research objects and selected 18 farms in Jiuzhou River basin as sampling place. We got 369950 high quality microbial sequences for analysis. According to the analysis, the composition of microorganisms in the MA group changed dramatically after fermentation and lots of microorganisms including pathogens were decreased. Badly, we found many pathogens in WA and soil samples. Some high content pathogens exist in MA and we can find them in soil samples. We think WA may contribute to the pathogens in the soil. The content of pathogenic bacteria in the soil is low, but the harm should not be underestimated. We should improve the methods to remove pathogens in the WA. This paper confirmed with a large amount of data that fermentation can indeed change the microbial structure in feces, but new pathogens contamination may be introduced in the fecal treatment process.

MP221 The Combined effect of Mix biochar and Compost on Potato Plant uptake of Heavy metals

A. Mawaj, S. Prasher, McGill University / Bioresource Engineering; S. Bayen, McGill University / Food Science and Agricultural Chemistry; E. ElSayed, University of Guelph / School of Engineering; C. Nzediegwu, McGill University / Bioresource Engineering

Freshwater shortage, coupled with need of increasing food production for the growing population, has become a challenge for irrigated agriculture. Increased utilization of freshwater due to industrial development and urbanization has resulted in the production of massive volumes of wastewater posing its disposal problem. Wastewater use for irrigation could partly fulfill water demand and solve disposal problem. In several developing countries, knowingly or unknowingly, partially treated and/or untreated wastewater is used to irrigate food crops. However, the presence of contaminants, including heavy metals in wastewater, could pose a risk for human health and aquatic life. Therefore, low-cost simple treatment methods are needed to reduce contaminant transmission to crops. A field lysimeter experiment was conducted for two years (2017/18) to investigate the effect of mixing barley straw biochar and compost in soil on the mobility of heavy metals from wastewater to potatoes. Potatoes were planted in sandy soil and irrigated with synthetic wastewater containing organic contaminants and heavy metals (Cd, Zn, Cu, Fe, Pb, and Cr).
Four treatments 1- wastewater irrigation to non-amended soil (WW), 2- wastewater irrigation to soil amended with 7% compost (C-WW), 3- wastewater irrigation to soil amended with 1% biochar (B-WW), and 4- wastewater irrigation to soil amended with Mix 7% compost and 1% biochar (CB-WW), in triplicate. After eight irrigations potatoes were harvested. The edible parts of the potato plant (flesh and peels) and root were analyzed to determine heavy metals using ICP-MS. In 2017, Cd concentration in potatoes flesh were WW 1.51 μg/g, BC 1.07 μg/g, and BC+ Compost 0.63 μg/g. In 2018, these were WW 5.3 μg/g, BC 4.46 μg/g, and BC+ Compost 2.19 μg/g. Similarly, in 2017 the concentrations in the root were WW 121.1 μg/g, BC 95.7 μg/g, and BC+ Compost 43.2 μg/g, and in 2018 were WW 2.43 μg/g, BC 223.7 μg/g, and BC+ Compost 76.8 μg/g. These results in two years indicated that there was a significant reduction (P<0.05) in plant uptake of (Cu, Cd, and Zn) for Mix BC+ Compost as compared to WW Control, Compost and BC 1%. The immobilization effect in BC-WW treatment was attributed to changes in the soil physicochemical properties such as higher pH, increased soil organic matter, cation exchange capacity, and dissolved organic carbon in the soil.

MP222 Assessment of risk to hoary squash bees (Peponapis pruinosa) and other ground-nesting bees from systemic insecticides in agricultural soil
D. Willis Chan, R.S. Prosser, University of Guelph / School of Environmental Sciences; J. Rodríguez Gil, University of Ottawa / Department of Biology; N. Raine, University of Guelph / School of Environmental Sciences
Using the hoary squash bee (Peponapis pruinosa) as a model, we provide the first probabilistic risk assessment of exposure to systemic insecticides in soil for ground-nesting bees. To assess risk in acute and chronic exposure scenarios in Cucurbita and field crops, concentrations of clothianidin, thiamethoxam and imidacloprid (neonicotinoids) and chlorantraniliprole (an anthranilamide) were measured in soil samples. The probability of exceedance of several exposure endpoints (LC50s) was compared to an acceptable risk threshold (5%). In Cucurbita crops, under acute exposure, risk to hoary squash bees was below 5% for honey bee LC50s for all residues evaluated but exceeded 5% for clothianidin and imidacloprid using a solitary bee LC50. For Cucurbita crops in the chronic exposure scenario, exposure risks for clothianidin and imidacloprid exceeded 5% for all endpoints, and exposure risk for chlorantraniliprole was below 5% for all endpoints. In field crops, risk to ground-nesting bees was high from clothianidin in all exposure scenarios and high for thiamethoxam and imidacloprid under chronic exposure scenarios. Risk assessments for ground-nesting bees should include exposure impacts from soil and could use the hoary squash bee as an ecotoxicology model.

MP223 Impact of metals in sewage sludge on soils and plants stress response including DNA damage and expression of genes encoding metal transporters
M. Jaskulak, Czestochowa University of Technology / Faculty of Infrastructure and the Environment; A. Grobelak, Czestochowa University of Technology / Institute of Environmental Engineering; F. Vandenhulse, Université de Lille / Fonctionnement des Ecosystèmes Terrestres Anthropisés Cité Scientifique
The recent increase in soil supplementation with sewage sludge (SS), is gaining a lot of interest, and the proper evaluation of its safety is critically needed. Heavy metals (HMs), that are often seen in sewage sludge, such as lead and cadmium pose a threat to all members of the food chain and are considered to be the most crucial inorganic soil contaminants. Still, our understanding of the specific effects of metals on plants physiology and metal uptake are strictly limited. Simultaneously, the disposal of sewage sludge poses a severe threat to the environment, and today there is an increasing pressure to minimize landfilling of SS which leaves two possible ways of its disposal: incineration or application to land, which is considered to be a beneficial method because it allows for nutrient recycling. Thus, a better understanding of interactions between contamination and mechanisms by which plants respond to such exposure is a prime objective in plant research. In this study, S. alba was exposed to degraded but not contaminated soil, characterized by a severe lack of organic matter due to overexploitation. In order to research the safety of SS application to soil and plants physiological response to such actions, the soil was supplemented with 4 different types of sewage sludges. Two out of four of those sludges contained trace amounts of heavy metals, but still manage to pass the norms for HM contamination. The measurement endpoints were: biomass, roots length, metal accumulation in plants shoots, activity of peroxidase, expression of The ATP-binding cassette transporters (ABCs) genes by real-time quantitative PCR and the level of DNA damage via comet assay. Overall the expression was elevated in samples with municipal sewage sludges after 7 days of exposure and continued to increase through the timepoints. Moreover, we observed a increase in plants oxidative stress and DNA damage. Therefore, the supplementation of soil with sewage sludge containing even trace amounts of HMs causes an adverse impact on plant physiology and hence, the use of more sensitive biomarkers that take into consideration plants metabolic pathways of dealing with such stress is needed to thoroughly test the safety of selected waste product to be applied to land. Hence, we propose that the measurement of DNA damage and ABCs expression could be potentially used in such safety evaluation process as an early indicator of metal stress - before any visible signs of toxicity will occur.

MP224 Influence of stereochemistry on the partitioning of selected ortho and non-ortho polychlorinated biphenyls between aqueous solution and soil system
G.C. Advinka, University of KwaZulu-Natal / Chemistry
The influence of sorbate characteristics such as stereochemistry on the partitioning of selected non-ortho and ortho-substituted polychlorinated biphenyls (PCBs) between aqueous solution and soil collected along the river course of uMgeni River of KwaZulu-Natal, South Africa located in sub-Saharan Africa was investigated in this study. Specifically, PCB 77 and PCB 52 were selected in this study to represent the non-ortho and ortho-substituted system. These congeners were chosen due to their historical environmental problems and varying degree of hydrophobicity characters despite their equal numbers of chlorine atoms. Soil physicochemical characteristics were quantified such as soil organic matter, cation exchange capacity, surface area, pore volume distribution, and pore diameter as well as various functional groups present in the soil humic materials using Walkley Black, BET adsorption-desorption, and FTIR methods respectively. Batch adsorption experiments were used for the sorption studies. The results of the investigation revealed that non-ortho substituted congener was found to show more preference for soil compared to its di-ortho substituted counterpart congener of the same homolog. The effect of initial concentrations on both revealed that low initial PCB concentrations were mostly favoured for the sorption while sorption was generally low for ortho-substituted PCBs at high concentration. This could be due to the soil interlayer pore blockage which may be influenced by the position of the chlorine. Also, non-ortho PCB 77 was said to be more hydrophobic due to the orientation of chlorine atoms which allows for the free rotation of chlorine atoms between the phenyl rings and practically impossible in PCB 52 thereby making it more susceptible to aqueous solubility. Due to the susceptibility of ortho-substituted congeners to aqueous solubility, it is, therefore, more likely for this pollutant to re-suspended back to surface water or leach to the groundwater more easily when sorbed by soil and may possibly pose more risk to the aquatic ecosystem relative to its non-ortho substituted congener of the same homolog. However, PCB 77 are more likely to result in steady sorption by soil and become less available to the aquatic life which may then become more available to filter feeder organisms who source their food from surface sediment.
**MP225 Environmental Impacts of Spent Oil Lubricants on Soil Properties and Environmental Segments in Orji Mechanic Workshop, Imo State Nigeria**

M.L. Chukwuemeka, Scientific Equipment and Development Institute / Laboratory; C.K. Uhama, Enugu State University of Science and Technology / Biochemistry

The study investigated the effects of spent oil lubricants on soil physical and chemical properties. Twelve (12) different soil samples were collected from the auto-mechanic villages and from the Federal University of Owerri (FUTO) university agricultural land that served as the control. Two (2) samples were collected from these three points 50.31.114N 7002.703E, 5031.165 N 70.2670E and 5023.35N6059.176E at profile of 0-15cm and 15-30cm. Twenty three (23) different parameters were analyzed for the soils such as pH, bulk density, total organic carbon, particle size distribution, heavy metals of Ni, Cu, Zn, Ar, Cd, Hg and Pb. Standard methods were employed in the course of the analysis. All the parameters tested was in good condition except for the soil pH and concentrations of heavy metals which were more significant as pH of the auto-mechanic soils were acidic in the range of 4.3 - 5.0 in comparison with the control with mean value 5.6. Heavy metals were higher and richer in auto mechanic soils than in the control and their concentration decreases in this trend Cu 0.940 > Hg 0.211 > Ni 0.093 > Zn 0.051 > Pb 0.021 > Cd 0.015 > Ar 0.003; Hg 1.385 > Cu 0.853 > Ni 0.079 > Zn 0.041 > Cd 0.04 > Pb 0.034 > Ar 0.004 for the soil auto-mechanic soil 1 and 2. Ar had zero values in the soils of the control. Pearson Correlation coefficient was computed in testing the hypothesis using SPSS v. 20 where significant positive correlations were obtained at values 0.957 and 0.99. P value 0.000; 0.874 and 0.999, P 0.000; 0.997 and 0.912, P 0.000; 0.997 and 0.918 P 0.000 all at 0.01 level of significance. The null hypothesis was rejected on the basis of the significant correlations for relationships between the use of lubricants and physico chemical variables, physico chemical variables and depths of the soil across the profile, use of oil lubricants and soil particle size distribution, use and disposal of oil lubricants and soil texture. Recommendations were made like adherence to proper disposal of auto mechanic wastes, use and enforcement of Environmental Management Plan in auto-mechanic workshop villages and remediation measures to correct the concentration of parameters as identified using phyto-remediation for a sustainable soil and environmental management in the vicinities of the workshop.

**MP226 Extraction approach to analyze organoaarsenic species such as dimethylmonothioarsinic acid (DMMTAV) and dimethyldithioarsinic acid (DMDTAV) in soil**

S. Park, Korea Basic Science Institute; Y. Kim, Yonsei University / Natural Science Research Institute; M. Cho, H. Park, S. Jeong, Korea Basic Science Institute; H. Yoon, Korea Basic Science Institute / Seoul Center

Various arsenic species are present in the environments and these species can be transformed according to the environmental conditions. Among the arsenic species, it was reported that the inorganic arsenics have higher toxicity than organic arsenics. However, some organic arsenics such as dimethylmonothioarsinic acid (DMMTAV) and dimethyldithioarsinic acid (DMDTAV) have relatively high toxicity. These species can be transformed from low toxic arsenic species such as dimethylarsinic acid (DMAV) under sulfidic condition. In our previous studies, it was confirmed that the DMAV can be thiolated to DMMTAV and DMDTAV according to environmental conditions. This transformation can occur in actual environments and the strong candidates are landfill and mine site. In these sites, DMMTAV and DMDTAV can be present as an adsorbed form onto soil, and consequently the toxic organoaarsenic can be exposed to the plants, animals, and human. However, the analysis method of DMMTAV and DMDTAV extracted from soil was not reported. Therefore, the aim of this study is to find the extraction method of DMMTAV and DMDTAV adsorbed from the soils. The experiment was carried out using the clay minerals because it reduces interference by soil factors such as sulfide and iron. These factors can be significantly influenced to adsorption and extraction reaction of organoaarsenic species. The soil experiments will be attempted after this clay mineral experiment. First of all, we made DMMTAV and DMDTAV be adsorbed on the clay minerals. And the various extracting solutions, including methanol/water mixture, inorganic acid, and organic acid, are employed to extract DMMTAV and DMDTAV from clay minerals. For extraction, solid and solution was appropriately mixed and sonicated. After then, the mixture was centrifuged and filtered to separate the supernatant and solid. The separated supernatant was analysis using HPLC-ICP-MS to compare the extraction efficiency of DMMTAV and DMDTAV. Through this study, we infer the potential on extraction of DMMTAV and DMDTAV. In addition, it can be investigated which one is the most effective to extract DMMTAV and DMDTAV from clay minerals, and simultaneously this result can be basis on the application of actual soil environment. This research was supported by a grant from the Korean Basic Science Institute (Project No. C39707).

**MP227 Source Identification and Human Health Assessment of Heavy Metal Contamination by Multivariate and Hazard Index Analyses**

A. Ogunlaja, Redeemers University / Biological Sciences; O.O. Ogunlaja, Lead City University / Chemistry; D. Okewole, Redeemers University / Department of Mathematics

Petroleum contamination is a significant contributor of elevated level of toxic heavy metals, which are of great concern to human health, due to their non-biodegradable nature. Agaye community has experienced frequent gasoline spills due to pipeline vandalism, resulting in the contamination of soil and water sources. The concentrations of metals (Cd, Cr, Cu, Mn, Ni, Pb, V and Zn) in groundwater, surface-water and soil were determined from a total of 216 samples acquired bi-monthly for two years by Inductively Coupled Plasma-Optical Emission Spectrometry (ICP-OES) to evaluate the impact of oil spills. Multivariate analyses using principal component analysis (PCA) and cluster analysis (CA) were also used to study the interactions between metals and identify the possible sources of contamination. The concentrations of heavy metals in soil and water samples (surface and groundwater) were in decreasing order of Mn > Ni > Zn > Cu > V > Cr > Pb > Cd and Ni > Zn > V > Cu > Mn > Pb > Cr > Cd respectively. Ni concentration ranged from 0.42-8.05 mg kg-1 and 0.10-2.85 mg L-1 for soil and groundwater respectively. Ni and V were more enhanced (P < 0.05) in soil samples. This study showed that there was significant relationship between elevated levels of Cr, Cu, Ni and Zn and oil spillage, due to petroleum spills and that residents were vulnerable to and at greater risk of non-carcinogenic hazards if they consumed groundwater. Multivariate analyses showed significant anthropogenic intrusions of two diagnostic heavy metals (Ni and V) for petroleum contamination in the soils and water sources.

**MP228 Toxic Effect Concentrations of Rare Earth Elements by Total and CaCl2 Extraction Including Comparison of Bioaccessibility to OECD Soil**

A. Pellegrino, MTE Consultants, Inc. / Toxicology and Risk Assessment; B. Pereira, University of Guelph; B.A. Hale, University of Guelph / SES

Rare earth elements (REEs) are a group of 17 elements including the lanthanide series, yttrium and scandium. They co-occur naturally in mineral deposits, have similar properties, and are being used increasingly in new technologies. At low REE concentrations in soils, plant growth can be stimulated; at higher concentrations, toxicity has been identified for some REEs. Through 14 day growth studies, toxicity thresholds (shoot/root length) for radish, tomato and durum wheat to three REEs: cerium, neodymium, and europium, were determined. A hormetic response was not observed for any of the data, however many endpoints displayed thresholds. Bioaccessible REE concentrations determined by CaCl2 extraction were very low - less than 0.05% - for each REE. The range of observed toxicity thresholds (EC 25900-7600 mg/kg) was greater than that reported...
in previous studies, likely due to the low bioaccessibility of REEs in the highly organic soil used in the present study. Internal tissue concentrations may better relate to the dose at the site of toxicity.

MP229 Quantification of nano-zero-valent iron in soil for toxicity testing of soil invertebrates

R. Akre, L. Vasiliuk, University of Guelph / School of Environmental Sciences; P. Smith, University of Guelph; J. Nichols, W. Martin, MTE Consultants, Inc.; B.A. Hale, University of Guelph / SES

Nano zero-valent iron (nZVI) has been used for several years in the remediation of contaminated groundwater and has more recently been proposed as a method for soil remediation. It can reduce the toxicity of contaminants such as polycyclic aromatic hydrocarbons, pesticides, and heavy metals that are resistant to microbial degradation and weathering (degradation and immobilization). Before nZVI can be widely used in soil remediation efforts, toxicity testing must be done to compare the toxicity of the existing contaminants to potential toxicity of the nZVI. Some literature exists on the toxicity of nZVI to soil biota, but these studies report nominal concentrations or reduction in bioactivity of a contaminant rather than measured concentration of nZVI, which undermines confidence in the data. The purpose of this research is to adapt a method of nZVI quantification from groundwater research that uses indigo disulfonate as a specific chemical redox probe. A standard curve was developed by reacting indigo disulfonate with known concentrations of nZVI in water to produce a colour change measured by ultraviolet-visible spectroscopy. This curve was then used to quantify nZVI in soil pore water extracted from nZVI amended soils. Toxicity to the soil invertebrates Folsomia candida and Eisenia andrei was then assessed using the endpoints of avoidance, lethality, and reproduction. These endpoints were combined with the method of measuring nZVI to express toxicity thresholds in terms of the realized dose in the soil. This allows for better extrapolation to field exposure scenarios and development of guidelines for the use of nZVI in soil remediation.

MP230 Use of QSAR models in Environmental Management Information System for soil pollution

A. Neira-Albarron, University of Chile; L. Caceres-Jensen, J. Rodriguez-Becerra, Metropolitan University of Educational Sciences; M. Escudey, University of Santiago de Chile

Assessment and regulation of environmental impacts of organic pollutants in soils and groundwater can be costly and time-consuming. These problems are compensated by different Environmental Management Information Systems (EMIS) that accelerate the decision-making process by tracking pollution, monitoring impacts and environmental fate, describing background soil conditions, choosing of alternative compounds for better practices, etc. In all these cases, the adsorption of pollutants in soil organic matter (logKoc) is a key parameter. In this sense, several QSAR models (QSARs) to predict logKoc from empirical data measured under laboratory conditions had been published and proposed for regulation. However, differences between laboratory and field conditions imply uncertainty about the applicability of QSARs with this focus. This work proposes an QSAR-based approach to environmental management by connecting QSARs and EMIS through a quality improvement methodology. The method divides the process of creation and application of QSARs on four steps, based on PDCA cycle: (i) Plan, including the data mining and generation of datasets; (ii) Do, where datasets are classified according to an objective, such as assessment of potential risk, and the QSARs are created. In this step, the mathematical complexity of model (linear or non-linear) is based on the system complexity, i.e. relationship between the initial descriptors pool and the variability of endpoint data; (iii) Check, using different chemometric tool for the statistical validation of QSARs, such as cross-validation, external validation, bootstrapping, and adding an empirical validation consisting of generate and analyze empirical data in situ, considering environmental conditions such as pedogenetic, climate, soil-water potential, temperature, among others. Finally, (iv) Act, where the results of empirical validation are used to redefine and/or improve the applicability domain and mechanistic explanation of QSARs. In addition, the experimental data can be used as input to a new and more accurate QSARs, while the fails on predictivity can help to propose new descriptors that include the unexplained variability of the current model. The use of Baseline Environmental Assessment as empirical data is also a way to connect scientific and political work, and the applicability of QSARs in local contexts allows a greater commitment among citizen, regulators and scientists.

MP231 Risk assessment and toxicological evaluation of the impact of lead-mining activities in Agalegu, Ebonyi State, Nigeria

C. Onwarah, University of Nigeria / Educational Foundation; I. Dike, University of Nigeria; A.C. Udebuani, Federal University of Technology / Department of Biotechnology

In this study, we examined the levels of contamination of some vegetable crops, soil and water arising from the mining activities in Agalegu in Ebonyi State. Toxicity of water samples were tested using the “ostracod (Heterocypris incongruens) toxicity assay kit” and that of soil using earthworms as test organism. Results show that the concentrations the various vegetables, soil and water samples decreased as distances progressed from the mining site. There was no observed mortality of earthworms after 72hours of exposure to the various lead-soil samples. However, 10% mortality of earthworms (after 7 days) and 22.2% mortality (after 14 days) were observed in lead-soil samples collected 0.05km away from the mining site, while 10% mortality was observed (after 14 days) in lead-soil sample collected 2km away from the mining site. Percentage mortality of ostracod crustaceans exposed to lead-water samples decreased as distances progressed from the mining site, but remained constant after distance of 4km. In Agalegu community, Ebonyi State, Nigeria the total THQ values of adults and children through consumption of vegetables and water intake were 4.12 and 5.41, respectively, suggesting that the residents may be facing health risks due to vegetable consumption and that children in particular were vulnerable to the adverse effects of heavy metal ingestion.

MP232 Arsenic Contamination and its Impact on Cellular Functions in Wound Healing

O.R. Lujan, Northern Arizona University / Biological Sciences; B.I. Pinto, Northern Arizona University / Center for Bioengineering Innovation; T.A. Bardsley, Northern Arizona University / Biology; A. Gutierrez, Northern Arizona University; C.R. Propper, R.S. Kellar, Northern Arizona University / Biological Sciences

Arsenic (As) is a naturally occurring element found in the environment and is harmful to humans at elevated concentrations. Erosion of natural arsenic mineral deposits can lead to contaminated water wells that communities use for bathing, drinking and agriculture. Following human exposure, As has been shown to negatively impact major organs, cellular functions, and gene expression, potentially increasing the risk for developing pathologies. The cellular and molecular underpinnings of As effects on these disease states are similar to those seen during wound healing, suggesting that arsenic exposure impacts normal cell function in wound healing. In these studies, human fibroblast (hDF) skin cells were exposed to environmentally relevant concentrations of As (sodium arsenite). Fibroblasts are critical for many aspects of wound healing and can be cultured in a monolayer to study contaminated wounds. Cellular migration, metabolic activity and viability of hDF cells exposed to As were evaluated using three independent in vitro assays. In a scratch cellular migration assay, treatment of hDF with As for 24 hours prior to scratch reduces the effective As dose 20-fold (from 10 μM to 0.5 μM) compared to treating at time of scratch (p< 0.05). In the cell metabolic activity and viability assays, pretreatment (24-72 hours) of hDF with As decreases metabolic rate at 1 μM, reduces proliferation at 2 μM, and is lethal to both metabolic rate and viability at 5 μM and 10 μM (p< 0.05). These results suggest that As may deleteriously affect wound healing, which may directly translate to future in vivo studies.
MP233 Environmental contamination: The toxic legacy of a Native American tribe continues
K. Fetecie, O.N. Avenbuan, New York University School of Medicine / Environmental Medicine; D. DeFreesee, Ramapough Lenape Nation / New Jersey; M. Zhong, J.L. Bloom, J. Zelikoff, New York University School of Medicine / Environmental Medicine

Beginning in the early 1960s through the late 1970s, Ford Motor Co. dumped paint sludge and other toxic metals from its Mahwah plant into the local suburbs, including Ringwood, NJ. As a result, Ringwood became riddled with contaminated soil and water, placing a large environmental health burden on the very people who have lived on this land for generations - the Ramapough Tribal Nation. Upon community request, soil samples were collected from chemically-impacted areas of Ringwood by citizen scientists and NYU graduate assistants in order to evaluate soil metal concentrations. Samples were collected by digging 3-5 inches deep into the soil with a plastic trowel. Once dried, samples were crushed and homogenized and digested by adding 2 ml of nitric and 1ml of hydrochloric acid to 1 g of soil. The soil digest was then diluted with water and filtered using a 0.45mm filter to capture any particulate matter. Using ICP-MS, 36 metals were identified and their levels compared to New Jersey Direct Contact Soil Standards for dermal, ingestion, and inhalation exposure. Vanadium (V), a transition metal readily taken up by plants, was found in several soil samples at levels that exceeded the NJ soil standard of 78 mg V/kg. At high concentrations, ingestion of Vanadium has been correlated with adverse health effects in the human gastrointestinal, cardiovascular and renal systems and its cancer-causing potential is still being debated. Given the elevated V concentrations in the soil samples of this region, residents consuming plants grown in this area or recreating in the area could be at increased risk for adverse health effects. Supported by NIEHS Core Center Pilot Grant.

MP234 Application of Box-Bennken design in the optimization of organic amendments during the bioremediation of kerosene polluted soils
M.O. Chukwu, University of Nigeria, Nsukka / Microbiology

Nigeria is one of the major oil-producing countries and as a result, is faced with various forms pollution emanating from crude oil exploration, transport and utilization. This has hampered the agricultural activities and endangered most aquatic organisms owing to the toxicity associated with the pollutants. To this end, the current study was undertaken to optimize the composting materials during the bioremediation of the polluted soil. The optimization of the organic amendments was performed using the Box-Behnken statistical experimental design. This design consisted of 15 runs of 3 factors (poultry droppings, sawdust and grass trimmings) at 3 levels which included three central points to analyze the model robustness. The rate of total petroleum hydrocarbon removal, lipase and dehydrogenase activities were considered as the experimental responses for monitoring of the effectiveness of the biodegradation. The statistical design suggested that a mixture of grass trimmings (158.2 g), poultry droppings (50g) and sawdust (602.7g) resulted in best total hydrocarbon removal rates (R2 =0.9776). The dehydrogenase and lipase activities of the soil microbes were effective biomonitoring tools during the remediation. This study clearly shows that cheap organic amendments are indispensable in the removal of pollutants from the environment.

Natural and Ambient Soil Background Studies and Their Utility in Risk Assessment

MP235 Analytical Investigation of Physicochemical Properties of Soil and Water From Coal Mining Environment of Enugu State, Nigeria
O. Francis, University of Nigeria Nsukka

Underground coal mining are likely to disturb the underground water and soil in terms of quality. Added to this is the problem of leachates from the large number of industrial waste and overburden dumps that are in abundance in mining areas. It was observed that pH level of Ngwo soil compared to that of Udi and Akwuke soil which is below W.H.O standard may be attributed to anthropogenic sources. The specific gravity and bulk density of soil from, Ngwo, Udi and Akwuke were below the WHO allowable limit. The anion levels, NO3, PO4, SO4 and Cl levels in soil from the three communities studied were within permissible limit (EPA, 2012), though PO4, SO4 and Cl2 level of Udi soil were significantly higher than the values in the communities. The decrease in pH of well water from Udi and Akwuke, 4.80±0.01 and 5.54±0.01 respectively was an indication of acidity of the well water. These values are above W.H.O standard level (6.5) for portable water. The conductivity levels of well water from the three communities investigated were within the EPA permissible level (5-50µhos/cm3) for drinking water. The observed levels of total solid, total dissolved solid and total suspended solid of well water from the three communities were within the WHO permissible limit for drinking water, except chloride level (916.00±1.00) in Udi well water which was above W.H.O permissible limit (250mg/l) for chloride.

MP236 QSAR models to predict pesticide sorption in soils:
Application in environmental decision-making
A. Neira-Albornoz, University of Chile; L. Caceres-Jensen, J. Rodriguez-Becerra, Metropolitan University of Educational Sciences; M. Escudey, University of Santiago de Chile

Soil and water pollution by pesticides is an issue of global concern because of its multiple impacts and complex fate pathways, principally dependent on adsorption. In this sense, QSAR models (QSARs) to predict sorption of pesticides in soils are usually used as screening tools to evaluate environmental and health risks. The OECD propose the use of logKoc as endpoint, assuming that sorption is hydrophobic and occurs only in organic matter (OM). Moreover, only one logKoc value per pesticide is used, resulting from the average of sorption coefficients among different soils. However, this procedure hides the variations in sorption mechanisms among different soil orders due to environmental and physicochemical soil properties. This reduce the accuracy and relevance of QSARs in specific scenarios, affecting their use in environmental decision-making. Considering the sorption mechanisms in pesticide-soil systems as a source of uncertainty for QSARs, the current study analyzes the sorption mechanisms from a molecular view, focused on soil and solution properties using a bibliometric approach that involved a total of 1488 articles. First, sorption data was separated by kind of molecule and sorbent, then sorption mechanisms for all the combinations were studied and finally, logKoc values were compared with QSARs validated by the OECD, considering if (i) logKoc is representative of sorption mechanisms and (ii) prediction of QSARs is connected to the mechanistic assumptions. The results showed differences inter-soil and inter-pesticide related to the speciation of both, particularly between ionizable and non-ionizable pesticides, or between variable and permanent charge soils. The most frequent sorption mechanism is hydrophobic in OM, however, we found some prediction errors in OECD QSARs, associated to the functional groups and humification degree of OM and clay-humus complexes. On the other hand, the most uncommon sorption mechanisms occur in variable charge soils, including sorption of anions, cation-pi interactions and sorption pH-dependent for ionizable and non-ionizable pesticides, with inapplicability of OECD QSARs. These results are useful to contextualize the endpoint to the specific soil properties and sorption mechanisms, improve the applicability domain of QSARs, support a decision-making soil by soil and facilitate the comparison of sorption trends and future soil policies among OECD countries.
Mining Environments in a Changing Climate

MP237 Assessment of pollution levels and some heavy metal in the coal mining environment of Ngwo, Akwuke and Udi communities of Enugu State

Q. Francis, University of Nigeria Nsukka; C. K. Urama, Enugu State University of Science and Technology / Biochemistry

Soil and water in the coal mining communities of Enugu State were investigated for the presence of heavy metals in the soil and water. Three of the communities are coal mining impacted areas, though coal mining has been stopped for over 20 years now in these communities. The heavy metal and water from these areas were investigated, using Atomic Absorption Spectrophotometer (AAS). The result of Heavy metal levels in soil of the three communities are within the permissible limit which could be attributed to anthropogenic and mining activities that took place in the area, and the used of fertilizer. The heavy metal levels in well water followed the same trend as observed in soil. However Mn, Cr and Pb level in well water from the three communities were above W.H.O. (2005) permissible limit of 0.05 mg/l, 0.05 mg/l, and 0.01 for Mn, Cr, and Pb respectively. The high level of these metals in well water could be attributed to anthropogenic source as well as underground water pollution due to leaching of these metals in the soil to underground water. It was observed that pH level of Ngwo soil compared to that of Udi and Akwuke soil which is below W.H.O standard may be attributed to anthropogenic sources. The specific gravity and bulk density of soil from Ngwo, Udi and Akwuke were below the WHO allowble limit. The anion levels, NO3, PO4, SO4 and CI2 levels in soil from the three communities studied were within permissible limit (EPA, 2012), though PO4, SO4 and CI2 level of Udi soil were significantly higher than the values in the communities. The decrease in pH of well water from Udi and Akwuke, 4.80±0.01 and 5.54±0.01 respectively was an indication of acidity of the well water. These values are above W.H.O standard level (6.5) for portable water. The conductivity levels of well water from the three communities investigated were within the EPA permissible level (5-50 μhos/cm) for drinking water. The observed levels of total solid, total dissolved solid and total suspended solid of well water from the three communities were within the WHO permissible limit for drinking water, except chloride level (916.00±1.00) in Udi well water which was above W.H.O permissible limit (250 mg/l) for chloride.

MP238 Climate-related changes to arsenic cycling in northern lakes: Implications for future environmental monitoring of mine sites

C. Miller, Queen’s University / Department of Geological Sciences and Geological Engineering; M. Parsons, Natural Resources Canada, Bedford Institute of Oceangraphy; H. Jamieson, Queen’s University / Department of Geological Sciences and Geological Engineering; G. Ardakani, Natural Resources Canada, Geological Survey of Canada; G. Swindles, University of Leeds / School of Geography; B. Gregory, N. Nasser, T. Patterson, Carleton University / Ottawa–Carleton Geoscience Centre and Department of Earth Sciences; J. Galloway, Natural Resources Canada, Geological Survey of Canada/Aarhus Institute of Advanced Studies, Aarhus University

Continued climate warming may affect the cycling of naturally occurring metal(loids) and the long-term stability of mining-derived contaminants in lakes. In sub-Arctic environments, it is not known how the cumulative effects of resource extraction and climate warming will influence geochemical baselines or the cycling of arsenic (As) that can be naturally elevated in mineralized bedrock or as a result of legacy mining activities. This study integrates As geochemistry, mineralogy, organic petrography, multivariate analysis of paleoclimate proxies, and radiometric dating to determine the influence of climate on the concentration and cycling of As in lake sediments during the late Holocene (ca. 5,000 yrs. cal BP). Analyses of sediment cores collected from two lakes in the central Northwest Territories, Canada, document increases in sediment and porewater As coincident with changes in the source and composition of total organic matter. In both lakes, detrital As-bearing minerals (e.g., arsenopyrite and scorodite) are present. However, sediments also contain abundant As-bearing minerals (e.g., framboidal pyrite and Fe-(oxy)hydroxides) formed in situ and mixed porewater oxidation states, suggesting that remobilization of As occurred in lakes where labile organic matter, such as algal-derived lipids and cell walls, increased relative to generally inert terrestrially-derived organic matter. These findings provide evidence that past climate warming has influenced the cycling of As in these lakes through its effect on aquatic primary productivity, terrestrial organic matter composition, and catchment weathering. This study demonstrates the value of studying long sediment cores from different lakes in a catchment to determine natural variations in background metal concentrations. New geoscience knowledge produced from this study can be used to predict future climate-driven variations in metal(loid) cycling in lakes and help guide the interpretation of environmental monitoring results at northern metal mines.

MP239 Customized reactive capping blend for enhancing natural recovery of wetlands impacted by contaminated legacy gold mine tailings

E. Chapman, Saint Marys University; C. E. Moore, Intrinsik Corp.; L.M. Campbell, Saint Marys University / Department of Environmental Science

Gold mine tailings generated in the late 1800’s still contains elevated concentrations of mercury (Hg) due to the amalgamation process used to extract the gold, and arsenic (As) due to the naturally high levels of arsenopyrite present in gold-bearing rock. At that time, before environmental legislation, tailings were simply discarded into nearby lakes, wetlands or rivers without treatment. More than a century later, multi-generational exposure to tailings has occurred, potentially impairing ecosystem function and impeding biological recovery. Innovative, non-intrusive, low-cost approaches are urgently needed to manage risks associated with legacy tailings in sensitive aquatic habitats. The purpose of this project was to complete proof of concept testing of customized capping blends for limiting the mobility, bioaccumulation and toxicity of Hg and As in wetland sediment impacted by legacy tailings. Sediment was collected from two wetlands in historical gold mining districts. A clean control sediment was also prepared mimicking the texture of the contaminated sediments. Capping applications were assessed in terms of success in limiting the toxicity and bioaccumulation of contaminants in invertebrates exposed to the sediments, as well as the ability of the capping blends to reduce mobility of contaminants from the sediment to the water column. Due to the extremely high concentrations of Hg and As, invertebrates exposed to untreated contaminated sediment exhibited high mortality, growth impacts, and high bioaccumulation of both contaminants. The capping application that showed best results in limiting these impacts was a blend of fine silica sand, two different clays, and zeolite-supported nanoscale zerovalent iron slurry. This capping blend dramatically improved the survival of Hyalella azteca and Daphnia magna to levels observed in clean control sediments, and significantly reduced the bioaccumulation of Hg and As. Sediment concentrations of Hg and As were reduced by 88% and 99% respectively. Our proof of concept bench top testing with this capping blend shows potential. However, before the capping blend can be used in the field to reduce risks it is necessary to complete testing using more environmentally realistic mesocosms.

MP240 Effects of tailings dust on surface water chemistry

A. Cleaver, H. Jamieson, Queen’s University / Department of Geological Sciences and Geological Engineering; P. Huntsman, CanmetMINING, Natural Resources Canada; C. Rickwood, Natural Resources Canada

Canada’s climate is warming and reductions in summer rainfall are projected for parts of southern Canada. The resulting increased risk of water supply shortages in summer months means that dry tailings are more likely to blow into nearby surface waters. However, dust as a source of metal contamination to surface waters has not been evaluated. This
research aims to address this knowledge gap by investigating the effects of metal-bearing mine dust on surface water chemistry and how climate change may influence these effects. During this study, two abandoned mine sites in Nova Scotia, Canada with apparent aerial erosion and nearby water bodies were investigated; Stirling mine and Goldenville. To ensure representative samples and to evaluate different dust sampling methods, a variety of sampling methods were used. These methods included passive air samplers, high volume air sampler, and sieved tailings samples (as a proxy for windblown dust). Dust filter sampling was completed seasonally, occurring approximately every three months since December 2017. Seasonal sampling allows for a better understanding of seasonal trends and correlation to climatic conditions. Bulk geochemistry and mineralogy of the sieved tailings and filters were analyzed to determine metal concentrations and the primary and secondary metal-bearing phases. This is important due to differing solubilities associated with each mineral phase. Additionally, shaker flask tests were conducted to investigate the dust’s behavior in water. This information combined with dust deposition rates will help evaluate the potential risk tailings dust poses to surface water chemistry in the field. These results will be related to climate change scenarios by comparing observed seasonal trends in dust generation and dust composition to local climate change models.

MP241 Evaluation of chemical and physical variables as a predictors of sediment toxicity to C. Dilutus and H. Azteca

K. Batchelor, P. Stecko, Minnow Environmental, Inc.; C. Hughes, Mount Polley Mining Corporation

A foundational failure of the perimeter embankment of the Mount Polley Tailings Storage Facility on August 4th 2014 resulted in a breach that released approximately 25 million cubic meters of debris. Toxicity testing has been used as one tool in monitoring breach-affected sediments from deep areas of lakes impacted by the event (areas which represent locations of sediment accumulation/fate). Previous toxicity testing of sediments from one of the impacted lakes has indicated adverse effects to the growth of Chironomus dilutus and Hyalella azteca, with more limited effects on survival. Breach-affected sediments are characterized by low total organic carbon (TOC) and high concentrations of some metals (copper in particular). Prior evaluations have been unable to separate chemical (i.e., copper) and physical (i.e., TOC) variables as potential predictors of the adverse growth responses to breach-affected sediment. In this study, a number of endpoints were evaluated to further evaluate potential drivers of the growth responses that continue to be observed. These included overlying water chemistry, porewater chemistry, and labile metal concentrations (measured using Diffusive Gradients in Thin-Film) assessed in the field and laboratory, in addition to sediment chemistry. To create a gradient of exposure concentrations for this assessment, sediment was collected from two impacted areas and one reference area, and from field locations with intermediate sediment metal concentrations. Intermediate samples were also created by mixing exposed and reference sediment in the laboratory. Physical and chemical endpoints were assessed across this sample gradient to determine which best predicted the growth responses to breach-affected sediment for both C. dilutus and H. azteca.

MP242 Human Health and Ecological Risk Assessment in Support of the Canadian Environmental Assessment Process

M.J. Denyes, Wood Environment & Infrastructure

A Human Health and Ecological Risk Assessment (HHERA) was completed to define and quantify potential risks to human health and ecological receptors as a result of exposure to chemicals in the existing environment as well as predicted chemical concentrations as a result of mining activities during all phases (construction through abandonment) of the proposed Goliath Gold Project (Project). The Project is in the late stages of achieving approval under the Canadian Environmental Assessment Act, 2012. The HHERA assessed potential risk at three study areas where human and ecological receptors would experience the highest magnitude, frequency, and duration of chemical concentrations for baseline conditions, the Project alone, and the combination of baseline conditions and Project as per current Environmental Assessment guidance. The Project is located in Northwestern Ontario, within an area where traditional land and resource use is currently practiced. Therefore, the detailed human health risk assessment considered ingestion country foods and inhalation of criteria air contaminants including nitrogen dioxide and particulate matter within the property boundary where traditional land use is practiced. Inclusion of all Project phases, study areas and assessment scenarios, resulted in 21 unique human health and ecological conceptual site models. To support the interpretation of this large data set, data were organized into an HHERA model specifically designed for the Project. The development of a Project-specific HHERA model, allowed for efficient incorporation of new data including effluent and water quality predictions as a result of ongoing improvements to the engineering design of the Project related to climate forecasts and the long-term viability of a wet cover for the tailings storage facility. The results of the HHERA are being used by the Proponent to develop mitigation measures, monitoring programs and aid in on-going consultation activities. This presentation will detail the methodology for the development of the conceptual site models and HHERA model including rationale for all operable exposure pathways from environmental media (air, soil and surface water) and project-specific media (tailings, waste rock, pit-lake water), and offer insight into the regulatory expectations for approval in Canada.

MP243 Paleolimnology tracks the impacts of metal smelting on biota of Phantom Lake, Flin Flon (MB): Implications to mercury concentrations in northern pike

B. Simmatis, K.M. Rühlund, Queen’s University / Department of Biology; M. Evans, Environment and Climate Change Canada / Water, Science and Technology Directorate; J.L. Kirk, S. Roberts, X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C. Meyer-Jacob, J.P. Smol, Queen’s University / Department of Biology

Information stored in lake sediments can provide long-term context to past environmental conditions prior to active monitoring. At its peak, the Cu-Zn smelter in Flin Flon, Manitoba, was one of the largest Hg emission sources in Canada. Despite this, northern pike in nearby lakes appeared healthy, with low liver and fillet Hg concentrations (< 0.1 µg/g), possibly because high metal concentrations in lake sediments inhibited mercury methylation. To investigate metal toxicity trends, we used a 210-Pb dated sedimentary record from Phantom Lake, located ~5 km south of the Flin Flon smelting operations, to examine long-term trends in metals, diatoms, and invertebrates to track the environmental history of the region over the past ~200 years. This work examined (1) whether Phantom Lake acidified in light of high sulphur loading, (2) how metal concentrations and fluxes changed in response to increased smelting activity, operational improvements, and closure of the smelter in 2010, and (3) whether biological assemblages responded to smelting and other environmental changes. Metal concentrations were determined using ICP-MS. Diatoms and invertebrate assemblages were used to examine direct and indirect industrial effects. There was no evidence of acidification with the increased sulfur loading; the lake has a moderately high conductivity (184 uS/cm) and hence a strong buffering capacity. Metal concentrations in lake sediments increased with smelter operation expansion and then decreased with technological improvements and eventual smelter closure. Several metals were above CCME probable effects guidelines for sediments and remain so suggesting that toxicity was likely. Although the magnitude of change was variable, changes in all proxies (especially diatoms) were consistent with those expected in response to high levels of metal toxicity during active smelting. Despite reductions in metal concentrations, biological proxies did not return to their pre-smelting states. Post~2000 biological proxies suggest modest declines in metal toxicity, but climate change may also be affecting recent changes. These results support the hypothesis that lake biota, including methylating bacteria, have and continue to experience the effects of sediment toxicity. This could impair mercury methylation and may explain why mercury concentrations in northern pike have remained low and not responded to changes in smelting activities.
MP244 Point source atmospheric metal(loid) pollution history from Thompson Manitoba Smelter in Canada using lake sediment cores
S. Roberts, J.L. Kirk, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Wiklund, University of Waterloo; A. Gleason, G. Lawson, F. Yang, Environment and Climate Change Canada; J. Keating, Environment and Climate Change Canada / Water and Science Technology Directorate; M. Evans, Environment and Climate Change Canada / Water, Science and Technology Directorate

The Thompson Manitoba nickel (Ni) and copper (Cu) smelter was constructed in 1961 CE, following a decade of mining exploration in the region. The smelter was a major producer of Ni globally, and the Thompson region is unique to focus on, due to the scarcity of regional temporal metal(loid) deposition studies. Thus, this study reconstructs high-resolution atmospheric anthropogenic metal(loid) deposition over the last c. 100 years using $^{210}$Pb dated lake sediment cores collected from 9 lakes located at varying distances and directions from the Thompson smelter, in order to explore the local point-source deposition history. Thompson lake sediments were moderately enriched (average enrichment factor 2 - 5) in antimony (Sb) > Hg > lead (Pb) > cadmium (Cd) > Ni, and slightly enriched (average enrichment factor < 2) in arsenic (As) > strontium (Sr) > bismuth (Bi) > Cu > zinc (Zn) > uranium (U). Deposition decreases with distance from the Thompson smelter for 6 of 11 enriched metal(loid)s (As, Bi, Cd, Cu, Ni, Sr), whereas the remaining enriched metal(loid)s (Hg, Pb, Sb, Zn, U) appear to be largely sourced from long range atmospheric deposition rather than predominately local pollution from the Thompson smelter. Ni and Sr deposition in Thompson area lakes are higher (up to 100-fold and 4-fold respectively) compared to Flin Flon area lakes. For the other enriched metal(loid)s (As, Bi, Cu, Cd, Hg, Pb, Sb, Zn) in the Thompson lake sediments, deposition is higher in the Flin Flon area lakes in comparison to the Thompson area lakes. Anthropogenic fluxes for all the enriched metal(loid)s have been declining over the recent 9-year period between 2005 to 2014 CE, in alignment with the reported emissions from the Thompson smelter. Whereas Hg anthropogenic fluxes are continuing to increase post-2005 CE despite the reported Hg emission declines. One likely explanation for this discrepancy is catchment soil saturation, with historically deposited Hg being remobilised and leached into the Thompson area lakes, from climate-driven permafrost thaw in the Manitoba region. Thus, the catchment areas of the Thompson area lakes could be a major source of legacy Hg into the lakes with the rising regional temperatures, resulting in the continued ongoing fluxes of Hg into the lakes.

MP245 Tracking dust under a changing climate: Investigating the environmental fate and effect of dust-bound metals from abandoned mine sites
C. Rickwood, Natural Resources Canada; P. Huntsman, S. DeSisto, CanmetMINING Natural Resources Canada; A. Cleaver, H. Jamieson, Queen’s University / Department of Geological Sciences and Geological Engineering

Changes in average temperatures, precipitation and extreme weather events at mine sites across Canada are altering the environment and increasing the challenges for mine waste and water management. Climate models suggest that many southern regions in Canada (i.e. south of 60 degrees parallel) will become warmer and drier during the summer months. With this change in climate there is a risk of increased dust generation with greater impacts on the surrounding environment. Dust pollution from extreme droughts is a serious concern to both environmental and human health. Recent studies in some mine sites have shown a significant contribution of metals associated with particulate matter entering watersheds due to localised wind erosion of waste piles, dust from roads and atmospheric deposition during snow/rain fall events. The metals associated with these dust particles have the potential for remobilization in the environment leading to impacts on ecosystems. CanmetMINING and Queens University are investigating the fate and effect of metals associated with dust particles from abandoned mine tailings. This presentation outlines the results of sampling at two abandoned mine sites in Nova Scotia, the Stirling Zn/Cu/Pb mine and the Goldenville Au mine. Results from a number of field and lab techniques will be presented including sediment and water analysis and toxicity assessments. Results from this work will fill knowledge gaps with respect to our understanding of the impacts of climate change on resource development in addition to improving our understanding of the cumulative effects of dust impacts away from the immediate bounds of mine sites.

MP246 Tracking water quality in a changing climate
C. Miller, Queen’s University / Department of Geological Sciences and Geological Engineering; P. Huntsman, CanmetMINING, Natural Resources Canada; R. Bouwhuis, Environment and Climate Change Canada / Ecological Assessment Division; C. Rickwood, Natural Resources Canada

Both the quality and quantity of water in watersheds is expected to be altered due to climate change. However, there is insufficient scientific knowledge to predict how these changes are likely to be manifested. One approach is to look at long-term trends in past data to evaluate changes over time and space (e.g. watershed and regional variability). CanmetMINING, in collaboration with Environment and Climate Change Canada are compiling national and provincial water quality data in areas located close to active and abandoned mine sites. By compiling and examining water quality data over the past couple of decades we aim to determine if baseline water quality is changing over time, which could reflect climate change impacts. This work will help us to identify a number of important observations: 1) Identify indicators - are there specific metals or water quality parameters that show consistent responses to climate change that could be used as ‘indicators’ for future projections. 2) Hot spots - are there specific areas in Canada that are more sensitive to changes in climate? By collaborating with provinces and the federal family this project provides an opportunity to establish a national database that could track and monitor water quality in a changing climate, which would be of use to research organizations, governments as well as offering potential for citizen science applications.

MP247 Use of biomonitoring and remote sensing to track mine dust in a changing climate
P. Huntsman, CanmetMINING, Natural Resources Canada; H. White, Canada Centre for Mapping and Earth Observation / Natural Resources Canada; J. Percival, Geological Survey of Canada / Natural Resources Canada; C. Rickwood, Natural Resources Canada; A. Cleaver, Queen’s University / Geological Sciences and Geological Engineering

Many active and abandoned mining areas across Canada are vulnerable to weather extremes from a changing climate. Increases in snowfall and rate of snowmelt will cause surface runoff, followed potentially by drier summer periods, allowing for aerial deposition of dust from dry tailings into nearby surface waters. Two abandoned mine sites in Nova Scotia, Canada, with visible aerial erosion and nearby water bodies, were investigated during this project. To supplement the more traditional dust monitoring methods, including high-volume and passive air samplers, lichen was collected at each site and assessed for metal content/uptake. Patterns of metal dust deposition on passive air samplers were compared to metal content in the lichen at both sites. In addition, optical (spectral) satellite imagery was added to the suite of tools to monitor dust and identify land cover types that trap dust in the environment, with ground-truthing by hand-held VNIR-SWIR spectrometers. The spectral signature of the waste rock dust was evaluated for detection in the imagery, with the aim to identify land cover types that capture dust (either down wind or downstream). This project is assessing tools to monitor dust distribution from tailings areas and improve our ability to predict and mitigate the cumulative impacts of climate change on metal mines across Canada.
Challenges and Strategies for Linking Adverse Effects to Endocrine Modes of Action

**MP248 Evaluation of the effects of bisphenols on TM3 Leydig cells in vitro**

_T. Jambor, H. Grejfova, A. Kovacik, N. Lukac, Slovak University of Agriculture in Nitra / Department of Animal Physiology; P. Massanyi, Slovak University of Agriculture in Nitra_

In the last decades, many epidemiological studies have focused on the potentially hazardous effects of a wide range of chemicals present in the environment. Nowadays, we recognize many chemicals with endocrine disruptive properties and one of the most studied is bisphenol A (BPA). Overleaf, many BPA alternatives such as bisphenol S, F or B have been found in agrochemicals, personal care products epoxy resins or in the plastics packaging. Due to their wide usage, a large number of bisphenols are discharged into the ecosystem and evokes a public health risk. A significant body of evidence based upon laboratory experiments indicates that exposure to bisphenols is associated with male reproductive malfunctions, impairment of spermatogenesis followed by irreversible changes in steroidogenesis. The purpose of the present in vitro study was to elucidate the hazardous effects of bisphenols on TM3 Leydig cell line through the evaluation of steroid hormone production, mitochondrial activity and membrane integrity of exposed cells. Mice Leydig cells were cultured for 24 h with addition of 0.2-25 µg/mL of bisphenol A, B, S or F and compared to the non-treated cells. The level of steroid hormones in cell culture media was determined by enzyme linked immunosorbent (ELISA) assay, while the quantification of mitochondrial activity and membrane integrity was assessed using alamarBlue and CFDA-AM assay. The results showed that testosterone production was significantly (P< 0.001) reduced at 10 and 25 µg/mL of bisphenol A and bisphenol B. The same experimental doses of bisphenol S and bisphenol F initiated a successive decrease; however, the differences were not significant. Obtained data clearly demonstrated that the higher experimental concentrations (10 and 25 µg/mL) significantly (P< 0.001; P< 0.01) decreased mitochondrial activity. Furthermore, a significant (P< 0.001; P< 0.01) loss of cell membrane integrity was recorded at 10 and 25 µg/mL of bisphenol S and bisphenol B. Overleaf, only highest dose of bisphenol A and bisphenol F reduce membrane integrity significantly (P< 0.001). Taken together, the results of our study help to determine bisphenols effects on TM3 Leydig cells and increase the understanding of molecular mechanisms responsible for the adverse effects of selected bisphenols on the male reproductive system. This work was supported by the Slovak Research and Development Agency under the contract No. APVV-16-0289 and VEGA 1/0539/18.

**MP249 Human and Xenopus laevis type 3 iodothyronine deiodinase enzyme cross-species sensitivity to inhibition by ToxCast chemicals**

Deiodinase enzymes are critical components of the thyroid system that activate or inactivate thyroid hormones when and where needed in vertebrate development, as well as in amphibian metamorphosis. From a screening study of the ToxCast Phase 1, Phase 2 and e1k chemical libraries for inhibitory activity toward human Type 3 iodothyronine deiodinase (DIO3) enzyme we identified a subset of 357 chemicals to test for amphibian (Xenopus laevis) DIO3 inhibition. Recombinant X. laevis DIO3 enzyme was produced in cell culture and used in 96-well plate screening assays at a single test chemical concentration (200 uM). Our goals were to further determine specific chemical inhibitors of DIO3 and cross-species sensitivity. From the initial single concentration screening results with X. laevis DIO3, 80 chemicals were tested in concentration response mode to compare inhibitory activity between the two species. Results showed a general relationship between LogP (octanol:water) and Hill slope. Fourteen of the most potent chemicals with IC50 of 30 uM or less, 10 with LogP < 4.5, had Hill slopes near -1 and were not significantly different between species. These 14 chemicals, 11 of which are used as pesticides, may be specific inhibitors of DIO3 for both species, likely due to conservation of the enzyme active site amino acids between these species. Of the 43 chemicals with a LogP > 4.5, 33 had steep Hill slopes (much less than -1) for one or both species, with the X. laevis DIO3 more likely to have a higher IC50; for 19 of these chemicals the IC50 for either species was also > 90 uM. Other chemicals with steep Hill slopes for both species but with LogP < 4.5 include 4 PFAS compounds, other surfactants, and chemicals that did not reach complete inhibition at 200 uM. In general, our results indicate that human DIO3 responses to the ToxCast chemicals tested can be predictive of X. laevis DIO3 sensitivity to those chemicals.

**MP250 Species Extrapolation of a Quantitative AOP Describing Inhibition of Aromatase in Fishes: The Importance of Reproductive Traits**

Quantitative adverse outcome pathways (qAOPs) include descriptions of quantitative response-response relationships between key biological processes that facilitate prediction of the probability or severity of an apical-level toxicity for a given magnitude of chemical interaction with a target biomolecule. Quantitative response-response relationships in a qAOP are intended to represent generalized patterns of responses to produce models with the broadest taxonomic applicability. However, this applicability is often tested. As an example, response-response relationships were developed using data from the fathead minnow for a qAOP linking inhibition of aromatase to decreased fecundity. The extent to which these relationships could be applied to other fishes with asynchronous oocyte development in common with fathead minnow (e.g. Japanese medaka, zebrafish) was unknown, let alone how applicable they would be to fishes with group-synchronous oocyte development (e.g. mosquitofish). To address this question, zebrafish, Japanese medaka, and mosquitofish were exposed to the model aromatase inhibitor, fadrozole, for 21 days. Empirical results were compared with predictions based on the fathead minnow-based qAOP. The qAOP simulated responses measured in zebrafish exposed to fadrozole with comparable accuracy as for fathead minnow but did not simulate responses measured in Japanese medaka. Basal levels of plasma 17β-estradiol, plasma vitellogenin, and fecundity were comparable between fathead minnow and zebrafish, but were different in Japanese medaka. However, after normalizing for differences in basal production, the qAOP accurately predicted responses of Japanese medaka to fadrozole. This suggests that quantitative response-response relationships are conserved across these three asynchronous fishes when considering relative change rather than absolute measurements. In contrast, mosquitofish have complex reproductive profiles and compensatory responses which are distinct from those of asynchronous fishes.
Therefore, although responses to fadrozole were qualitatively similar between mosquitofish and fathead minnow, the current qAOP could not quantitatively predict responses in this group-synchronous fish. Overall, this study illustrates the importance of reproductive traits, including oocyte development and basal production of biomolecules, in the species extrapolation of certain quantitative response–response relationships described in qAOPs.

MP251 Bioactivity models as tools for predicting endocrine-mediated adversity - regulatory significance

D. Feifarek, SC Johnson / GSARA; J.P. Staveley, M.E. McArdle, E. Freeman, Exponent, Inc.; W.E. Hillwalker, SC Johnson / GSARA

The World Health Organization (WHO) definition of an endocrine disrupting chemical (EDC) requires that the chemical 1) shows an adverse effect in an organism or its progeny, 2) has an endocrine mode of action (MoA), and 3) the adverse effect is a consequence of the endocrine MoA. The endocrine MoA leg of the WHO definition relies on the understanding that for a chemical to be considered an EDC, endocrine activity must occur at a molecular level (initiating effect) and trigger downstream key events. As part of the determination for whether a chemical has the potential to interact with the endocrine system, regulatory authorities have developed standard tests for generating key in vitro and in vivo mechanistic evidence. While there is considerable publicly available in vitro evidence to provide indications of potential endocrine activity of a plethora of substances, in vivo mechanistic data is understandably sparse in comparison. Thus, considerable in vivo studies utilizing a large number of animals would need to be conducted to meet sufficient evidence for determining endocrine activity of chemicals. In response, bioactivity models, which take into account both potency and efficacy, were developed utilizing existing mechanistic evidence, and validated utilizing a large pool of reference substances, to predict whether an adverse outcome is probable, relative to the mechanistic activity. These models are highly beneficial in terms of reductions in cost and time of testing, reductions in animal use and utilization of robust scientific basis for decision making. One such model, the ToxCast ER (estrogen receptor) Bioactivity Model, was notably indicated by US and EU authorities as providing sufficient evidence to support a conclusion of not endocrine active for the estrogen pathway. Here, we examine the significance, appropriateness and implementation of this and other bioactivity models for use in regulatory decision-making on endocrine disruption.

MP252 Transcriptomics: A Tool for Identification of Endocrine Active Chemicals in Fish

T. Scown, FMC Agricultural Solutions; A.J. Jones, FMC Agricultural Solutions / Environmental Sciences; A. Samel, FMC Corporation / Environmental Sciences; L. Markell, FMC Corporation / Investigative Toxicology; D. Nabh, T. Gulati, S. Kim, FMC Agricultural Solutions

The fish short-term reproduction assay (FSTRA) is often required by international regulatory bodies such as the United States Environmental Protection Agency (USEPA) and the European Food Safety Authority (EFSA) for assessing a chemical for potential endocrine activity in fish. The study is costly, time consuming, requires a lot of test material, creates a large volume of effluent waste, and requires a large number of test organisms. Smaller scale in vivo tests examining biomarkers such as vitellogenin induction may assist in evaluating the potential for endocrine activity but their sensitivity and ability to identify all modes of action (MoAs) may be limited. Transcriptomic analysis has greatly improved the ability to detect and understand mechanisms of action and may be a useful tool for rapid and less costly identification of endocrine active chemicals if gene expression profiles for the various MoAs can be characterized. Ovary, testis and liver tissue were taken from fathead minnows exposed to a variety of endocrine disruptor positive control chemicals (estrogen/androgen agonist/antagonist, aromatase inhibitor) for 2 and 21 days. RNA-sequencing was conducted and transcriptome sequences aligned to the fathead minnow whole genome. Here we discuss the gene expression profiles that were generated, the effectiveness of this approach for identification of chemicals that may have endocrine activity in fish and its utility as a tool for prioritization of chemicals for testing in the FSTRA.

Environmental DNA (eDNA) Approaches to Enhance Biodiversity Monitoring and Risk Assessments

MP253 Evolution of a high-throughput environmental DNA (eDNA) sampling platform

A. Thomas, J. Howard, Smith-Root; C.S. Goldberg, Washington State University / School of the Environment

With the rise of environmental DNA as a surveillance tool for aquatic species, a need has also arisen for professionally engineered research tools specifically designed for eDNA applications. We created the first portable, purpose-built eDNA sampling stream in the form of a backpack smart-pump filtration apparatus and custom made eDNA filter packs for each sample. The eDNA-Sampler (previously ANDe) enables both point-location sampling and mobile sampling over a spatial distance, with the ability to standardize filtration parameters (e.g. flow rate, pressure, water volume, etc.). In this presentation we will describe the evolution of the eDNA sampling backpack and associated components, each designed to help streamline the eDNA sampling process and increase sampling efficiency. We have optimized the platform for mobile sampling by integrating GPS and data logging capabilities, in addition to modifying the chemistry of the eDNA filter packets to minimize the effort required for sample preservation. Results will be presented from a series of pilot studies in which the eDNA-Sampler capabilities were evaluated. Combined, the innovations described herein should help remove barriers to entry for potential eDNA practitioners and also improve overall eDNA data quality.

MP254 Benchmarking water eDNA metabarcoding for biomonitoring of Canadian Freshwater Fishes

Y. Xie, University of Saskatchewan / Toxicology Center; K. Prestie, University of Saskatchewan; A. DeBofsky, University of Saskatchewan / Toxicology Centre; S. Srayko, University of Saskatchewan; P. Ankley, University of Saskatchewan / Toxicology; A. Vien, University of Saskatchewan; T. Jardine, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; M. Hecker, P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre

Earlier studies have supported the use of eDNA metabarcoding of fishes to provide reliable biomonitoring information and were comparable with traditional capture methods. However, multiple factors from field sampling to wet lab procedures to bioinformatics pipelines can influence the final data matrix. Comprehensive studies are required to benchmark the eDNA metabarcoding pipeline for fish monitoring. Here, we benchmarked eDNA metabarcoding for Canadian freshwater fish monitoring from sampling effort, eDNA extraction methods, metabarcoding primers, sequencing effort, and bioinformatics pipelines against mock communities and fish surveys of rivers and lakes. Based on the benchmarking, module-based eDNA pipelines for fish monitoring were developed and can be customized for different end-users or scenarios. This work will enhance the capability of eDNA metabarcoding and boost the application of eDNA metabarcoding for Canadian freshwater fish monitoring. A framework of benchmarking/standardization eDNA metabarcoding should be considered before its wider application.
Aquatic multicellular organisms continually shed cellular and extracellular DNA into their environment, and by sampling their habitat for this environmental DNA (eDNA) it is possible to detect and monitor them. This sensitive and non-invasive tool allows for species in low numbers to be detected in the environment. However, the novelty of this tool leaves areas of uncertainty with regards to best practices and potential biases in the methodology. The objective of this study was to understand the influence of stream bed disturbances on eDNA recovery, thereby identifying and reducing areas of uncertainty in eDNA methodology in lotic systems. DNA is known to adsorb to sediment in aquatic systems, therefore when the stream bed is disturbed, and sediments are mobilized there is the potential for an artificial inflation of eDNA concentration, leading to biases and/or inaccurate conclusions. This study was completed in Washington Creek, a first order stream in the Grand River watershed in Southern Ontario, Canada, with a characterized brook trout (Salvelinus fontinalis) population. Water samples from the stream were collected before and after disturbance events in stream areas upstream (reference undisturbed) and downstream, at several time intervals, then filtered, extracted, and brook trout DNA was amplified via quantitative polymerase chain reaction. In addition, the effects of physical disturbance were assessed on a set of field positive controls that contained a known amount of brook trout biomass, exposed to disturbed and undisturbed water for 90 minutes. Disturbed water exhibited decreased eDNA recovery due to inhibitors present in turbid water preventing DNA amplification, resulting in lower eDNA yield. Immediately after a stream bed disturbance, eDNA signal was lost completely, then returned to baseline after 30 minutes. Positive control methodology was validated, and a correlation between brook trout biomass and eDNA amplification was observed. Next steps for inhibitor evaluation and removal have been identified. Once biases and knowledge gaps in eDNA practices are addressed it can become a powerful tool for monitoring aquatic organisms, including species at risk.

The collection of environmental DNA (eDNA) is an affordable and non-invasive technique for aquatic species monitoring. eDNA can be utilized as a natural tracer linking the fields of hydrology, ecology, and biology as its detection depends on the hydrologic characteristics of the system, including zones of transient storage and water quality. Certain areas of a stream, such as the streambed or pools, may result in greater accumulation of eDNA. eDNA allows one to track species diversity and distribution, however, there remain several knowledge gaps in terms of eDNA transport and storage due to the complexity of eDNA’s interactions with its surrounding environment. For instance, the hydrologic conditions during a storm, such as increased flow and turbidity, may bias eDNA amplification and its downstream interpretation. Under such conditions, eDNA may experience increased resuspension and/or sorption to suspended sediments. Existing literature shows eDNA does not behave as a conservative tracer in the environment as it exists as a complex mixture of particles with different properties. However, some components of eDNA may behave similarly to free DNA (fDNA), extracellular DNA, through a fluvial system, therefore having a potential to be treated as a surrogate to understand eDNA movement. Although fDNA has been used as a tracer in freshwater systems its environmental transport and fate is poorly understood. Washington Creek, in southern Ontario, is a headwater stream that has been the focus of several studies on brook trout (Salvelinus fontinalis) and the distribution of eDNA. This study investigates the behaviour of synthetic fDNAs injected into the creek during different hydrologic conditions (e.g., high flow, high turbidity versus baseflow) and it compares them to a conventional tracer (e.g., salt). Following the injection of fDNA and salt, water samples were collected at various time points and distances downstream of the source. The samples were filtered, and the fDNA mixture was extracted and further amplified using a quantitative polymerase chain reaction (qPCR) targeting the fDNA sequences. This study assesses transport of fDNA to better understand how it can be used as a tracer through aquatic stream systems. These tracers are nontoxic, sensitive and allow for multiple tracers to be applied simultaneously in a single system. Therefore can be used to better understand movement and degradation of components of eDNA.

Environmental DNA (eDNA) is a complex mixture of genetic DNA derived from various organisms inhabiting a specific environment. Despite its relatively low concentration and fast degradation, it is possible to isolate it from various samples (i.e., water, soil, air) and use to indirectly identify single or multiple taxa in a given sample. In this study a species-specific eDNA approach was used to identify brook trout (Salvelinus fontinalis) fish species and to monitor their population dynamics in a headwater stream in the Grand River sub-watershed (Ontario) and compare its sensitivity to traditional methods. Intense urbanization and agricultural activities in this part of Canada, that is also facing dramatic climate change, are overall threatening the cold habitats that these fish currently thrive in. This species and many others that prefer these rare habitats are of great concern for many ecologists and water managers in this area. eDNA offers a sensitive methodology that provides reliable results in a timely manner and at relatively low cost for monitoring species presence and their seasonal and spatial distribution. Beside its qualitative aspects it is important to further explore eDNA as a quantitative tool, that is, relating the amount of eDNA to fish abundance. The experimental design that was employed in this study used stream water sampling for brook trout DNA coupled with electrofishing that was conducted on monthly bases from April to December in a headwater stream of this sub-basin. The initial results suggest that the greater brook trout abundance and biomass in the summer months correspond to significantly higher detection of brook trout eDNA, supporting earlier literature findings of positive correlation between eDNA amount and species biomass/density. Considering the lack of standardized procedures in this new, still developing field, the experimental design of repetitive and consistent sampling with a set of field positive controls and sample inhibitor testing (with a foreign species) developed for this study, reduces error artifacts and increases the reliability of eDNA interpretation. This is extremely important since this technique is gaining on attractiveness and it is becoming a key component for bioassessment. Results from this and similar studies should fill in the knowledge gaps that currently exist and should allow eventual integration of the quantitative eDNA aspect within the fisheries management plans.
**MP258 Comparing electrofishing observations to environmental DNA metabarcoding detections along Bauman Creek, a tributary of Ontario’s Grand River**  
N. Harper, H. Ikert, M.D. Lynch, P. Marjan, A.C. Doxey, M.R. Servos, University of Waterloo / Biology; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; P.M. Craig, University of Waterloo / Department of Biology; B.A. Katzenback, University of Alberta / Biological Sciences

Environmental DNA (eDNA) is the assorted genetic material shed by resident organisms into their surroundings. eDNA can be isolated from various environmental matrices including water. Metabarcoding is a high-throughput technique that can assign taxonomic identity to DNA barcodes generated from environmental samples. eDNA metabarcoding of water samples is an emerging ecological survey technique that can non-invasively provide biodiversity information on the fish and amphibians inhabiting a waterway. To date, little research has examined the potential of eDNA metabarcoding to monitor fish and amphibians in tributaries of Ontario’s Grand River. Comparisons of eDNA metabarcoding to locally implemented survey techniques such as electrofishing are critical for local end-users when assessing the utility of eDNA metabarcoding. Our research aims to compare the detection rates of fish and amphibians obtained via environmental DNA metabarcoding to the detection rates obtained through conventional 3-pass electrofishing surveys, allowing for head to head comparisons of the two methods. Here, we present the results from a pilot study conducted in Bauman Creek, a 1.8 km long tributary to the Grand River (Ontario, Canada). Water samples for eDNA metabarcoding were taken from multiple locations along Bauman Creek. eDNA sampling was immediately followed by 3-pass electrofishing surveys. Water samples were filtered prior to eDNA extraction using commercially available kits. Before application, primers were validated in silico to predict species detection and production of unique amplicons, in vitro to confirm predicted species detections, and in situ to confirm amplicon production. Prior to sequencing, eDNA was quality checked for inhibitors through use of an internal positive control and for integrity by measuring intact plant DNA in the sample. Samples were sequenced, and the data was quality checked before assigning taxonomic identities to sequence reads. Metabarcoding reads were then compared to the communities observed during electrofishing. This allowed an examination of the utility of both sampling methods in detecting the species communities present at each sampling site. Ultimately, the validation of eDNA metabarcoding will facilitate monitoring and conservation of fish and amphibians in the Grand River watershed.

**MP259 Taking environmental DNA (eDNA) to the field: Methods, applications, and lessons**  
C. Naumann, S. Kalyn, L. Dilley, Dillon Consulting Limited / Natural Resources Management; C. Kwok, Dillon Consulting Limited

Environmental DNA (eDNA) refers to DNA that is shed by a species into the environment through its life history processes. These eDNA materials can be collected and analyzed using quantitative PCR techniques to identify the targeted species. In the last decade, research on eDNA has also been collected and analyzed using quantitative PCR techniques to identify the targeted species. In the last decade, research on eDNA has grown significantly, as evident by the number of peer-reviewed publications that have accumulated. The technology of analyzing eDNA is now more accessible and available at a commercial scale. However, the use of eDNA as a means to detect species can be limited by lack of acceptance by regulators, lack of qualified practitioners to appropriately collect and process eDNA samples, and general lack of awareness on what eDNA can be used for. This presentation is a case study of two projects in BC where eDNA was used in addition to traditional sampling methods to enhance detectability of several conspicuous species. We will discuss the applicability of eDNA on projects of varying scales and how eDNA can be incorporated into the field of environmental consulting.

**MP260 STREAM: Sequencing The Rivers for Environmental Assessment and Monitoring**  
C.P. Robinson, University of Guelph / Biodiversity Institute of Ontario; D.J. Baird, Environment Canada / Canadian Rivers Institute; K. Hartwig, Living Lakes Canada; E. Hendriks, WWF-Canada; L. Maclean, Environment Canada; R. Mallinson, Living Lakes Canada; W. Monk, S. Pappas, Environment Canada; C. Paquette, WWF-Canada; K. Trainor, Environment Canada; M. Hajibabaei, University of Guelph / Biodiversity Institute of Ontario

Globally, freshwater systems are essential for human and wildlife survival. Despite their importance, many freshwater ecosystems are under threat and currently there is lack of an effective technique to monitor the status of these ecosystems. In Canada, freshwater systems are vast and often inaccessible, rendering them difficult to monitor, which results in data deficiencies. Additionally, current methods of freshwater biomonitoring involving visual identification of benthic macroinvertebrate communities are costly, time-consuming and often lack species resolution. To address these issues, STREAM (Sequencing The Rivers for Environmental Assessment and Monitoring) aims to validate and implement DNA metabarcoding as a mainstream approach, to be utilised by ECCC (Environment and Climate Change Canada), WWF-Canada and LLC (Living Lakes Canada) for generating freshwater biodiversity data through community-based monitoring (CBM). STREAM combines the standard CABIN (Canadian Aquatic Biomonitoring Network) sample collection approach with DNA metabarcoding to assess macroinvertebrate community assemblages across a wide range of Canadian watersheds. Implementing this approach, STREAM expects to 1) educate and train communities of citizen scientists to expand geographic coverage of freshwater biomonitoring; 2) provide a timely capacity improvement for data generation and reporting (2 months as opposed to current 8-12 months) and 3) improve the taxonomic resolution and ecological diagnostic power via metabarcoding data. The unique combination of academic, government organisations and NGOs (non-government organisations) in conjunction with CBM, enables the STREAM project model to be applied across the whole of Canada and beyond to facilitate the generation of a clearer picture of the health of rivers for freshwater stewardship and conservation.

**Environmental Risk Assessment**

**MP261 Spatial and probabilistic risk assessment associated with drinking groundwater in Pingtung Plain of Taiwan**  
C. Liang, Fooyin University / Department of Nursing; J. Chen, National Central University / Graduate Institute of Applied Geology

Despite that the average of percentage of tap water served by Taiwan Water Corporation in Taiwan is above 90%, only approximately half of households in the Pingtung Plain have access to the public water distribution system. Residents without access to tap water supply thus extract groundwater to meet their household water demand because this area has abundant groundwater resource. A long-term groundwater quality survey in the Pingtung Plain has reported obvious groundwater contamination with the occurrence of chemicals such as arsenic, nitrate, manganese and iron in some of the monitoring wells. Health risk assessment associated with the drinking of contaminated groundwater is required for protecting and managing human health. Measurement data of water quality items clearly indicated considerable spatial variability in concentration levels, implying that the human health risk through the drinking of the groundwater will also vary from region to region corresponding to variations in the concentration levels of the contaminants in the groundwater. This study carries out a spatial health risk assessment associated with the drinking of groundwater in the Pingtung Plain. First, the spatial concentration of the groundwater quality items on each cell are calculated using a geostatistical approach. Subsequently, the spatial patterns of the Hazard Quotient (HQ) and target risk (TR) are computed based on the spatial concentration distributions of groundwater quality items on each cell.
To illustrate significant variability of the drinking water consumption rate and body weight of each individual person, health risk assessments on each cells are probabilistically conducted by using a Monte Carlo simulation by treating daily water intake rate and body weight as probability distributions. Ultimately, a maps showing the spatial distribution of occurrence percentage of high HQs and TR is demarcated. The results can provide a basis for improving the decision-making process for managing health risk associated with drinking groundwater.

**MP262 Ions and trace elements in groundwater in the city of Porto Velho-RO/Brazil**

_C. Ceolin Baia, W.R. Bastos, T.F. Vargas, V. Azevedo, W. Aleixo, Federal University of Rondônia_

Groundwater are heavily exploited for various uses, including human consumption. The main form of extraction of the same is by wells, which can be tubular or excavated. In the Amazon region, the use of excavated wells, commonly known as the “amazonas” well, is common. These wells, depending on their structure, can be an entry channel for various biological and inorganic contaminants. Inorganic contamination is by means of cationic and anionic ions (nitrate, sulfate, ammonium, etc.) and trace elements (arsenic, aluminum, zinc, cadmium, etc.), which depending on the concentration in the water and if this water is destined for human consumption and other uses of indirect ingestion (hygiene, preparation of food, domestic activities), can cause risks to the health of the one who ingests it. Therefore, it is necessary that these waters comply with the standards of potability established by the competent bodies. In this study, samples of 50 points (36 excavated wells and 14 tubular wells) were analyzed from the urban perimeter of the city of Porto Velho - RO / Brazil. Cation and anion determinations were made by ion chromatography and trace element determinations were made by induced plasma optical emission spectrometry. The levels for sodium, ammonium, potassium, calcium, magnesium, fluoride, chloride and sulfate ions did not exceed the limits established by Brazilian legislation for water intended for human consumption. The nitrate ion, whose water limit is 10 mg L⁻¹, presented a mean for excavated and tubular wells of 21.2 and 14.1 mg L⁻¹, respectively. This is indicative of the effect of anthropic activities, in particular, the lack of basic sanitation in the city, where waste water is released into the environment without any kind of treatment. In relation to trace elements, aluminum, copper, manganese, strontium and zinc were below established standards. Only the zinc element had higher concentrations in the tubular wells (mean for excavated wells = 0.019 mg L⁻¹ and average for tubular wells 0.042 mg L⁻¹), reflecting the mobility of this element and the leaching action. In view of the presented results, nitrate levels in the groundwater of the city of Porto Velho are the most worrisome, because nitrate is harmful to human health when there is exposure to high levels of this contaminant.

**MP263 Effects-driven site specific risk assessment of a complex operating site**

_R. Peters, Federated Co-operatives, Ltd. / Sustainability; K. Bradshaw, Federated Co-operatives Limited; S. Siciliano, University of Saskatchewan / Department of Soil Science_

Our project focused on a pesticide manufacturing and packaging facility located in Western Canada. This facility has operated for more than 60 years, and handled a wide range of compounds over that time. Historic operational practices and various accidental releases over the operating lifespan have left soil and groundwater contaminated with a complex mixture of parent and daughter compounds of both pesticides and solvents, including hydrocarbons. An initial site assessment determined that compound migration to aquatic waterbodies and indoor vapour inhalation of volatile compounds are the exposure pathways of potential concern to human and ecological receptors. Completing a traditional risk assessment at the site is difficult since many of the compounds present in the environment are unknown or have no toxicological information. Additionally, the impacts are present in a complex mixture and interactions between compounds are unknown. Research began to determine the effects of impacted soil and groundwater from the site on human and ecological receptors using in vivo and in vitro assays, including human cell lines, aquatic studies, and full animal exposure. In addition to site soil and groundwater exposure, we will expose cell lines to 20 different pesticides in 5 effect categories to assist in deriving a site specific estimate of risk. Following exposure studies, we will complete a site-specific risk assessment to inform safe work practices for construction activities on-site, as well as determine end of site life liability for facility partners.

**MP264 Establishment of data selection criteria for integrated risk assessment of phthalates**

_W. Jeon, M. Seo, S. Baek, S. Lee, M. Hwang, Y. Koo, Ministry of Food and Drug Safety / National Institute of Food and Drug Safety Evaluation_

In Korea, National Institute of Food and Drug Safety Evaluation (NIFDS) has launched human integrated risk assessment of 60 hazard chemicals such as heavy metal, dioxin, formaldehyde, nonylphenol or phthalates in consumer products and food from 2018. Phthalates are plasticizer widely used in consumer products as solvents, additives, and cosmetics. Some phthalates are known as an endocrine disrupter in human. In this study, seven phthalates (DEHP, DBP, BBP, DNOP, DINP and DIDP) were selected for evaluation. In order to improve the reliability of evaluation, we developed data selection criteria. Based on an extensive literature review and criteria, we selected data for phthalate levels in food and compared exposure levels of phthalate between domestic and international data. This data selection criteria will provide information about evaluation of external exposure for integrated risk assessment.

**MP265 Occurrence and risk assessment of pharmaceuticals in the water environment in Japan**

_H. Isda, Y. Kosugi, K. Watanahe, T. Suzuki, Tokyo Metropolitan Institute of Public Health / Environmental Chemistry; T. Nishimura, Teikyo Heisei University / Faculty of Pharmaceutical Sciences_

Used pharmaceuticals that are discharged into the aquatic environment mainly via sewage treatment have become a public concern because they might have adverse impacts on aquatic organisms. Thus, the Ministry of Health, Labor and Welfare of Japan issued “Guidance on environmental risk assessment (ERA) in new pharmaceutical development” in 2016. To evaluate the validity of phase 1 of Japan’s ERA guideline, we monitored the measured environmental concentration (MEC) of already approved pharmaceuticals in rivers flowing through urban areas and urban sewage treatment plants (STPs) in Japan and compared the MEC with the predicted environmental concentration (PEC). The calculation of PEC was based on the ERA of Japan (MHLW), the United States (USEPA), and Europe (EMEA). We collected water samples from seven rivers (2015-2016) and three STPs (2016-2017) in urban areas of Japan in each season and analyzed 54 kinds of pharmaceuticals by LC/MS/MS after concentrating by solid phase extraction to determine MEC values. Among the highest MECs in the river water, the concentrations of sulfadiazine, crotamiton, acetaminophen, and olmesartan were 500-1000 ng/L, and those of valsartan, DEET, azithromycin, clarithromycin, bezafibrate, epinastine, cefmetazole, erythromycin, irbesartan, ketoprofen, losartan, and candesartan were 100-500 ng/L. In the survey at the STPs, pharmaceuticals were higher in influent than in effluent. In the comparison between MEC and the PEC obtained from each ERA method, some pharmaceuticals exceeded 1 when MEC was divided by PEC in the case of default values. The possible reasons why PEC was underestimated follow: (1) the dilution factor (DF) was not suitable to the actual river condition, (2) the result for lorazepam, which is a psychotropic agent, might have been affected by deviation according to each region of use, and (3) the results for ketoprofen and epinastine might have been affected by underestimation of the quantity of consumption (production) in Japan. These results suggest that it is necessary to set DF = 2 as the worst case when calculating the PEC of a new pharmaceutical and to know the accurate quantity of production for already approved pharmaceuticals.
MP266 Correlating Water Quality Data to Assess Potential Risks to Human Health in the White River, AR
J. Chester; J.L. Bouldin, Arkansas State University / Biological Sciences

Pollution of streams and rivers in the United States is damaging the environment and risking the health of humans in recreational areas. Fecal coliform bacteria are an indicator bacteria for dangerous diseases such as Escherichia. Coli, hepatitis, and salmonella. The most common way to contract these diseases via polluted water is by oral ingestion or through breaks in the skin. Assessing and correlating water quality for fecal coliform bacteria can pinpoint locations where humans are at risk for contracting harmful diseases. Northern Arkansas is a major hotspot for recreational fishing, which can be a risk to human health if fishing in polluted waters. Fifteen tributary sites of the White River in Arkansas were tested twice a month to assess water quality parameters such as temperature, pH, dissolved oxygen, conductivity, turbidity, total suspended solids, total nitrogen, total phosphorus, and fecal coliform bacteria. Additionally, three of those sites where fishing is common were also chosen for a study to swab fish for fecal coliform bacteria on the skin of the fish. Statistical analyses were performed to determine the correlation between water quality parameters and fecal coliform bacteria. Geographical analyses were also performed to determine if land use was correlated to the aequous fecal coliform counts in the stream.

MP267 Oregon's Tiered Approach to Toxic Air Contaminant Health Risk Assessments
M. Poulsen, Oregon Department of Environmental Quality / Northwest Region; P. Allen, Oregon Department of Environmental Quality / Air Quality

The State of Oregon recently adopted a program called Cleaner Air Oregon to regulate toxic air contaminants from industrial sources. This is a risk-based approach, requiring industry to assess risks from air emissions to nearby populations. Incorporating elements from other states, the rules include a tiered approach to risk assessment. This allows industry to tailor the risk assessment effort to match the complexity of their site. All levels of risk assessment involve calculating annual and daily air concentrations at exposure locations, and comparing air concentrations with appropriate Risk-Based Concentrations (RBCs). RBCs were developed assuming a one-in-one-million excess cancer risk for carcinogens, and a hazard quotient of 1 for noncarcinogens. This comparison allows a facility to readily calculate risk, and compare the summed excess cancer risks and hazard indices with Risk Action Levels. A simple Level 1 assessment involves choosing dispersion factors from a table based on site-specific information. This includes stack height and distances to various exposure locations for stack emissions, and building height, dimensions, and distances to exposure locations for fugitive emissions. Facilities have the option to use a conservative, default dispersion factor. To screen emissions, facilities multiply each toxic air contaminant emission rate by the dispersion factor to calculate an air concentration for comparison with an RBC. Facilities can use site-specific information and perform modeling in the next two risk assessment levels. In Level 2, they can use U.S. Environmental Protection Agency’s EERSCREEN model or AERMOD model in screening mode, and in Level 3, they can perform complex modeling using AERMOD. In both levels, calculated air concentrations are compared with RBCs. As an option, facilities can directly model risk, rather than concentrations, thereby saving considerable effort in post-modeling calculations. The most comprehensive Level 4 risk assessment uses the same air dispersion modeling conducted in Level 3. In addition, facilities can consider factors to refine the exposure assessment. These factors include modified exposure assumptions, relative bioavailability, or multipathway considerations not covered by the values used to develop RBCs. The intent of a tiered approach is to let facilities optimize resources by selecting a risk assessment level appropriate to their emissions.

MP268 Anthropogenic threats associated with floods in precarious neighborhoods of coastal areas in the Río de La Plata river (Buenos Aires, Argentina)
M.V. Arias, A. Makianich, National University of Lanús / DDPYT; A.W. Elseser, C.R. Leyes, T.A. Martinez, CIC-National University of Lanús / DDPYT; J. Martinez Heres, IPN-National University of Lanús / Environmental Laboratory / Urban Environmental Management / Department of Productive Development and Technology; M.E. Garcia, IPN-National University of Lanús / Laboratorio Ambiental GAU DDPYT; S.O. Demichelis, National University of Lanús / Productive Development and Technology

The urbanized coastal areas of the Río de la Plata have large portions of their territory in low areas, so they have high risks of flooding caused by floods of the Río de la Plata (Sudestada) and abundant rainfall that produce overflowing streams. The objective of the study was to identify anthropogenic threats in post-flood scenarios in precarious neighborhood of coastal settlements of the Río de La Plata river, to assess modifiable risk factors in order to develop proposals for improving inhabitants life quality. Health, climate, natural and socioeconomic aspects were analyzed. UBN was evaluated from facilities (i.e. tap water availability, sewages and pluvial drains, etc.). Coastal urban areas vulnerable to flooding were selected in the counties of Quilmes and Punta Lara, selecting slums and precarious neighborhoods as study sites. The study methodology included: visits to the different neighborhood and the visual assess of habitatility, state of the dwellings and the green and built public spaces. Neighbors were surveyed searching information about frequency and duration of floods, the damages caused by floods, health problems and questions to assess risk perception of floods; the actions taken before, during and after events were also surveyed. Water samples were taken after flood events to measure physicochemical and microbiological parameters. Normalized data were analyzed using XLSTAT, PCA were performed exploratory. Significant differences were observed between the districts studied, where anthropic threats have been identified that increase the risks of natural hazards, these varied among the study sites, highlighting: the presence of dumps and dumping points, incineration of solid waste in the space public, proliferation of pests, presence of unlined ditches on public roads. Since these received black and gray waters without treatment and they overflow in flood events, these had become a route of exposure to pollutants for the population. Post-flood periods are characterized by an increase of exposure to contaminated water, lack of tap-water, power cuts and lack of communication ways. Bacteriological analysis of the samples revealed a high level of pathogens in stagnant waters (E. coli, salmonellas, pseudomonas, etc.), which correlated with higher incidences of health problems such as skin, respiratory, urinary and gastrointestinal affections. Regarding the perception of risk, inhabitants take preventive measures, such as listening to alerts, protecting their homes and self-evacuation, but are not aware of the link between floods and sanitary problems. We concluded that the risks of floods have multiple anthropogenic threats modifiable in the different studied sites. Therefore, health risks could be diminished by in-tubing ditches, in the short term and implementing health education to modify behaviors in order to improve the environmental quality of the neighborhoods.

MP269 Emission of PAHs from roasting of animals’ furs with used tyres; implication for schools in the vicinity of an abattoir in Nigeria
A.I. Onwurah, University of Nigeria, Nsukka / Environmental Management; O. Obiora Francis, Plateau State University, Bokkos, Nigeria / Department of Biochemistry; E.M. Onwurah, Nasarawa State University Keffi / Civil Engineering

Roasting of slaughtered cows, goats and sheep/rams in many abattoirs in Nigeria has become an everyday practice and this has been viewed to have an economic advantage in terms of cost and “recycling.” However, it has become obvious that this practice releases particulate matter, volatile organic compounds (VOCs) and hazardous air pollutants (HAPs) especially polycyclic aromatic hydrocarbons (PAHs) into the environment. Research has shown that these PAHs could trigger some health
problems ranging from respiratory irritation, cough, dermatitis, depressed immune system and a decrease in lung function. This study was aimed at evaluating the risk of exposure of primary school children whose schools are located in close proximity to these abattoirs. The study sought to determine the concentrations of some selected EPA priority PAHs, particulate matter in ambient air and around the school environment, concentrations of some PAH metabolites and some heavy metals in post-shift urine of selected primary school children and control subjects. Lung function, cytogenetic evaluation of DNA damage in buccal exfoliates and urinary phenol of subjects were undertaken. Some of the results show that the concentrations of 1-Hydroxypyrene (l-OPyr) (µg/molCret), a PAH metabolite, in the post-shift urine samples of the 85% of the children were 0.52±0.13 µg/molCret vs 0.20±0.07 µg/molCret while urinary phenol concentrations were 14.26 ± 1.19 mg/L vs. 4.44 ± 1.12 mg/L respectively in exposed children when compared with the control (children in primary schools far away from the abattoir). The buccal epithelial exfoliates showed that karyorrhexis and condensed chromatin bodies were significantly higher in the exposed children than in the control. The implications of these results for the exposed children are discussed in the light of the statement that “health is wealth.”

**MP270 Community risk assessment of ethylene oxide emissions near a sterilization facility in the Denver, Colorado, USA metropolitan area**

*K. Richardson, A. Bamber, T. Simmons, Colorado Department of Public Health and Environment / Disease Control and Environmental Epidemiology Division*

In August 2018, the USEPA released an updated version of the National Air Toxics Assessment (NATA) that indicated a potential increased risk of cancer in the area surrounding a sterilization facility near Denver, Colorado, USA. The previous NATA indicated a much lower cancer risk. The dramatic change in the potential cancer risk in the area is a result of EPA's 2016 revision of their ethylene oxide Integrated Risk Information System's toxicity assessment which indicated an estimated 30-fold increase in cancer potency. Because the NATA relies on modeling of emission data, we conducted a conducted a community level exposure investigation of ethylene oxide concentrations to better understand the risk from levels of ethylene oxide measured in the area surrounding the facility. The results indicated cancer risks at all sampling locations were elevated compared to the EPA's acceptable maximum risk of 1 excess cancer in 10,000 people, even after additional emission controls were installed at the facility. However, cancer occurrence was not elevated in the communities surrounding the facility. This risk assessment indicates that ethylene oxide may pose a hazard to human health in the area surrounding the sterilization facility and the need for additional research into toxicity of ethylene oxide in non-occupational, lower dose exposure scenarios.

**MP271 Effects of exposure to diesel exhaust particles and urban particles on blood brain barrier permeability**

*H. Kim, Chungbuk National University / Preventive Medicine; J. Kim, J. Seo, Chungbuk National University / Anatomy; S. Hong, Chungbuk National University / Preventive Medicine*

Air pollution has adverse effects on the central nervous system (CNS) and causes cerebrovascular disorders, including stroke, and neurodegenerative diseases. Tight junctions (TJs) in the epithelium play a critical role in the formation of a paracellular epithelial barrier against the extracellular environment. While the mechanisms underlying the CNS-related outcomes have not been fully elucidated, exposure to traffic-generated air pollutants has been associated with altered blood brain barrier (BBB) integrity and permeability. Nevertheless, evidence for that is still insufficient. In this study, we evaluated the alterations of BBB integrity caused by exposure to diesel exhaust particles (DEP) and urban particles (UP) using a murine bEnd.3 endothelial cell line, which was used as a BBB model. TJ formation and integrity were evaluated by measuring transepithelial electric resistance (TEER) and the expression of TJ proteins was assessed by confocal microscopy and western blot. DEP exposure decreased the expression of the TJ proteins Claudin-5 and ZO-1 by 55.33% and 58.58%, respectively, compared to the control; UP also decreased the expression of Claudin-5 and ZO-1 by 47.24% and 54.44%, respectively. In the TEER assay, DEP and UP exposure decreased the integrity of endothelial cells by 56.16% and 54.70% compared to the controls, respectively. The results of the present study, which are consistent with the results of our previous study performed using primary bovine brain microvessel endothelial cells, suggest that DEP and UP might alter the integrity and permeability of BBB and induce adverse effects in the CNS.

**MP272 Oxidative stress by diesel exhaust particulate exposure in primary glial cells from neonate rat brain**

*Y. Kim; J. Kim, Chungbuk National University / Anatomy; S. Hong, Chungbuk National University / Preventive Medicine; J. Seo, Chungbuk National University / Preventive Medicine; H. Kim, Chungbuk National University / Preventive Medicine*

Diesel exhaust particulate matter (DEP), a major component of air pollution, is a complex mixture of numerous toxicants. In the recent past, air pollution has been associated with diseases of the central nervous system (CNS), including stroke, Alzheimer’s disease, Parkinson’s disease, and neurodevelopmental disorders. However, a few in vitro studies have examined the effects of DEP on the CNS. The aim of the present study was to evaluate toxic effects, especially oxidative stress by DEP exposure, utilizing different primary cell types. Oligodendrocyte precursor cells (OPC), mature oligodendrocyte (mOL), and astrocytes (AST) were isolated from neonate rat brain. The cells were exposed to several concentrations of DEP (2, 20, and 200 µg/mL) for 24 h, and cytotoxicity was evaluated using Hoechst assay and MTT assay. The generation of reactive oxygen species (ROS) was evaluated using the dichlorofluorescein diacetate method, and the total antioxidant capacity (TAC) was evaluated using bathocuproinedisulfonic acid disodium salt. The results showed that DEP exposure decreased cell viability and induced oxidative stress by increasing ROS generation and decreasing TAC in a dose-dependent manner in all three primary glial cell types. The number of dead cells after DEP exposure (Hoechst assay) was 1.9-2.8 times for OPC, 1.7-2.2 times for mOL, and 1.3-1.6 times for AST, compared to the control. The cell viability after DEP exposure (MTT assay) was 91.0-81.2% for OPC, 95.7-84.9% for mOL, and 97.6-92.0% for AST, compared to the control. The fluorescence by DEP exposure in DCDF-H-DA assay was 112.1-124.8% for OPC, 105.2-113.3% for mOL, and 103.1-106.3% for AST, compared to the control. Finally, TAC decreased after DEP exposure to 88.2-78.2% for OPC, 91.1-82.8% for mOL, and 96.2-87.9% for AST, compared to the control. These results showed that the cytotoxicity and oxidative stress caused by DEP exposure were more prominent in oligodendrocytes than in AST, which suggests that DEP exposure may cause demyelination, especially during development, and may interfere with regeneration of neuronal cells in adults.

**MP273 Status, Source Identification and Human Health Risk Assessment of Heavy Metals in Water Sources around Bitumen Field in Ondo State, Nigeria**

*O.O. Ogulajia, Lead City University / Chemistry; O.O. Adesanya, Redeemer's University / Biological Sciences*

The heavy metals concentrations, distribution and the chronic health hazard associated with the consumption of water sources in three communities that experienced bitumen seepages were assessed. The concentrations of Cr, Cu, Fe, Mn, Pb, Ni, V and Zn in sediment, surface and groundwater were determined in a total of 180 samples acquired bi-monthly from June 2012 to December 2013 by Atomic Absorption Spectrophotometer to evaluate the impact of bitumen spills. Principal component analysis (PCA) and cluster analysis (CA) were also used to study the interactions between metals and identify the possible sources of contamination. The concentrations of heavy metal in groundwater, surface water and sediment samples were in decreasing order of Fe > Mn > Zn > Cu > Pb > Ni > V > Cr, Mn > Fe > Zn > Cu > Pb > Ni > V >
Cr and Mn > Fe > Zn > Pb > Ni > V > Cu > Cr respectively. The average concentrations of Fe, Pb and Mn in groundwater were found to be above the World Health Organization (WHO) drinking-water quality standard of 0.1, 0.003 and 0.4 mg L⁻¹ respectively. In addition, the V/Ni ratios in groundwater samples ranged from 0.98 to 1.21 indicating the migration of these trace metals form bitumen into the water sources in this community. Furthermore, the PCA and CA showed significant intrusions of two diagnostic heavy metals (Ni and V) for petroleum contamination in groundwater samples. Conclusively, this intrusion, as well as the multivariate analyses showed positive significant correlation to petroleum contamination and could lead to heavy metal bioaccumulation in residents with a potential threat to public health.

MP274 Applying Environmental Risk Assessment for Managing Coal Combustion Residuals

G.M. Huddleston, Syn Terra Corporation

Environmental risk assessment has application in management of coal combustion residuals (CCR), commonly known as coal ash. CCR is created when coal is burned by power plants, and is a major industrial waste generated globally. In the United States, regulations for safe disposal of CCR are based on a culmination of extensive study on the effects of coal ash on the environment and public health. The country’s “CCR rule” establishes technical requirements for CCR landfills and surface impoundments under the Resource Conservation Recovery Act (RCRA), the nation’s primary law for regulating solid wastes. Coal ash can contain inorganic constituents that, if present in sufficient concentrations and certain forms, can pose risks to human health and wildlife if exposure occurs. Screening and “baseline” (quantitative) human health and ecological risk assessments were conducted for multiple coal ash impoundments as part of comprehensive site evaluations for developing corrective action plans. Risk assessments followed federal, regional, and state protocols. Without the risk assessments, proposed remedies may have been based primarily on comparison of coal ash constituent concentrations to state groundwater and soil standards. Comparisons to regulatory standards alone often omit context and consideration of natural conditions, as well as introduce greater uncertainty associated with potential environmental risks. By implementing standard risk assessment procedures, in combination with groundwater modeling and consideration of site-specific conditions (e.g., geology, hydrogeology), utility owners and regulatory agencies can select the best remediation strategies to manage risks associated with CCR to acceptable levels.

MP275 Determining Effluent Exposure and Cumulative Risk to Macroinvertebrates at The Mclean Lake Mine in Northern Saskatchewan using Autonomous Sensors

B. Cup Flores, M. Mendes, K. Liberator, University of Saskatchewan / Toxicology Center; M. Nestoret, Institut National des Sciences Appliquées

Treated effluent from the McLean Lake uranium milling operation in northern Saskatchewan is released into the east basin of McLean Lake. This could potentially represent a toxicological risk to aquatic organisms. The goal of this study is to determine the cumulative risk from effluent exposure to benthic macroinvertebrates and identifying risk variations in different parts of McLean Lake. Ten monitoring locations were established in and near McLean Lake using real-time water quality monitoring sensors (Libelium® Smart Water). Each sensor was deployed to measure routine water quality (pH, conductivity, EC), turbidity, dissolved oxygen, and temperature) and send data every 4 hours for 4 weeks (Aug-Sept 2018). Water, sediment, and macroinvertebrate samples were collected at the same 10 monitoring locations. Major ions, dissolved metals, and routine water quality were measured in water, and total metals in sediments. The toxicological risk was estimated by calculating Hazard Quotients (HQs) based on water and sediment quality benchmarks for the long-term protection of freshwater aquatic life. Real-time conductivity data and other results (metals) were used to describe changes in contaminant exposure and help estimate the variability in toxicological risk. Preliminary results indicate that there were significant spatial and temporal variations in effluent exposure in Vulture Lake, and McClean Lake east basin. The individual HQs for zinc, arsenic, selenium, sulfate, and fluoride were higher than water quality benchmarks at some locations. Additionally, individual HQs for vanadium, nickel, arsenic, selenium, molybdenum, and cadmium were higher than sediment quality benchmarks at all monitoring locations. The cumulative risk for surface water was >1 in Vulture Lake and McClean Lake east basin. For sediments, cumulative HQs were >1 at all sampling locations and individual HQs >1 at several sites. This suggests that these metals and anions may represent a possible risk of adverse effect to macroinvertebrates. However, the taxon richness and abundance of macroinvertebrates were relatively low at all the stations and generally, community composition indices showed no correlation with field measurements of EC, which was used as a surrogate for effluent exposure. Thus, results to date suggest that there are no measurable adverse effects on macroinvertebrate communities at these locations.

MP276 Characterization of Wastewater from Ship’s Hull Cleaning by Hydrolasting – Chemical Compositions and Toxicity Potentials of Antifouling Biocides

M. Kim, Korea Institute of Ocean Science and Technology / Risk Assessment Research Center; Z. Soon, Korea University of Science and Technology / School of Ocean Science; J. Jung, J. Kang, Korea Institute of Ocean Science and Technology / Risk Assessment Research Center; C. Yoon, Korea Basic Science Institute; M. Jang, Korea Institute of Ocean Science and Technology / Ballast Water Research Center

During periodic haul-out maintenance of ship, high-pressure water is sprayed to clear off foulants and antifouling paint on the ship’s hull. The sprayed water can be contaminated with particles and active substances released from the paints, and then introduced directly into the adjacent marine environment, if no further treatment of the waste was implemented. The particles and active substances can be sources of hazards to marine organisms in the environment. Wastewaters were collected for analyses of booster biocides and metals during ships’ hull cleanings. Total suspended solid and particle size distribution in the wastewater were also characterized. Copper and zinc were the most abundant metals in the wastewater, as were in the original composition of antifouling paint, exceeding local regulatory discharge standards and NOEC or LC50 values of almost all test species reported in the ECOTOX database. Zinc pyritohione and copper pyritohione were the most abundant booster biocides, exceeding the LC50s of 35 – 60% of test species, based on the database. Diuron was also detected in the wastewater collected from a ship painted for coastal navigation. Suspended solid contents were also far exceeded some local regulatory criteria. Particle size distributions differ among hull cleaning cases. Most particles distributed in the size range of less than 50 μm. General relationship between particle size and cumulative distributions was deduced, which may provide a possible treatment design (filtering size) for removal of particles in the wastewater before discharging into the environment. The physical and chemical characterization of wastewater from ship’s hull cleaning will give insights to the possible risk to the marine environment brought by hull cleaning activities and thus provide guidance for environment management of hull cleanings in terms of chemical hazard and biosecurity concerns.

MP277 Increased demand for chemical elements of emerging technologies. Is it a concern for environmental health?

W.E. Espejo, Melimoyu Ecosystem Research Institute / Department of Aquatic Ecosystems; G. Chiang, Melimoyu Ecosystem Research Institute / Department of Science; P.A. Bahamonde, Melimoyu Ecosystem Research Institute / Biology; J. Celis, University of Concepcion / Department of Animal Science / Faculty of Veterinary Science

In recent years there has been an increase in the manufacture of several emerging technologies (computers, cell phones, robotics and all the gadgets we know). Similarly, there is an increase in the production of products used in renewable energy (photovoltaic and electricity). To be able to produce these are necessary some elements that are critical for their manufacture as it is very difficult to replace in addition to its scarcity in
the environment. These are the so-called technology critical elements and energy critical elements. It has been observed that some of these elements (EERs) have the capacity to bioaccumulate and produce biological effects. On the other hand, we recently observed that Tantalum shows biomagnification in aquatic ecosystems. It has been reported that REE levels have increased due to anthropic activities in China (China has started REE monitoring program). Globally, it has been reported that these elements have not increased, which may be due to the recent use of these elements. If there is no adequate life cycle of these elements and good recycling and e-waste disposal this could become a global problem. There is a lack of studies for these elements (baseline, biogeochemical process, effects on the environment as on human health), mainly on tantualum, gallium, germanium, indium, niobium, tellurium, thallium. Acknowledgements: FONDECYT regular 1161504, FONDECYT Initiation 1118091 and INACH RG01-18.

**MP278 Adult dragonflies as indicators of environmental metallic elements**

**V. Lesch, North-West University; H. Bouwman, North-West University / Unit for Environmental Science and Management**

Odonata are divided into two sub-orders, damselflies (Zygoptera) and dragonflies (Anisoptera). Dragonflies are both prey and predator in both life stages, favouring the bioaccumulation of toxic substances. Adult dragonflies are aerial predatory invertebrates that occur globally except in the polar regions such as Antarctica. Although a number of organisms have been used as indicators of environmental pollution, we know of no research on adult dragonflies as potential indicators of metallic elements in the environment. Furthermore, there is no information available about adult dragonflies and their responses to toxic metallic elements, nor the relative contribution patterns between sites, species, size classes, habitat types, and relation to possible pollution sources. However, research does show that metallic elements are toxic in elevated concentrations to all organisms. Given the unique life cycle of dragonflies, and their abundance in the environment we predict that adult dragonflies would be suitable indicators of elevated elemental concentrations. We analysed 105 adult male dragonflies from 21 sites across South Africa for 33 metallic elements including arsenic, lead, selenium, nickel, copper, cadmium, and chromium. The results indicated that all species of dragonflies, regardless of body size, are suitable indicators. Furthermore, different aquatic habitat types did not affect the metallic element concentrations at the scale of this study. Dragonflies collected near wastewater treatment plants showed concentrations of certain elements such as gold to be higher than from elsewhere. Elements such as arsenic and lead were found at elevated concentrations (relative to the other sites) in dragonflies collected near mining activities. Dragonflies from sampling sites near potential pollution sources, but had seemingly isolated water sources with no influx of external water sources, showed lower metallic element concentrations when compared with sites that have an influence of different water bodies. We conclude that adult dragonflies would be good indicators of environmental metallic elements regardless of size, species, habitat types, or distance to possible pollution sources.

**MP279 Using the USEPA's Species Sensitivity Distribution Toolbox for Environmental Risk Assessment**

**K. Koehrn, K.M. Eisenreich, US Environmental Protection Agency / Office of Pollution Prevention and Toxics; M. Eterson, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division**

The U.S. Environmental Protection Agency (EPA) is piloting a new application of the Species Sensitivity Distribution (SSD) Toolbox, a resource created by its Office of Research and Development (ORD). While exploring options for how to integrate environmental toxicity data during systematic review, EPA's Office of Pollution Prevention and Toxics (OPPT) used the SSD Toolbox to assess the toxicity of trichloroethylene (TCE) in aquatic species. Acute toxicity data for algae, aquatic invertebrates, fish, and amphibians were curated to prioritize study quality and to assure comparability between toxicity values (e.g. comparing EC50s to EC50s). With this dataset, the Toolbox was used to apply a variety of algorithms to fit and visualize SSDs using different distributions. The tool’s output contained several devices for choosing an appropriate distribution and fitting method. However, for small datasets the ability for these measures to distinguish between distributions is limited, so during the analysis of TCE's data, visual inspection of the distributions was also useful. For each distribution the SSD Toolbox calculated a hazardous concentration for a percentage of species (HCp), which can be used in a risk evaluation like a concentration of concern or COC (a hazard value divided by uncertainty factors). For this case study, two SSDs were created, one using only algae hazard data and the other using hazard data for all aquatic species. HC05s were calculated for both SSDs and compared to other methods of integrating data. OPPT found the results of the SSD Toolbox would provide depth and context to the TCE risk assessment, especially for the hazard characterization of algae. This taxonomic group had a wide range of toxicity values, not easily characterized by one toxicity value from a single species. The HC05 for algae used toxicity values from nine species to estimate a concentration that would protect 95% of algae species. Also, the two SSDs provided visual representations of species’ sensitivities, allowing OPPT to quickly analyze whether certain groups of species are more sensitive than others. The tool is currently available on EPA's website. ORD is peer reviewing the tool and plans to make an updated version available in 2019. The views expressed in this manuscript are solely those of the authors and do not represent the policies of the USEPA. Mention of trade names or commercial products should not be interpreted as an endorsement by the EPA.

**MP280 Acute toxicity study of two chemicals to three terrestrial plants and species sensitivity distributions approach for environment risk assessment**

**S. Kim, S. Park, D. Kim, Korea Institute of Toxicology / Gyeongnam Department of Environmental Toxicology and Chemistry; Y. Dong-Hyuk, Korea Institute of Korea (KIT) / Global Environmental Regulation and Compliance Center**

It is estimated that approximately 12,000 kinds of chemical are distributed commercially in the world and about 40,000 kinds of chemical are distributed in Korea. The chemical regulation system such as EU-REACH has been established in various country and Korean government implemented the K-REACH (Hwa-Pyeong Law in Korean) in 2015 to control new or existing chemical. However, there is no regulation to prevent the use of products containing hazard substances (ex. carcinogenicity, mutagenicity, reproductive toxicity, high persistence/concentration) in advance. Although a risk assessment based on the K-REACH should be carried out in order to establish a control system, there are only few available (experimental) toxicity data for risk assessment. In particular, various studies on aquatic organisms have been conducted but toxicity studies on terrestrial organisms have been lacking and toxicity data are not sufficient. Korea has specified 21 substances that cause soil contamination including cadmium, copper, arsenic, mercury, cyanide and so on as controlled soil contaminants in the ‘Soil Environment Conservation Act’ and the management of these chemicals need to be strengthened. Two major chemicals (cadmium and cyanide) causing soil contamination were selected and toxicity effects to three terrestrial plants (Oats, Carrot and Chinese cabbage) were evaluated for the purpose of environmental risk assessment in Korea. Recently, the use of the SSD (Species Sensitivity Distribution) approach is recommended in risk assessment of chemicals. Therefore, in this study, SSDs were constructed based on acute toxicity data of those three species and the ECOTOX database for other species of different taxonomic groups. Hazardous concentrations (ex, HC5) for PNEC (predicted no effect concentration) of soil was estimated from SSD and predicted environmental concentration (PEC) of soil was calculated by Simplebox program using emissions amount (of pollutant release and transfer register system) and soil pollutants data provided by Ministry of Environment. A comparison of the PEC and the PNEC (the PEC_PNEC ratio) was applied for chemical exposure assessment in Korea.
MP281 In vivo and in silico analyses of estrogenic potential of equine estrogens in zebrafish (Danio rerio)
K. Arizona, Pref. Univ. Kumamoto / Faculty of Env Symbiotic Science; M. Hirano, National Institute of Technology / Kumamoto College / Biological and Chemical Systems Engineering; H. Ishibashi, Ehime University / Faculty of Agriculture; M. Uchida, National Institute of Technology, Ariake College / Creative Engineering; N. Tominaga, Ariake National College of Technology / Department of Creative Engineering; A. Kubota, Ohihiro University of Agriculture and Veterinary Medicine / Veterinary Medicine

Equine estrogens (EEs) have been isolated from the urine of pregnant mares, and widely used as a material of hormone replacement therapy pharmaceutical in post-menopausal women. Several previous studies have shown the occurrence of EEs in the aquatic environment. However, limited data are available on the potential estrogenicity and risk of EEs in aquatic organisms, including fish. The objective of this study was to evaluate the estrogenic potentials of major EEs, such as equilin (Eq), 17α-dihydroequilin (17α-Eq), 17β-dihydroequilin (17β-Eq), equilenin (Eqn), 17α-dihydroequilenin (17α-Eqn) and 17β-dihydroequilenin (17β-Eqn), on zebrafish (Danio rerio) using in vivo and in silico assays. Our quantitative real-time RT-PCR analyses revealed that the expression level of cytochrome P450 (CYP) 19A1b gene in developing zebrafish responded to various types and concentrations of EEs in a dose–response manner. The order of in vivo estrogenic potencies of EEs was as follows: 17β-Eq > 17α-Eq > Eq > Eqn > 17β-Eqn > 17α-Eqn, and the 50% effective concentration (EC50) of 17β-Eq and 17α-Eq were lower than that of 17β-estradiol. To further investigate the interaction potential of EEs with zebrafish estrogen receptor (ER) subtypes in silico, a three-dimensional model of the ligand-binding domain (LBD) of each ER was built and docking simulations were performed. Results revealed that six EEs interact with the LBDS of ERα, ERβ1 and ERβ2. Overall, the order of in silico interaction potentials of EEs with each ER LBD was as follows: 17β-Eq > 17α-Eq > Eq > 17β-Eqn > 17α-Eqn > Eqn. Furthermore, we identified the key amino acids interacting with EEs in each ER LBD, suggesting that amino acids identified may be attributable to the ligand-specific interaction with each ER. This is the first report showing the comprehensive analyses of in vivo and in silico estrogenic potential of EEs in zebrafish.

MP282 Computer-Aided Discovery and Redesign for aquatic toxicity (CADRE-AT): Predicting aquatic toxicity of pesticides and informing design of safer analogs
A.M. Vouthkova, George Washington University / Chemistry; S.M. Ramer, George Washington University; J. Kostal, The George Washington University / Chemistry

The ubiquitous use of pesticides is expected to increase in coming years with the need to increase agricultural productivity. The large quantity of pesticides applied to crops underscores the need to develop robust methods to predict environmental hazard and apply rational design principles to minimize hazard prior to commercialization. Predictive methods to evaluate aquatic toxicity of pesticides are yet to displace animal testing. Here we describe the development of an in silico tool for predicting acute aquatic toxicity, CADRE-AT (Computer-Aided Discovery and Redesign for aquatic toxicity), which affords continuous predictions of toxicity based on quantum-mechanical electronic reactivity parameters, bioavailability estimates and identification of possible metabolites. We validate CADRE-AT for predicting ecotoxicity of a prominent group of pesticides and their metabolites. Acute mean lethal concentration values were predicted for each pesticide, and the results were compared with experimental values. We also compared the performance of CADRE-AT to that of another model developed in our groups, “rule of three,” which applies bioavailability and electronic reactivity parameters to define a “safe” chemical space for aquatic species. Both models were developed for commercial chemicals and had not been assessed for performance on pesticides. The rule of three correctly classified all pesticides with experimental data in their experimentally-determined category. The CADRE-AT approach misclassified three chemicals by one category of concern. These chemicals were further examined for their toxicity mechanisms and metabolic transformations to improve the model performance. Overall, the results demonstrate that the two in silico approaches are sufficiently robust and of relevance to both industry and regulatory decision makers in assessing environmental hazard associated with pesticides. These computational methods provide a fast and economically efficient method for screening pesticides before distribution so that their efficacy can be optimized, while minimizing unintended harm to environmental health.

MP283 Assessing the Potential Risk of Pesticides to Small Streams Using High Frequency Sampling in Southwestern Ontario Streams
M. Chemeris, R.S. Prosser, University of Guelph / School of Environmental Sciences

The Provincial (Stream) Water Quality Monitoring Network (PWQMN) program had been quantifying and tracking changes of water quality in rivers and streams across Ontario since 1964. However, the main limitation of this network is that it does not monitor current-use pesticides. The OMCEP and OMAFRA do coordinate a pesticide monitoring program for current-use pesticides, but only 4-10 samples are taken per year from only 18 locations across Ontario. Therefore, due to the lack of field data on the quantity of pesticides in streams during flow events, the temporal dynamics of the concentration of pesticides in Southwestern Ontario remain poorly characterized. To increase our understanding on how pesticide exposure changes during flow events and to investigate an alternative approach for monitoring pesticides, three autosamplers were deployed at six different sites in the Kettle Creek Watershed over a two-year period. The autosamplers were programmed to collect water samples every hour over the growing season from July to October in 2018 and June to September in 2019. The cost-effectiveness of this approach was increased by selecting the samples for analysis based on rainfall and flow data at the sampling sites. Water samples were analyzed for the presence of over 500 pesticides using GC-MS/MS and LC-MS/MS. The analysis showed that pesticides were detected at higher concentrations after significant rain and flow events. This type of data helps us to understand the baseline and peak concentrations of pesticides that aquatic systems can experience along with the frequency and duration of these peaks. The land use in the upstream catchment of each sampling site was quantified along with land use detected to individual crop types. This allowed for an examination of any relationships between upstream land use and crop type and the frequency, magnitude, and variety of pesticides detected in surface water.

MP284 Water quality monitoring and assessment of volatile organic compounds in petrochemical wastewater
J. Kim, S. Kim, Gwangju Institute of Science & Technology / School of Earth Science and Environmental Engineering

Excessive use of chemicals has emerged as results of a growing number of chemical accidents and increasing the amount of environmental damage. Generally, chemical accidents occur most often at industrial estates where a huge quantity of hazardous materials are stored, transported, and used, and therefore, concerns about the management of industrial chemicals have led to regulations in many countries. In this study, water samples from a reservoir near the petrochemical complex where a massive fish kill occurred in 2018 due to benzene spill were analyzed for volatile organic compounds (VOCs). Additionally, aquatic ecological risk assessment was conducted for detected VOCs based on the analyzed results. Samples were collected by grab sampling by following EPA method 5035A and the instrumental analysis was performed using Headspace-gas chromatography-mass spectrometry (HS-GC-MS) for 29 VOCs listed on EPA 500 series methods which cited under the Safe Drinking Water Act (SDWA) and chloroform. As a result of instrumental analysis, the method detection limits (MDLs) were found to range from 0.13 to 0.84 µg/L, the recoveries ranged between 59 % to 105 % except for 1,1-dichloroethylene (18.35 %), dichloromethane (34.86 %), and trans-1,2-dichloroethylene (46.53 %) with coefficient of variation (CV) less than 25 % except for 1,1-dichloroethylene (39.51 %) and cis-1,2-Dichloroethylene (40.40 %). From the
water samples, the concentration of detected VOCs ranged from 0.19 (trans-1,2-dichloroethylene) to 23.85 (chloroform) μg/L and particularly the concentration of benzene was 1.65 μg/L. As a result for ecological risk assessment, the ratios of a predicted environment concentration (PEC) and a predicted no effect concentration (PNEC) of the detected VOCs were lower than 1 which suggest that these substances were considered to present a risk to the aquatic ecosystem. Further studies should be performed with additional sample collection for four different seasons, different method for sample collection and instrumental analysis, and more standard solutions for monitoring and assessing the water quality.

MP285 ToxMate, a new tool for self-monitoring of the toxicity of water discharges by video-tracking the locomotor behaviour of aquatic invertebrates

D. Neuzeret, A. Decamps, ViewPoint; O. Geffard, Irstea / UR RIVERLY Laboratoire Ecotoxicologie; F. Maulin, M. Dauphin, ViewPoint; H. QUEAU, L. Garnero, Irstea Lyon / UR MALY Laboratoire Ecotoxicologie; A. Chaumot, Irstea / UR MALY Laboratoire Ecotoxicologie

Context : Water resources, biodiversity and health are major societal concerns. One of the prerogatives to preserve them is to limit the release of contaminants into the environment. It is in this context that self-monitoring of the toxicity of discharges is gradually emerging in legislation. To meet this need, standardized biotests are available, the most commonly used of which is based on the impact of spot samples on daphnia mobility (Daphnia magna) (ISO 6341 : 2012). This type of approach does not allow us to understand the toxicity of a release whose quality varies over time, so the results obtained are dependent on the sampling. In order to propose an innovative solution, a partnership between ViewPoint and the ecotoxicology research laboratory at Irstea Lyon was initiated in 2014. Methodology used : Toxicity assessment is based on the monitoring of locomotor behaviour, a sensitive, generic biomarker with an extremely short response time. The invertebrates used (Gammaridae, Lymnaeidae and Erpobdellidae) are species present in aquatic biocenoses in Europe and belong to different phylogenetic groups in order to obtain a wider range of sensitivity to contaminants. Main results: development and feedback : A laboratory phase made it possible to develop a behavioural analysis protocol and an indicator sensitive to the presence of contaminants while excluding so-called confounding factors (temperature, oxygen, noise, etc.). This new tool has been validated by putting it in a natural situation on two industrial sites. They made it possible to evaluate online, and with an autonomy of 30 days, the toxicity of a water at the end of the treatment plant and thus to detect several episodes of toxicity. Once the prototype has been developed, the ToxMate allows 48 organisms to be monitored in real-time, with secure online transmission and without the need for an on-site test condition. On-site online assessments were carried out on two wastewater treatment plants (La Feyssine-Lyon and Les Bouillides-Sophia-antipolis) as well as on a rainwater retention and infiltration basin. These follow-ups now allow self-monitoring and can inform the water manager in real time during a toxicity episode.

MP286 Design of a multidimensional density dependent matrix population model for assessing ecological risk to fish populations

D.H. Miller, USEPA / Mid-Continent Ecology Division; B.W. Clark, D.E. Nacci, US Environmental Protection Agency / Atlantic Ecology Division

Modeling exposure and recovery of fish and wildlife populations after stressor mitigation serves as a basis for evaluating population status and remediation success. Herein, we develop a novel multidimensional density dependent matrix population model that analyzes both size-structure and age class-structure of the population simultaneously over time. This population modeling approach emphasizes application in conjunction with field monitoring efforts (e.g., through effects-based monitoring programs) and/or laboratory analysis to link effects due to chemical and/or nonchemical stressors to adverse outcomes in whole organisms and populations. For demonstration purposes, we applied the model to investigate population trajectories for Atlantic killifish (Fundulus heteroclitus) exposed to 112, 296, and 875 pg/g of 2,3,7,8-tetrachlorodibenzo-p-dioxin with effects on fertility and survival rates. The Atlantic killifish is an important and well-studied model organism for understanding the effects of pollutants and other stressors in estuarine and marine ecosystems. For each exposure concentration, the corresponding plots of total population size, population size structure, and age structure over time were generated. For example, exposure to 875 pg/g of 2,3,7,8-tetrachlorodibenzo-p-dioxin resulted in a 13.1% decline in population size after 2 years, a 22.1% decline in population size after 5 years, and a 27.9% decline in population size over 10 years with plots of all size classes and age classes exhibiting declines. The present study serves as an example of how multidimensional matrix population models are useful tools for ecological risk assessment because they integrate effects across the life cycle, provide a linkage between endpoints observed in the individual and ecological risk to the population as a whole, and project outcomes for multiple generations.

MP287 Environmental Risk Assessments for Topical Antiseptic Ingredients: Benzalkonium Chloride

Benzalkonium chloride (BAC) is a cationic surfactant used in a variety of cleaning and personal care products, as well as agricultural and industrial applications. As the use of triclosan and triclocarban compounds in topical antiseptic products such as hand washes and rubs has been phased out, BAC has been used as a replacement that provides antiseptic benefits. The American Cleaning Institute (ACI) undertook an evaluation of the environmental safety of BAC used in the U.S. cleaning product industry, based on best available environmental fate and effects data for BAC from scientific literature and privately held sources. The risk assessment included conservative scenarios for current and future uses of the ingredients, using published data and modeling to estimate environmental exposures. Specifically, surface water and sediment monitoring data were used to characterize recent exposure levels, while the iSTREEM(R) model was used to estimate aquatic exposure distributions for the future scenario. Terrestrial exposures due to land application of biosolids were assessed based on BAC concentrations in wastewater treatment plant biosolids, as estimated using the SimpleTreat model in conjunction with concentration-dependent surfactant sorption. Aquatic toxicity data for BAC were extensive, with acute and chronic data available for freshwater and marine invertebrates, algae, and fish. Soil toxicity data were available for plants, invertebrates, and microbial processes related to soil fertility, and limited sediment toxicity data were also included. Taken together, the available data indicate no unacceptable risks associated with any central-tendency exposure estimates or with high-end exposure estimates in soil. Risks of chronic effects on invertebrates from BAC in effluent-dominated aquatic systems are difficult to interpret, because multiple reproduction studies with the most sensitive species (Daphnia magna) yielded vastly differing results. A priority for future research should be to clarify how factors such as dissolved organic carbon affect chronic BAC toxicity to invertebrates.

MP288 Environmental Risk Assessments for Topical Antiseptic Ingredients: Benzethonium Chloride

Benzethonium chloride (BZC) is a cationic surfactant used in topical antiseptic products to reduce infectious bacteria on hands in consumer, institutional, health care, and food handler settings. It is one of several compounds that may be used to replace triclosan and triclocarban, as their use in topical antiseptic products such as hand washes and rubs is phased out. The American Cleaning Institute (ACI) undertook an assessment of the environmental safety of BZC use in the U.S. cleaning
The field of manufactured nanomaterials (MNMs) is undergoing rapid development. Due to the diverse variants possible when synthesizing MNMs, multiple identities are possible for a given substance. The Canadian definition used under the Chemicals Management Plan (CMP) identifies nanomaterials as chemical substances manufactured at the nanoscale (1-100 nm) in at least one dimension internally or externally, or materials that exhibit at least one nanoscale property/phenomenon. Canada regulates these MNMs domestically under the Canadian Environmental Protection Act. The ecological risk assessment of MNMs will follow a similar regulatory process as other chemicals regulated under the CMP. The Canadian risk assessment approach will address the specific physical considerations required for MNMs, including fully characterizing their identity (size, shape, chemical composition), physicochemical properties (water solubility, dispersion stability, etc.), and toxicological effects. To bridge data gaps and standardize laboratory practices, the use of existing methodologies and tools, including the OECD test Guidelines and Guidance Documents for both MNMs and chemicals (with adaptations for MNMs), is encouraged. Traditional risk assessment principles applied for chemical substances assessment which should apply to MNMs include the use of weight-of-evidence in risk assessments, precautionary principle, use of analogue data and modelling tools to bridge data gaps, and use of a tiered approach tying together risk characterization and uncertainty. Specific challenges for the risk assessment of MNMs include defining shape and size variability effects, determining the impact of physicochemical properties for environmental fate, properly estimating the bioavailability potential, developing options to estimate data gaps (i.e. through environmental exposure models), and defining the impact of nano-specific properties. Developing strategies to work with knowledge gaps during the risk assessment process (such as read across and grouping strategies), are important to reduce uncertainties for supportable risk conclusions. Canada is involved in several international projects, and closely following other international projects, which aim to address these regulatory challenges and strategies for the risk assessment of MNMs.

MP289 Environmental Risk Assessments for Topical Antiseptic Ingredients: Chloroxylenol

Chloroxylenol (also known as parachlorometaxylenol or PCMX) has long been used in topical antiseptic and disinfectant products in health care and home settings. As the use of triclosan and triclocarban compounds in topical antiseptic products such as hand washes and rubs has been phased out, PCMX is being used as a replacement that provides antiseptic benefits. The American Cleaning Institute (ACI) undertook an environmental safety assessment for PCMX use in the U.S. cleaning product industry, integrating best available environmental fate and effects data for PCMX from published and privately held sources.

Chloroxylenol concentrations in U.S. surface waters have been extensively monitored, and data are also available to characterize concentrations in wastewater treatment plant (WWTP) effluent and percent removal during wastewater treatment. These data were supplemented with modeling (equilibrium partitioning and SimpleTreat) to estimate PCMX concentrations in sediment and in soil receiving land-applied biosolids. Predicted sediment and soil concentrations were low, because PCMX is only moderately hydrophobic. A conservative future scenario was also assessed using the iSTREEM® model, based on triclosan replacement with PCMX. Available toxicity data characterized acute effects of PCMX on freshwater fish, invertebrates, and algae, and a conservative margin of safety was targeted to compensate for the lack of chronic toxicity data.

MP290 A Canadian approach towards a risk assessment framework for manufactured nanomaterials
J. O’Brien, M. Sauve, Environment and Climate Change Canada; J. Gauthier, Environment and Climate Change Canada / Ecological Assessment Division

The field of manufactured nanomaterials (MNMs) is undergoing rapid development. Due to the diverse variants possible when synthesizing MNMs, multiple identities are possible for a given substance. The Canadian definition used under the Chemicals Management Plan (CMP) identifies nanomaterials as chemical substances manufactured at the nanoscale (1-100 nm) in at least one dimension internally or externally, or materials that exhibit at least one nanoscale property/phenomenon. Canada regulates these MNMs domestically under the Canadian Environmental Protection Act. The ecological risk assessment of MNMs
MP292 Monitoring the health and contaminant levels in Canadian Arctic beluga whales to help assess and communicate risks and benefits to Inuit

M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Stow, Fisheries and Oceans Canada; Z. Gillespie, Health Canada; A. Caughey, W. Joy, Government of Nunavut; L. Williams, Government of Northwest Territories; C. Watt, Department of Fisheries and Oceans; S. Ferguson, Fisheries and Oceans Canada; M. Gauthier, S. Ricard, Government of Quebec; E. Way-Nee, Fisheries Joint Management Committee; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; E. Jenkins, University of Saskatchewan; L.L. Loseto, Fisheries and Oceans Canada / Central and Arctic Region

Beluga whales (Delphinapterus leucas) are important country (traditional harvest) foods for Inuit. The health of the Arctic ecosystem, belugas and humans are all closely connected in the Arctic. The monitoring of beluga’s health and contaminant concentrations in country food has been a priority of the Canadian Government since 1991 via the Northern Contaminants Program. On an annual basis, health indicators (i.e., diet, hormones, diseases) as well as mercury and organic compounds have been monitored in hunted belugas in partnership with northern community members at Tuktoyaktuk, (Northwest Territories), Sanikiluaq and Pangnirtung (Nunavut). Results of biological parameters and pollutants, such as polychlorinated biphenyls, organochlorine pesticides, flame retardants and polyfluoroalkyl substances as well as mercury, are reported to the communities as well as regional and federal health agencies. These results are used to assess ecological risks of contaminants in whales. Concerns from community members have also emerged on the human health aspect of beluga whale consumption. As a result, a Beluga Risk/Benefit Communication working group was created in 2018 to support regional health authorities of the Inuvialuit Settlement Region and Nunavut Territory on the assessment of human health risks related to contaminants in beluga. The orientation of this group will follow assessment work conducted in Nunavik. This team, composed of Inuit organizations, regional health authorities, community co-management boards, human and beluga health experts as well as chemists and toxicologists, are also helping address the communication challenge of risk-benefits of beluga consumption. During initial discussions, regional health authorities have shared their needs and scientists have summarized the information available for each beluga whale population. Using existing data on mercury in beluga and previous health surveys in regional Inuit communities, a human health risk assessment was initiated to characterise the main sources of risk (e.g., contaminant, tissue, preparation method) and nutritional benefits (e.g., healthy fats, selenium) of eating beluga whale, as well as identify vulnerable groups of concern (i.e., young children, pregnant females). Critical gaps will be highlighted and communication plans and materials that effectively share information and results to communities will be developed in an effort to promote health of the Arctic marine ecosystem, beluga populations, and Inuit.

MP293 Could chemical activity based environmental quality guidelines replace traditional media concentration-based guidelines?

A. Dunn, Environment and Climate Change Canada; D.J. Spry, Environment and Climate Change Canada / Science and Risk Assessment Directorate

Environmental quality guidelines (EQGs) continue to be recognized and trusted tools for the assessment of chemicals, interpretation of monitoring data and development of risk management goals and performance targets. The methodologies published by the Canadian Council of Ministers of Environment (CCME) and many individual Canadian provincial/territorial jurisdictions continue to rely on empirical toxicological bioassay data with fish, invertebrates and plants. In contrast, risk assessments have made use of a broader range of inferential tools (QSAR, read-across, trend analysis, chemical activity) to arrive at hazard evaluations (PNEC=probable no effect concentrations) not currently used in guideline/criteria development. Since chemical activity relies purely on physical/chemical properties and may be easily modelled using spreadsheet based calculations, the approach has the potential to accelerate guideline/criteria development, reduce the use and reliance on test organisms and deal with mixtures of chemicals exhibiting baseline (narcosis) mode of action. Here we examine the use of the chemical activity approach to develop a ‘safe activity level’ (derived from an analysis of the activity levels of existing, empirical-based chronic EQGs for non-biomagnifying, nonpolar narcotics) and its use in EQG development for prospective substances with baseline MOA. The exercise was conducted for methods development, not regulatory purposes.

MP294 Effects of Cement Dust on Soil Microbial Population Around Lafarge Cement Industry in Ogun State, Nigeria

L. Ogunyebi, University Of Lagos / Department of Cell Biology and Genetics; K. Obeleagu, University of Lagos, Akoka / Department of Cell Biology and Genetics

The study investigated the impact of cement dust pollution from Lafarge Cement Industry, Ewekoro on physicochemical and microbial diversity of the soil. Soil samples were collected inside the cement factory and from the surrounding at 0 meters, 500 meters and 1000 meters away from the cement factory with the aid of soil auger at a depths of 0-10cm and 10-20cm and kept in a sterile nylon bags with appropriate labels. The soil samples were transported to the Laboratory in University of Lagos for chemical analysis. The soil pH was determined using pH meter, moisture content was determined by oven drying method, electrical conductivity was determined on a 1:1(V/V) soil/water mixture composed of a 10 gram soil scoop and 10 ml double-deionized water. The heavy metals contents were determined using Atomic absorption Spectrophotometer. Population diversity of microbial species was also examined using disc diffusion method. The methods showed that, pH of the soil ranged from 6.27±0.03 - 6.47±0.03. The highest pH values (6.47) was recorded at 500m away from the factory. The soil moisture content ranged from 15.78±2.52 - 9.65±1.16, with values decreasing progressively away from the factory site. The levels of heavy metals except Mg, Zn and Na were higher within the factory than in the control. Cr, Fe, Pb, Cd, Ca and Cu were significantly higher at P< 0.05 in all locations than in control. Isolated microbial flora consists of 5 bacteria genera belonging to, Corynebacterium, Clostridium, Bacillus, Flarobacterium and Micrococcus, and 8 fungal genera belonging to Aspergillus, Penicillium, Trichoderma, Mucor, Noecroia, Geotrichum, Rhizopus and Fusarium. The bacterial counts in both polluted and control soil were lower than the fungal counts in both soils. The lower counts of bacteria compared to fungi may be as a results of nutrient status of the soil. Microbial population diversity increased steadily away from the factory. The isolates are Considered are tolerant to slightly acidic pH and heavy metals from cement dust. Thus, the variation is attributed to the impact of pH and heavy metals on microbial population.

MP295 Ambient Air Quality Assessment around Lafarge Cement Factory in Nigeria

A.L. Ogunyebi, University of Lagos, Akoka / Department of Cell Biology and Genetics; T. Soyebo, University of Lagos, Akoka / Department of Cell Biology and Genetics

This study investigated the impact of cement dust pollution from Lafarge Cement Factory, Ewekoro on physicochemical and microbial diversity of the soil. Soil samples were collected inside the cement factory and from the surrounding at 0 meters, 500 meters and 1000 meters away from the cement factory with the aid of soil auger at a depths of 0-10cm and 10-20cm and kept in a sterile nylon bags with appropriate labels. The soil samples were transported to the Laboratory in University of Lagos for chemical analysis. The soil pH was determined using pH meter, moisture content was determined by oven drying method, electrical conductivity was determined on a 1:1(V/V) soil/water mixture composed of a 10 gram soil scoop and 10 ml double-deionized water. The heavy metals contents were determined using Atomic absorption Spectrophotometer. Population diversity of microbial species was also examined using disc diffusion method. The methods showed that, pH of the soil ranged from 6.27±0.03 - 6.47±0.03. The highest pH values (6.47) was recorded at 500m away from the factory. The soil moisture content ranged from 15.78±2.52 - 9.65±1.16, with values decreasing progressively away from the factory site. The levels of heavy metals except Mg, Zn and Na were higher within the factory than in the control. Cr, Fe, Pb, Cd, Ca and Cu were significantly higher at P< 0.05 in all locations than in control. Isolated microbial flora consists of 5 bacteria genera belonging to, Corynebacterium, Clostridium, Bacillus, Flarobacterium and Micrococcus, and 8 fungal genera belonging to Aspergillus, Penicillium, Trichoderma, Mucor, Noecroia, Geotrichum, Rhizopus and Fusarium. The bacterial counts in both polluted and control soil were lower than the fungal counts in both soils. The lower counts of bacteria compared to fungi may be as a results of nutrient status of the soil. Microbial population diversity increased steadily away from the factory. The isolates are Considered are tolerant to slightly acidic pH and heavy metals from cement dust. Thus, the variation is attributed to the impact of pH and heavy metals on microbial population.
the stacked filter unit and concentration of particulate matter of a specific aerodynamic diameter was recorded. Relative humidity, wind speed and temperature were measured using CW-HAT 200 handheld tester. CO, NH3, and H2S were measured using Tetra multi-gas monitor. SO2 was measured using BW (Model 0539). Noise level was measured with a CET-DT 805 sound level, VOC measured with the self-regulating gas alert Micro5Prid meter. The results generally showed low levels of CO while PM levels were above the WHO standards. Concentration of air pollutants studied decreased with distance (0-30m). The concentrations of particulate matter (PM0.3, PM2.0, and PM10) varied respectively between 141147 μg/m3, 2919 μg/m3, 171.0 μg/m3 in the first week; 40514 μg/m3, 1150 μg/m3 and 27 μg/m3 in the second week and 117327 μg/m3, 653 μg/m3 and 0 μg/m3 in the third week respectively. The temperature, relative humidity and wind speed measured in all sampling stations were within WHO Standard. The concentrations of particulate matter at all the seas- sons exceeded WHO and NAAQS guidelines. However, concentrations of PM were higher in the dry seasons compared to the wet season. Higher concentration of PM0.3 (141147 μg/m3), PM2.5 (2919 μg/m3), PM10 (171 μg/m3) and noise level (77.2 dBA) in particular was recorded. Higher concentration of PM was observed at specific distance (0-40m). Based on the observations in this study, continuous monitoring of PM levels and other air pollutants is required to ensure compliance with recommended regulations and for health risk assessment.

MP296 When a Neighbour Complicates Matters: Offsite Flow-through Issues for Fish and Aquatic Invertebrates at a Hydro Works Yard
M. Anderson, J. Widmeyer, SLR Consulting (Canada) Ltd.; B. Hatch, BC Hydro
SLR Consulting (Canada) Ltd. was retained by BC Hydro Power and Authority (Hydro) to conduct a Human Health and Ecological Risk Assessment (HHERA) of a former BC Hydro District Office works yard. The goal of this work was to assist Hydro in obtaining a BC Certification of Compliance to sell the property located in Port Alberni, BC, Canada. The challenge associated with this project were the multiple receptors, contaminant sources, and land use combinations requiring assessment and resolution as part of the certificiation process. The focus of the current presentation explains how contaminant sources were identified and risks were evaluated for benthic invertebrates and fish exposed to metals in surface water (copper, iron and manganese) and sediments (arsenic, chromium, lead and zinc). The property had two key sources of metals: one originating from onsite soils and the second originating from an offsite upstream creek traversing the site. Onsite groundwater investigations confirmed that metals originating from onsite soils (arsenic) did impact groundwater, but that the plume was stable, and groundwater was not discharging arsenic into the creek. Multiple drains contributing truck wash water and storm run-off from the offsite property were identified present and discharging into the creek. Seasonal surface water and sediment sampling confirmed that concentrations of metals in upstream sediments and surface waters (end of pipe and within the creek) were present and associated with the neighbouring property. Metals concentrations were highest in the creek closest to the offsite input drains and did not always attenuate to levels below the regulatory standards within onsite sediments and surface waters. The combination of the creek and offsite sources created a contaminant flow through scenario for metals. As part of the HHERA, concentrations of metals in sediment were used in combination with sediment toxicity testing to assess impacts to the benthic invertebrate community. Concentrations of metals in surface water were used in combination with fish trapping and habitat quality assessments to assess impacts to the fish community. Overall risks were concluded to be low and risk-based standards were met for these results.

MP297 Assessing Health Risk of a Chlorinated-Solvent-Contaminated Site Using a Novel Analytical Transport Model
J. Chen, National Central University / Graduate Institute of Applied Geology; C. Liang, Fooyin University / Department of Nursing
Chlorinated-solvent-contaminated site poses a significant threat to the human health and environment. It is too expensive and labor-intensive to obtain a sufficient amount of data for constructing numerical transport models of individual sites which generally require a detailed physical description of the hydrogeology and specification of the initial and boundary conditions as well as a sufficient number of hydrogeological parameters. Therefore, simple and rapid tools based on analytical transport models are widely used to assess (at an early stage) whether a site might pose a threat to groundwater. This study presents an analytical model for rapid assessment of health risk from exposure to the chlorinated solvent contaminated groundwater. This fast tool is achieved based on the analytical solutions derived for a set of simultaneous three-dimensional transient advection-dispersion equations (ADEs) coupled with sequential first-order biodegradation reactions. The accuracy and robustness of the derived analytical solution tool is evaluated and confirmed by comparisons of results obtained from the newly derived model and the currently available analytical model in the literature. The results show that the newly derived model agree well with the previous solution with a significant reduction in the computational time. An application example of the derived analytical solution tool is evaluated, and the final conclusions of results obtained from the newly derived model and the currently available analytical model are presented. The derived solution will be an effective and efficient tool for assessing health risk of chlorinated-solvent-contaminated sites.

MP298 Long-Term Ecological Effect Assessment After Chemical Accident
H. Jung, Korea Institute of Toxicology / Environmental Fate & Exposure Research Group
Recently, chemical spill accidents are becoming more frequent as industrial development progresses. The impacts of chemical accidents can be deadly, for both human beings and the environment. Many different types of chemicals can be toxic effect immediately in plant. However, even when an exposure occurs at a concentration too low to cause non-toxic effect, the chemical may accumulation over time in plant. Chemicals can exist in plant at low concentrations, which can affect genetic level and metabolism. In this study, we attempted to evaluate the phenotype, genetic level and metabolic effects of Arabidopsis thaliana L. plants at low concentrations of major chemicals (strong acids and organic compounds) long-term effect. Hydrochloric acid and hydrofluoric acid were selected as the sulfuric acid substances and phenol and toluene were used as the organic compounds substances. In the phenotype effect of chemical in Arabidopsis, they were exposed to control, 100, 1000, 5000 and 10000 mg/kg of each chemicals for 14 days. Each chemicals caused decrease of plant dry weight at highest concentration compared to control. Genetic levels and metabolic effects at low levels toxic effects on phenotypes were investigated. To investigate genetic level and metabolism, ongoing efforts are studying: 1) To understand the transcriptional changes under chemicals, Validation of appropriate reference genes for real-time quantitative PCR (RT-qPCR) gene expression analysis in Arabidopsis plants exposed to chemical stresses. 2) The use of metabolomic analysis to dissect plant responses to chemical stresses.

MP299 Peroxymonosulfate/chloride versus sodium hypochlorite disinfection on the formation and estimated cytotoxicity of disinfection by-products
T. Chen, Tongji University; T. Xu, Tongji University / College of Environmental Science and Engineering
The use of peroxymonosulfate (PMS) as an oxidant is receiving increasing interest for drinking water disinfection. However, it does not possess continuous disinfection ability compared with sodium hypochlorite (NaClO). PMS/Cl- can produce reactive chlorine species and thus provide
a persistent disinfectant residual in distribution systems. This study investigated the effect of PMS/Cl₂ disinfection versus NaClO disinfection on the formation and estimated cytotoxicity of CX₃R-type disinfection by-products (DBPs) under the same free chlorine dose. Results showed that HOCl/OCl⁻ produced in PMS/Cl₂-reacted with organic compounds to produce CX₃R-type DBPs. During PMS/Cl₂-disinfection, chlorofluorocarbon (CF) was dominant DBP and its concentrations increased as the reaction time, pH and Cl₂ dose increased. Chloral hydrate (CH₂) also increased steadily with the increase of reaction time and Cl₂ produced in PMS/Cl₂-process, but CH₂ concentrations increased first and then decreased as the pH increased. Due to the hydrolysis of haloacetonitriles (HANs) and haloacetamides (HAMS), their concentrations increased first and then decreased as the Cl₂ from PMS/Cl₂-increased or decreased as the pH increased during PMS/Cl₂-disinfection. Compared to NaClO disinfection, CX₃R-type DBPs concentrations varied Cl₂ dose, pH and reaction time exhibited similar trend during PMS/Cl₂-disinfection. After 24 h at pH = 6 and Cl₂ dose = 0.25 mM, the concentrations of CF, CH₂, DCAN, TCAN, DCAM and TCAM formed from tyrosine (Tyr) were 94.1, 18.5, 337.8, 0.7, 6.5 and 2.2 nM, respectively in PMS/Cl₂-disinfection, which was lower than that (236.6, 25.1, 351.7, 0.8, 6.7, and 2.3 mM) in NaClO disinfection. This is probably attributed to the oxidizability of PMS, which can oxidize Tyr and then prevent the formation of CX₃R-type DBPs. The cytotoxicity calculated from all investigated CX₃R-type DBPs produced in PMS/Cl₂-disinfection also showed a similar trend with NaClO disinfection, and the cytotoxicity is also significantly lower than that during NaClO disinfection. This study demonstrated the advantages of PMS/Cl₂ as an alternative disinfectant compared with NaClO, which may be important implications in drinking water disinfection.

**MP300 Contents and Migration-based Risk Assessment of Hazardous Chemicals in Children’s Products**

Y. An, Seoul National University of Science and Technology / Environmental Engineering; S. Chun, FITI Testing & Research Institute; K. Kim, Seoul National University of Science and Technology / Environmental Engineering

As the concerns over exposure to chemicals in products are increasing, there is a need to quantitatively assess the risk of exposure to chemicals in children's products. DEHP, cadmium and boron, which are commonly found in products, have been investigated in educational toy, pencil cases, and slimes. In this study, the contents-based risk assessment was set up as detailed as the migration-based risk assessment in children's products. The contents and migration of DEHP and metals (i.e. cadmium and boron) were analyzed by GC-MS and ICP-OES. Scenario-based exposure assessments were conducted using deterministic methods by ages (range 0-6, 7-12 and 0-12 years). Based on analysis results, the exposure dose and hazard quotient (HQ) were calculated and compared between the contents-based and the migration-based exposure scenario. In educational toy, the HQ of DEHP exceeded 1 in oral exposure at 0-6 years. In slimes, the HQ of boric acid exceeded 1 at oral exposure of 0-6 and 0-12 years. In conclusion, the results were the same for HQ-1 about the product, substance and age group in the content and migration-based risk assessment. Secondly, based on the content-based risk assessment, it was possible to assess the level of migration-based risk assessment. Proper regulation of products to reduce the number of birds used for testing. However, besides being a relevant study for plant protection products with certain chemical properties, the avian short-term dietary study has a feeding regimen that is more representative of how birds forage in the field than does the acute oral study. The dietary study can be an important refinement in a higher tiered ERA. Decision criteria are needed to determine a path forward that accomplishes the goal of reducing vertebrate animal testing but also allows for the use of the avian dietary study in risk refinement. The first goal of this project is to develop such criteria. Second, we will provide recommendations to address the design of avian dietary studies to ensure that the data are optimized to support an acute avian assessment. In addition, we will provide case studies to demonstrate the use of the criteria to decide when a dietary study could be used as a higher-tier refinement and how the study should be designed to support use in standard FIFA and endangered species assessments.

**MP301 A Meta-Analysis of Perfluorooctane Sulfonate (PFOS) Concentrations in Birds Around the World**

R. Flamenco, California State Polytechnic University, Pomona / Biology; A. Bonisoli Alquati, California State Polytechnic University, Pomona / Department of Biological Sciences

Perfluorooctane sulfonate (PFOS) is an emerging contaminant restricted under Annex B of the Stockholm Convention on Persistent Organic Pollutants (POPs). It is carcinogenic and teratogenic. PFOS was shown to bioaccumulate and biomagnify in top predators in marine food webs due to its proteophilic properties, yet no comprehensive analysis exists of variation in its concentrations across species, time and space. This meta-analysis explores variation in the concentration of PFOS across bird species, which are reliable sentinels for monitoring the concentrations of organic contaminants and their associated ecological risk. We collected more than 500 estimates of PFOS concentrations in eggs, liver, and blood from studies of more than 100 different bird species across all continents, to explore temporal, geographic, and taxonomic variation in PFOS concentrations. This allowed us to test which environmental and species-specific characteristics best predict PFOS concentrations in wildlife. Our results demonstrate a > 3.5-fold increase in PFOS concentrations in bird eggs from the 1970s to the 2010s, with the largest increase occurring in the temperate region. Average concentrations were significantly higher in the temperate region than in the polar region in both eggs and liver, but not in blood. Birds from temperate freshwater and marine environments had higher mean concentrations than temperate terrestrial and polar marine ones. These results are consistent with most anthropogenic sources of PFOS being at temperate latitudes. This is expected as high concentrations are found in fish and PFOS biomagnifies in food webs, it would also have much higher concentrations than more remote polar regions. Diet played an important role in explaining PFOS tissue concentrations. Piscivores and opportunists had the highest concentrations among all feeding guilds, while herbivores had the lowest. This study shows a global, widespread temporal increase in the concentrations of PFOS in birds’ tissues, with a few birds reaching liver concentrations that exceed values associated with documented adverse effects. This study will help identify bird groups that are at greater ecological risk from PFOS. Future developments of this study will incorporate information about the life history of the different species while accounting for their shared phylogenetic history to further clarify ecological risk and susceptibility of birds to PFOS contamination.

**MP302 The utility of the avian dietary toxicity test in ecological risk assessment and a path forward for reduction of animal use**

A. Bone, Bayer CropScience / Environmental Safety; L.W. Brewer, Compliance Services International / Department of Wildlife Toxicology; C. Habig, Compliance Services International; S. Levine, Bayer AG / Crop Science Division / Regulatory; D. Moore, Intrinsic Environmental, Inc.; S.R. Mortensen, BASF Corporation; S. Plautz, BASF / The Institute of Environmental and Human Health

There is a long history of the USEPA requiring both avian short-term dietary and acute oral studies to inform avian risk assessment for pesticides. Recently, the USEPA collaborated with People for the Ethical Treatment of Animals (PETA) to determine whether the results of the acute oral avian toxicity test or the short-term dietary toxicity test drove the avian acute ecological risk assessments (ERAs) for pesticides from 1998-2016. Their study concluded that in 99% of the cases, the dietary study did not change the risk conclusions derived using the acute oral study (OPPTS 850.2100, OCSP 850.2100 or similar). Therefore, EPA and PETA suggested waiving the dietary study for most plant protection products to reduce the number of birds used for testing. However, besides the relevant study for plant protection products with certain chemical properties, the avian short-term dietary study has a feeding regimen that is more representative of how birds forage in the field than does the acute oral study. The dietary study can be an important refinement in a higher-tier ERA. Decision criteria are needed to determine a path forward that accomplishes the goal of reducing vertebrate animal testing but also allows for the use of the avian dietary study in risk refinement. The first goal of this project is to develop such criteria. Second, we will provide recommendations to address the design of avian dietary studies to ensure that the data are optimized to support an acute avian assessment. In addition, we will provide case studies to demonstrate the use of the criteria to decide when a dietary study could be used as a higher-tier refinement and how the study should be designed to support use in standard FIFA and endangered species assessments.
The objective of the study was to apply simple air quality assessment techniques in urban sites that can be used as tools in environmental management programs. Two urban areas with vehicular traffic differences in Punta Lara (La Plata, Argentina) were selected as preliminary study sites. The Breezometer Meteoblue software was used as a secondary database of air pollution during the summer of 2019, a randomized temporary sampling of air pollutant concentration data was performed during the period January 1 and March 29. In situ sampling of lichen morphotypes was carried out to apply the Environmental Purity Index (IPA). The IPA index is calculated for each morphological type, such as the sum of the frequency (or coverage) of that morphological type in the total sampled trees. The IPA defines 5 pollution levels (A-E); the lowest index values indicate the highest air pollution. A protocol for taking and recording data was established. Concentrations of pollutants and weather data (temperature, atmospheric pressure, wind chill, direction, velocity, and humidity) were recorded. Data were tested by the Kolmogorov-Smirnov and normalized and the differences between sites were statistically analyzed by MANOVA (XLSTAT). Two wooded areas were selected January 2019 for the calculation of the IPA: area 1 (with a total of 50 trees) 16 presented lichens; and area 2 (with a total of 14 trees) 9 presented lichens. The percentage of lichen coverage was recorded in each tree. A rack (55 cm high x 25 cm wide) subdivided into 20 sub-frames and located at a height above 1.20 m. The frequency and percentage of coverage of different lichen morphotypes (croseo, foliose, fruticulous, and filamentous) was recorded. The IPA was calculated for each morphotype using the data obtained from frequency and coverage. The concentrations of polluting gases (in ppb) were: CO 161 ± 181; NO2 9 ± 4; SO2 1 ± 2 and O3 26 ± 11 (with maximums 1101, 27, 23 and 65 respectively). The concentrations of PM (ug / m3) were 19 ± 9 (P10) and 12 ± 7 (PM 2.5) with maxima of 58 and 63 respectively. The prevailing winds in the evaluated period were 25% from the NO and 27% from the SE. The result of the IPA in area 1 was 14.2 and in area 2 it was 17.8. Result that in both cases indicates a high level of contamination (B). This indicates that the main impact on lichens is mainly due to the effect of fixed sources of pollution and not to mobile sources.

The Breezometer Meteoblue software was used as a secondary database of air pollution during the summer of 2019, a randomized temporary sampling of air pollutant concentration data was performed during the period January 1 and March 29. **Publicly Accessible Data Analytic Tools for Environmental Toxicology, Chemistry, and Risk Assessment**

**MP306 Benchmark dose estimation for event-time data using the statistical software R**

S. Jensen, N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences; F. Khlex; ADAMA Deutschland GmbH; C. Ritz, University of Copenhagen / Department of Nutrition, Exercise and Sports

The benchmark dose (BMD) methodology is a regression-based approach for hazard characterization. It is recommended by several authorities due to its advantages over the no observed adverse effect level approach. However, the methodology is still mainly used for binomial and continuous data, although BMD estimation is also feasible and relevant for other types of endpoints. In particular, there has been no BMD definition for event-time data. We propose a non-mechanistic method for benchmark
dose (BMD) estimation for event-time data. The method combines existing methodology for event-time data analysis and benchmark dose estimation in a two-step approach. Specifically, we will introduce the proposed approach in the context of the existing BMD methodology. We demonstrate the approach through an example from the literature. The method is implemented in the statistical environment and software R in the recently developed extension package **bmd**.

**MP307 Choosing the right version of Positive Matrix Factorization**

*L.A. Rodenburg, Rutgers University / Environmental Sciences*

Positive Matrix Factorization (PMF) has emerged as a useful tool for source identification and apportionment of organic pollutants, including polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins and -furans (PCDD/Fs), brominated diphenyl ethers (BDEs), perfluoro alkyl substances (PFAS), and polycyclic aromatic hydrocarbons (PAHs). PMF has been used to identify the sources of these chemicals in a wide variety of environmental compartments including surface water, sediment, wastewater effluents, organism tissues, atmospheric deposition and air, groundwater, etc. There are several versions of PMF available. The early PMF versions were created by Pentti Paatero and his colleagues. The most widely used of these early versions is PMF2. More recently, the USEPA built upon the original Paatero versions to create their own versions of PMF, the most recent being PMF 5.0. This presentation will compare and contrast PMF2 with PMF 5.0 for use in environmental source apportionment. PMF2 is a DOS program with no graphical user interface (GUI) and is not free. In contrast, PMF 5.0 has a GUI, is a free download, and includes bootstrapping and displacement routines than can be helpful in identifying the optimal number of factors contained in a data set. Despite these advantages, PMF 5.0 has some disadvantages: it often cannot converge on satisfactory model solutions and sometimes suggest a non-optimal number of factors. The differences between the two PMF versions will be illustrated using case studies.

**MP309 Holistic assessment of trophic level sensitives: A big data WOE case study**

*K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; M.G. Barron, US Environmental Protection Agency / Gulf Ecology Division; M.R. Embry, Health and Environmental Sciences Institute (HESI)*

Regulators have been slow to adopt animal alternative assays (AA) into environmental risk assessment frameworks. Large environmental toxicity databases (e.g., EnviroTox, ECOTOX) and analytic tools can be used to develop qualitative weight-of-evidence (WOE) arguments to define when AA approaches may be appropriate. Derivation of a Predicted No Effect Concentration (PNEC) for ecosystems is the primary deterministic form of hazard extrapolation used in environmental risk assessment and it is driven by the most sensitive measured endpoint amongst the standard aquatic toxicity assays (e.g., acute and chronic tests in algae, invertebrates, and fish). These PNEC values, when viewed as probabilistic distributions for groupings of a large number of chemicals, can also be used to derive ecological thresholds for toxicological concern (e.g., TCCs). The fish embryo toxicity (FET) assay has been proposed as an AA assay for the acute fish toxicity assay. However, there is concern that the FET to fish correlation may not be adequately conservative for certain chemical classes or modes of action (MOA), specifically neurotoxicants. The EnviroTox database contains 738 chemicals with full acute datasets (acute and chronic tests for algae, invertebrates, and fish), and the PNECs for ~80% of these chemicals are driven by the sensitivity of algae or invertebrates, not fish. The PNECs for the acetylcholinesterase inhibitors are also driven by algal or invertebrate results (62 chemicals, with only 15% of PNECs driven by fish). In this presentation we will demonstrate how large datasets can be used to develop a WOE argument to support the use of AA. Specifically, we will explore trophic level sensitivities across chemical classes and modes of action in order to understand what factors drive PNEC variation. We will also discuss the importance of MOA and species selection on ultimate PNEC derivation.

**MP310 Protecting human health and the environment by regulating contaminants for the remediation of contaminated sites located in British Columbia, Canada**

*H. Osachoff, BC Ministry of Environment and Climate Change Strategy / Land Remediation Section*

In the province of British Columbia (BC), Canada, science and policy inform regulatory decisions to support contaminated sites remediation. The regulator sets environmental standards to protect human health and the environment, and persons responsible for contamination conduct remediation to meet the numerical or risk-based environmental standards. Recently, BC went through a process of updating 8500 environmental standards in 3 environmental media (soil, water and vapour) for 600+ substances. Standards to protect aquatic life, drinking water, terrestrial receptors, residential land use and more, were updated for current substances, or prescribed for new emerging substances such as poly- and per-fluorinated compounds. Implementation of such large scale standards setting and subsequent lessons learned will be shared for other regulatory policy and decision makers to consider when setting environmental benchmarks for remediation purposes. Additionally, decision makers in the regulatory oversight of BC contaminated sites are faced with different types of information, including factors relating to societal issues, economic implications, and scientific information, which all must be considered under administrative law to remediate contaminated sites appropriately and reasonably. Setting standards for contamination clean-up may also be influenced by these same factors so regulators setting standards balance influences while remaining transparent, defensible and credible. Examples of processes or strategies used to set environmental standards will be discussed including: (1) legislating a 5-year cycle of review to curate the science-based standards via routine maintenance thereby avoiding massive infrequent updates and enhancing business certainty; (2) enabling a 1-year period of transition before updated/new standards come into legal force, again for business certainty; (3) allowing remediation to be completed to the previous standards, and allowing the risk-based assumptions used to derive updated/new standards in detailed risk assessment, up to the coming into force date; (4) developing criteria to establish future standards updating practices (responding to urgency due to latest advancements in emerging contaminants and toxicology); (5) releasing 30 new or updated policy documents concurrent with the coming into force date of the updated/new standards to assist remedial practices with the latest requirements for site investigation and risk assessment.

**MP311 The Risk Assessment in the 21st Century (RISK21) web-tool**

*M.R. Embry, Health and Environmental Sciences Institute (HESI); S.E. Deglin, ILSI Health and Environmental Sciences Institute (HESI)*

The HESI Risk Assessment in the 21st Century (RISK21) project developed an integrated risk assessment framework that enhances efficiency and risk management. The project was initiated to develop a scientific, transparent, and efficient approach to risk assessment, relying on a problem formulation-based, exposure driven, tiered data acquisition. This RISK21 framework allows informed decisions on safety to be made when sufficient evidence is available, and it maximizes the ability to inform decisions and optimize resource usage. The program also developed a web-based tool that allows users to easily graph their risk assessment data and effectively communicate risk-based decisions, whether for a screening and prioritization purpose or a definitive risk assessment. This tool is freely available at www-risk21.org. The utility and uptake of this approach and the web-tool has been demonstrated via several hands-on case study workshops, led by RISK21 team members and hosted or sponsored by various groups, including government agencies. These workshops have engaged participants in real-world case examples, and combined, have already reached over 500 people with direct, hands-on use and application
of the web-tool in the US, China, Taiwan, Brazil, Argentina, and Canada, with additional workshops planned. Although application to-date has focused largely on human health risk assessment, the approach and the associated web-tool are broadly applicable across disciplines for risk assessment, prioritization, communication, and outreach. This presentation will provide a demonstration of the utility of the tool with a focus on applications for ecological risk assessment.

MP312 Using the AOP Wiki for the development of an acetylcholinesterase inhibition adverse outcome pathway

K. Conrow, Y. Garcia-Martín, Arizona State University; N. García-Reyero, US Army Engineer Research and Development Center; K.H. Watanabe, Arizona State University / School of Mathematical and Natural Sciences

Developing user-driven tools used for analyzing systems is of significant benefit to a variety of areas of research due to their wide applicability. Motivated by the push toward big data, these tools can allow access to useful data and models for various purposes, like environmental toxicology and risk assessments. User-driven tools rely on input from the community of researchers to create a wider base of knowledge. The AOP Wiki focuses on the construction of adverse outcome pathways (AOPs). These pathways link key events, which start with a molecular initiating event and result in an adverse outcome at a higher level of biological organization. This poster focuses on the process of contributing to the knowledge base of the AOP Wiki through the development of an AOP for acetylcholinesterase inhibition leading to neurodegeneration. A comprehensive literature review resulted in approximately 200 papers, with the 100 most relevant papers containing data from 12 species. We classified these papers according to their relevance for specific key events, which helped with the composition of appropriate entries and weight-of-evidence for the AOP Wiki. Our work revealed unanticipated benefits and weaknesses in the AOP Wiki in areas such as user-friendliness, scope of data needs for the weight of evidence, re-use of key events from existing AOPs or those being developed, and other practical insights from a new user's perspective. We provide recommendations to improve the accessibility, quality control and standardization of AOP entries and suggest new applications of the AOP Wiki knowledge base.

Life Cycle Assessment - Advancements and Applications

MP313 Life Cycle Assessment of an Aquaponic Food Production System, Identification and Mitigation of Environmental Hotspots

R. Ghamkhar, A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering; F. Wu, Jinan University / School of Environment

There has been a fast increase in global food demand, due to a rapidly increasing world population. Ecosystems have been degraded over time due to unsustainable agricultural practices, such as the overuse of nitrogen and phosphorus fertilizers. It is critical that future innovations in food production be sustainable on a large scale in order to meet growing protein and produce needs. Natural fish production environments are in danger of losing their carrying capacity due to anthropogenic activities, such as overfishing, waste emissions, and ecosystem change. One approach for fish production that minimizes waste and damages to ecosystems is tightening nutrient cycles. Aquaponic food production is considered a prospective solution to reduce the adverse environmental impacts of food production, including nutrient losses and water consumption. In aquaponics, a seafood-producing environment (aquaculture) is integrated with a soilless plant-production environment (hydroponic) with nitrifying bacteria in a symbiotic circulating setup. Combining these systems is anticipated to provide a more environmentally and economically sustainable food production process in comparison to separated aquaculture and agriculture systems. In this work, a comprehensive cradle-to-gate life cycle assessment utilizing multiple environmental impact categories (such as embodied water, and greenhouse gas emissions) is performed on an aquaponic system, which cultivates multiple vegetable species as well as carnivorous hybrid walleye (a native Midwestern fish breed). This provides the opportunity to investigate the environmental impacts of using closed-loop aquaponics compared to open natural systems to meet the increasing global demand for food production in a cold weather environment. Additionally, the main contributors to the system's environmental impacts are recognized. Heat, electricity, equipment, and fish food are contributing to >88% of environmental impacts in all investigated categories. Finally, practical alternatives on using different real-case scenarios (such as effective space heating, possible equipment lifespans, fishmeal-free fish food) are proposed and evaluated.

MP314 Insights from life cycle assessment of nano-silver enabled consumer products

A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering

Silver has been utilized for its antimicrobial properties since antiquity. Nano-scale silver (nAg) with dimensions of less than 100 nanometers (nm) is one of the most commonly used nanoparticles in consumer products due to its antimicrobial efficacy which has been found to be enhanced compared to bulk silver. These products include textiles, food storage containers, sprays, toothpaste, among others, with the goal of providing an antimicrobial characteristic to these products. A major question has been whether the benefits bestowed by the addition of nAg to consumer products outweighs the environmental costs. Life cycle assessment (LCA), a systematic tool for determining the environmental impacts of products and processes throughout their lifetime, has been applied to evaluate the environmental impacts of nAg enabled products. In most instances the additional environmental burden due to the incorporation of nAg is relatively small, however, that is not universally true across all products and environmental impact categories. This work utilizes life cycle assessment to frame the discussion as to the relative environmental costs (or impacts) and benefits (such as antimicrobial efficacy) enabled through the addition of nAg to consumer products, highlighting multiple consumer products. The findings suggest that although the additional environmental impact is often small, in some instances, due to the antimicrobial ineffectiveness of the nAg, the nanoeabling is not worthwhile. This may serve as the starting point for a framework to determine when the benefits of nanoeabling consumer products with nAg outweigh the costs.

MP315 Environmental Impacts of Phosphorus Recovery in Wastewater Treatment

M. Sena, University of Wisconsin, Madison / Civil and Environmental Engineering; M. Seib, Madison Metropolitan Sewerage District; D.R. Noguera, A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering

Wastewater treatment currently focuses on removing phosphorus (P) and nitrogen (N) due to their potential to cause eutrophication in bodies of water. With growing concern for the longevity of global phosphate rock stores, however, there is now interest in recovering these nutrients. One method for recovering P and N is through the precipitation of struvite (magnesium ammonium phosphate) which helps control unwanted precipitation of struvite in pipes and on other surfaces at the treatment plant lessening a challenging maintenance problem, and produces a valuable alternative fertilizer product. A potential concern with this technology is that the environmental impacts struvite recovery creates through the use of additional chemicals and energy are not offset by its benefits. A life cycle assessment (LCA) case study of the full-scale wastewater treatment plant (WWTP) in Madison, WI USA was used to assess the environmental tradeoffs of struvite recovery in wastewater treatment. Results showed that although the WWTP operation with the struvite system had environmental costs in all considered categories, there was improvement in the majority of the categories compared to operation of the plant before the struvite recovery system was implemented. Additionally, the struvite recovery system on its own showed a mix of positive and negative
environmental impacts across different categories. Thus, we conclude that struvite precipitation and recovery has an overall neutral environmental impact offsetting emissions it creates in other areas.

MP316 Global Environmental Footprints of Silver Nanoparticle Synthesis Methods and Industry Based Impact Projections Using Life Cycle Assessment
S. Temizel Sekeryan, University of Wisconsin / Civil and Environmental Engineering; A. Hicks, University of Wisconsin, Madison / Civil and Environmental Engineering
Silver nanoparticles (AgNPs) are well known mainly for their antibacterial, electrical and optical properties, which make them the most commercialized engineered nanomaterials (ENMs). They account for more than 50% of the global nanomaterial consumer products. Their sizes range from 1 nm to 100 nm and control their characteristics. Different synthesis methods are appropriate for different morphologies of AgNPs, therefore specific sizes require different mechanisms for production. The average production amount of AgNPs was approximately 370 tons/year for 2018, and this is expected to reach 800 tons/year by 2025, globally. Although ENMs are small fractions (~1E-06%) of the products by mass, their synthesis method has a high impact on the overall life cycle results of the products they are embedded. AgNPs may be synthesized through chemical, physical and biological techniques. This research performs cradle-to-gate life cycle assessments (LCAs) in order to evaluate global environmental footprints of seven different AgNP synthesis routes along with fifteen different inventories on a mass-based functional unit of 1 kilogram of AgNPs, using SimaPro 8.5.2 Software and TRACI 2.1 Impact Assessment Methodology. Results showed that one of the physical routes, flame spray pyrolysis with melt-spin incorporation method has the highest impacts across almost all potential environmental impact categories. Conversely, one of the most common wet chemistry methods used in the literature, chemical reduction with sodium borohydride is found to be the most environmentally conscious method among others. The LCA results are then combined with both the skeptical and optimistic AgNPs production amounts and global estimations are presented. Additionally, industry-based environmental impacts are projected for industries where AgNPs are mostly used such as textiles; coatings, paints, and pigments; consumer electronics and optics; cosmetics; medical and packaging. Given that each industry requires a specific size range, disaggregated global projections are created per industry. As some methods are more environmentally demanding than others, it is found that the industry-based impacts are not exactly proportional to the industrial shares. Since synthesis methods may affect the overall environmental performance of AgNPs embedded products, it may be worthwhile to shift methods to have more environmentally friendly products and to take a step towards sustainable solutions.

MP317 Life Cycle Hazard Assessment of Advanced Battery Technologies for Grid-Scale Energy Storage
D.B. Mayfield, A.S. Lewis, D.M. Mims, A.L. Dale, Gradient; A.C. Rohr, EPRI
Power-producing utilities are exploring opportunities to expand energy storage capacity, particularly through adoption of advanced battery technologies. As utilities begin to commit to specific battery technologies, there is a need to comprehensively understand potential public health and environmental impacts. This project examined potential risks for two broad categories of batteries (secondary and redox-flow), including lithium ion, lead acid, sodium sulfur, nickel cadmium, nickel metal hydride, vanadium redox-flow, and zinc bromide flow types. We examined possible exposure pathways, key chemicals, and known potential health or environmental risks at each stage of the life cycle, with a focus on lithium ion batteries. For example, the impacts of mineral extraction and refining are generally well known for key metals (e.g., cadmium, nickel, lead) used in battery technologies. However, with the shift to lithium ion and other battery types, the production capacity of minor metals (e.g., cobalt, lithium, vanadium) is expanding globally. Certain extraction processes (e.g., lithium processing from brines) are unique and may require additional study to ascertain any potential occupational or public exposures. Battery manufacturing processes are similarly evolving as new battery compositions are discovered. Accordingly, health and safety implications must be reconsidered as new battery chemistries are advanced. As domestic grid-scale manufacturing facilities develop, additional efforts are needed to generate and evaluate exposure and toxicological data in order to develop workplace safety standards. In-use batteries are not currently anticipated to be a significant source of exposure except in the case of accidents (fires or other physical damage). Disposal and recycling, however, have the potential to create exposure pathways that may affect both public health and the environment. Understanding potential human health and environmental impacts is difficult with current life cycle assessment tools given the lack of available toxicological information on key battery materials. Alternatives assessment may offer a more refined way to assess the comparative toxicity (and data gaps) of chemicals associated with batteries. For all tools to be effective, additional research is needed to understand exposure pathways, exposure concentrations, and chemical hazards associated with developments in grid-scale electric energy storage.

MP318 Reducing the environmental impact of fullerenes using an iterative approach combining life cycle assessment and green chemistry
M. Heidari, E. Lee, A. Ancilii, Michigan State University / Civil and Environmental Engineering
Fullerenes are nanomaterials which are used for energy, medical, water purification, composites and other applications. The material purity depends on the application and for solar cells, it needs to be higher than 99%. Purification has the largest environmental and cost impact in fullerene manufacturing. In this work we compared the environmental, health and cost impact of existing fullerene purification methods and developed an alternative process using an iterative methodology developed by our group. One key concern of nanomaterials is their potential toxicity for humans and the environment. The environmental toxicity of fullerenes without and with various solvents was calculated using Daphnia magna and the results included in the life cycle assessment. We compared chromatography, crystallization and complexion methods for fullerene purification. The complexion was identified as having the lowest environmental, health and cost impact and the use of 3,3',5,5'-Tetramethylbenzidine (TMB) was identified as the main concern in the current process. Fullerene purification using the complexion method was performed with TMB and optimized to maximize the yield for two alternative green solvents. The material and energy inventory were collected during the experiment and used to perform life cycle assessment of all the alternatives. Final results showing the overall reduction in fullerene environmental, health and cost impact obtained by combining experimental work and life cycle assessment using an iterative methodology will be presented.

MP319 Sustainable bioenergy systems: Life cycle assessment of wood pellets and wood logs for residential heating
P. Quinteiro, L.A. Tarelho, University of Aveiro / Centre for Environmental and Marine Studies & Department of Environment and Planning; A.C. Dias, University of Aveiro / Centre for Environmental and Marine Studies & Department of Environment and Planning; A.C. Dias, University of Aveiro / Centre for Environmental and Marine Studies & Department of Environment and Planning; A.C. Dias, University of Aveiro / Centre for Environmental and Marine Studies & Department of Environment and Planning
The use of bioenergy, based on wood feedstock, has been encouraged due to its potential to reduce fossil fuels dependency and greenhouse gas emissions. This study applies life cycle assessment methodology to compare the environmental impacts of three wood-based combustion systems for producing thermal energy for domestic heating: i) a pellets
stove using maritime pine pellets as feedstock; ii) a wood stove using eucalyptus and maritime pine logs as feedstock; and iii) a fireplace using eucalypt and maritime pine logs as feedstock. The functional unit is 1 MJ of thermal energy produced for domestic heating. System boundaries include: (1) forest management from both eucalypt and maritime pine species; (2) pellets and wood logs production; (3) distribution of pellets and wood logs, and; (4) thermal energy conversion, also including ashes disposal in landfill. Inventory data are representative of the current typical technological systems in Portugal. Environmental impacts were calculated for seven impact categories from the ReCiPe 2016 midpoint method: global warming, fossil resources scarcity, terrestrial acidification, freshwater eutrophication, marine eutrophication, ozone formation (human health) and ozone formation (terrestrial ecosystems). From all the heating systems analysed, the fireplace presents the worst performance for all the impact categories with the exception of freshwater eutrophication and marine eutrophication, when maritime pine split logs are burned in the fireplace. For both fireplace systems, the stage of eucalypt and pine split logs combustion for the thermal energy generation is the most relevant to most impact categories (70 to 96 % of the total impacts), with the only exceptions being fossil resources scarcity, freshwater eutrophication and marine eutrophication. Comparing the pellet stove with the wood stove, none of the systems is better than the other, for all the impact categories analysed. Reducing the environmental profile throughout the value chain and improving the energy efficiency of all the systems studied contributes to a more sustainable value chain management.

**MP320 Alternative uses of ornamental flower crop waste for lower environmental impacts**

J. Torres Ortega, University of la Salle / Environmental Engineering; O. Contesto Rubio, University of la Salle / Ingeniería Ambiental y Sanitaria; I. Herrera, CIEMAT / Energy

The growth of biomass residues, associated with impacts and environmental dynamics, promotes the research proposal for an LCA study for a biorefinery focused on the production of high value products. Ornamental flower crop residues have been used to establish the requirements of raw materials, nutrients and operating conditions to obtain from biofuels to other products used in fine chemicals, farceutics and others. A life cycle analysis was developed to know the most relevant aspects in waste management in a crop to be used in a biorefinery. The ornamental culture is found in Cundinamarca (Colombia). The most relevant results are related, on the one hand, with the savings of emissions in the category of impact of global warming and, on the other hand, the effects of the change in the use of the land of the elimination of residues of biomass of the soil and its relevance in the global saving of greenhouse gas emissions.

**MP321 Interaction of dietary nanoparticles with proteins could negatively impact their nutritional and functional properties**

W. Phue, S. George, McGill University / Food Science and Agricultural Chemistry

The nanoparticles used in food interact with biomolecules such as proteins. The interaction of protein and nanoparticles influences the functional and nutritional properties of the proteins. Hence, an in-depth understanding of the mechanism of their interactions becomes critical in addressing the safety of nanomaterials. Food grade and non-food grade particles of silica and titanium (nano- and micro-sized) were interacted with proteins of relevance to digestion and nutrition. Milk proteins such as α-casein, β-casein, α-lactalbumin, β-lactoglobulin, and bovine serum albumin and enzymes such as trypsin, chymotrypsin, pepsin, protease, and lysozyme were studied for their fate after interacting with particles. The changes in the structure and function of proteins when interacted with nanoparticles were studied using spectroscopic, and biochemical assays. Among the particles tested, nanoparticles showed higher interactions with proteins in comparison to micron-scale particles. Silica particles had a higher binding capacity than titania nanoparticles. The secondary structure proteins changed after interacting with nanoparticles which decreased the digestibility of proteins. The protein-particle interaction was not only determined by the physicochemical properties of particles but also the properties of proteins such as isoelectric point, hydrophobicity, and type of amino acid residues. From the above results, it is observed that food grade nanoparticles have a higher binding affinity of proteins with potential negative influence on their nutritional and functional properties.

**MP322 LCA a proposal of public policies of incentives based on a case study**

L.J. Duro, IPN-National University of Lanus / DDPYT; A. Aguilar, National University of Lanus / DDPYT; S.O. Demichels, National University of Lanus / Productive Development and Technology

Every day, society uses and consumes natural resources, expression of a linear vision that leads to the depletion of natural resources, the generation of large amounts of waste, which lead to various problems such as soil, water and air pollution, saturation of disposal sites and waste of resources due to the bad treatment or disposal of these materials. In Argentina, the regulatory framework has a negative impact on the reuse and recirculation of waste. In order to know the causes that generate this problem, a research was developed, based on the inductive method, (from the singular to the general), taking as a case of study a plant of the sanitary ceramics industry, where the generation and the use of waste, public policies, industry incentives, life cycle analysis and circular economy in the territory were analyzed. From the vision proposed by a circular economy process, different opportunities arose for the recirculation of waste, which imply important economic benefits for the company and save unused raw material. The implementation of a management system for the developed practices is conducted through the elaboration of procedures and protocols with normative support. The approach establishes a relationship between three different actors that coincide in the territory, the university, the industry and the municipality, for the use and management of waste, cost reduction, operational benefits, waste reduction for final disposal, and decrease in the consumption of raw materials also related to a lower exploitation of ecosystems to obtain them. Other actors participate with different complementary functions such as financial support, adaptation of infrastructure and strategic knowledge. Distributed benefits are identified on a multiplicity of actors, better waste collection in the territory, cyt - industry, cyt state. From the correct execution of this project, it can be expected that the results will be positive in several aspects, such as the optimization of the economic resources of the industries, a better management of natural resources, which is manifested in a reduction of the waste generated that go towards the sanitary landfill, added to the activities proposed in this work, which bring together different specific results which depends on actors involved.

**MP323 Development of Life Cycle Assessment (LCA) Framework by Incorporating the Point and Nonpoint Sources of Microplastics**

A. Abeynayaka, Tokyo City University / Graduate School of Environmental and Information Studies; S. Karkour, N. Itsubo, Tokyo City University

Aquatic environments are contaminated with microplastic (MP) generated from anthropogenic activities. MP contaminants associated with plastic product life cycles create ecological impacts on aquatic organisms and health risks on human. Lack of solid framework and having plenty of knowledge gaps limits the incorporation of aquatic plastic into plastic product life cycles assessments. MP contaminating aquatic environments mainly divided into point sources and nonpoint (or diffused) sources considering the input location from land to water. Point sources are mainly wastewater treatment plants. Nonpoint sources are distributed over large area of land (such as cities and MP landfills) and difficult to locate the exact contamination point. This study focuses on the point and nonpoint MP contaminants in Japan and Thailand. Between 21 and 42% of global plastic waste is stored in landfills and reached water bodies through leaching. Especially in Asian developing countries, a major contributor of global MP the landfills is spread over the watersheds. In developed countries significant amount of MP are gone through wastewater treatment
Concentration predictions based on ocean numerical models have reported global temporal and spatial distributions of MP. The input to the models was based on the coastal coordinate based grid cells. The MP input quantities were estimated based on the mismanaged plastic wastes, gross domestic product, and future plastic waste in a specific region. However, in this study, we consider the inland point source and non-point source contributions and the stream flow impact using hydrologic models to estimate the MP flow into the ocean (the input into the ocean numerical models). Then a sensitivity analysis was carried out to find the importance of considering point sources, nonpoint sources and the application of hydrologic model for stream pollutant load carrying to the ocean. Considering the MP concentration variations in water, the potential effects related to ecotoxicity and effect on greenhouse gas emissions are discussed with the point of view of incorporating it to the Lifecycle Impact Assessment (LCIA). While the study focus on Asia region, the outcome of the study is applicable for the development of global framework to incorporate MP into LCA.

**MP324 Towards a consequential LCA of the future energy-transport nexus, with special focus on the role of lithium-ion batteries and their recycling**

M. Raugei, Oxford Brookes University; A.R. Hutchinson, Oxford Brookes University / Department of Mechanical Engineering and Mathematical Sciences

Modern societies are currently on the verge of two major interdependent transitions: a steady shift from fossil fuels to renewables as primary energy sources for electricity production, and a gradual replacement of internal combustion engines by electric power trains for transport (including growth in transportation-as-a-service, or TaaS). The increasing penetration of renewable, but inherently intermittent and hence non-dispatchable, energy sources in the grid mix will eventually require various degrees of grid-level energy storage. Lithium-ion batteries (LIBs) are a comparatively mature and reliable technology that can be easily scaled up to meet the requirements posed by grid balancing and buffering. At the same time, LIBs are also key to the growth of the Electric Vehicle (EV) sector, and the combined booming demand for Li, Co, Mn and Ni may pose challenges in terms of raw material availability and raise concerns about the associated ecological toxicity in mining. However, a widespread adoption of EVs would also lead to a corresponding availability of decommissioned battery packs, which opens the path to two potentially effective strategies: the second-life usage of LIBs in grid-connected stationary storage applications, and, eventually, the widespread adoption of LIB recycling schemes, enabling a large throughput of recovered metals to actively reduce the demand for the corresponding virgin raw resources. Our research aims to capture the complex interplay of all these factors by means of a high-level consequential life cycle assessment (CLCA), which sees the co-evolution of LIBs and their recycling as a vital cornerstone to enable both transitions to unfold. We present here a first, thorough attributional LCA (ALCA) of the primary Li, Co, Mn and Ni supply chains, intended as benchmarks against which to gauge the per-functional-unit environmental benefits of recycling, as well as the general layout of the CLCA work that is planned for the next two years.
Endocrine Disruptors, CECs and Agriculture in Developing Countries: The Nexus Bridging Environmental and Human Health

**TP001 Development of a screening method for TR disrupting chemicals by receptor-mimic chromatography**

T. Kudo, S. Yamamoto, Kyoto University / Grad School of Engineering; T. Tanigawa, Chemco Scientific, Co., Ltd.; T. Naito, Kyoto University / Graduate School of Engineering; D. Nakajima, National Institute for Environmental Studies; K. Otsuka, Kyoto University / Graduate School of Engineering

The MIPs showed higher selective retention ability only for TR-active chemicals and other non-active chemicals were rapidly passed through the column. By tuning the LC conditions, the TR-active and non-active chemicals were completely separated from the mixture sample. As results, the newly developed concept will be useful for the screening method of determination of receptor-active compounds. As TR-active chemicals, we employed Triiodothyronine, T3 and Thyroxine, T4. The MIPs were designed and prepared with acetylT4 as a template and 4-vinyl pyridine as a functional monomer. The prepared MIPs were packed into a column and evaluated by LC. In this study, we aim to prepare the adsorbents for thyroid hormone receptor (TR) active compounds, which are paid attention to influences as endocrine disrupting chemicals especially for children. According to the previous studies concerning of binding mechanism to TR, we prepared new molecularly imprinted polymers (MIPs) for the stationary phase in liquid chromatography (LC). We previously reported an estrogen-receptor (ER) mimic adsorbent and a screening of ER active compounds from the environmental water samples. The concept is an applicable procedure for certain receptor-active compounds. To clarify the possibility for use the concept, further appropriate evaluations are needed by the precise design based on molecular recognition mechanism on receptors, and then we can achieve the signals toward the strength of binding to receptors.

**TP002 In vitro assessments of endocrine disruptions of environmental contaminants via diverse receptors of the largemouth bass and the lake sturgeon**

S. Kohno, H.I. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory

Contaminants of emerging concerns have ubiquitously contaminated with both aquatic and terrestrial environments, and their biological effects are problematic in investigations at both field and laboratory. Especially, it is important to evaluate their long-term effects such as non-lethal endocrine problems to assess endocrine activities via nuclear hormone receptors (NRs) in vitro. Moreover, it is important to evaluate the effects of contaminant mixtures via co-existing receptors, since neither contaminant nor receptor exists alone. Here, we report developing NR trans-activation assay in vitro in the largemouth bass (LMB) and the lake sturgeon (LSG) as a model of estrogen receptor subtypes and different NRs, respectively. We characterized three isotypes of the nuclear estrogen receptors (Esr1, 2a, and 2b) using ESR-selective ligands for amniotes. The endogenous estrogen [17β-Estradiol (E2)] and ESR2-selective ligands (DPN and WAY200070) activated the transcriptions via LMB Esr1, whereas ESR1-selective ligand (PPT) did not activate LMB Esr1. All tested ligands activated the transcriptions via both LMB Esr1, 2a and 2b with a difference in the efficacy. These results suggested the importance of Esr subtypes to assess the estrogenicity of environmental samples. Indeed, the estrogenicity of surface water collected from the Maumee River showed a significant difference among LMB Esr subtypes. We also analyzed three NRs, androgen receptor (andr), esr1 and thyroid hormone receptor β (thrb) mRNA in LSG. Gonadal andr mRNA abundance was highest in tested 24 LSG tissues, while esr1 mRNA was higher in gonad and brain inferior lobe than other tissues in LSG. Cerebrum, eye, olfactory bulb, and inferior lobe expressed thrb mRNA more than other tissues of LSG. We revealed distinct tissue distributions of andr, esr1 and thrb mRNA in gonad and inferior lobe from other tissues in LSG. A proportion of these mRNA (andr: esr1: thrb) was 31:68:1 in gonad and 45:32:23 in the inferior lobe of LSG. To assess tissue-specific adverse effects, we will test the trans-activations of contaminants with mimicking these mRNA expression profiles in LSG in vitro. Results with a diversity of receptors and species and mimicking tissue in vitro provide a novel insight in risk and hazardous assessments of contaminants.

**TP003 Long and Short-Term Effects of Nitrate on Fathead Minnow (Pimephales promelas) Embryos and Juveniles**

Nitrate is a ubiquitous global aquatic pollutant, derived from fertilizers, manure, sewage, and industrial processes. Over the past ten years, nitrate has also been shown to be an endocrine disruptor that influences multiple endocrine pathways, including the hypothalamic-pituitary-gonadal axis, thyroid hormone regulation, and glucose regulation and metabolism. However, the outcomes of nitrate exposure can be highly variable, with nitrate being pathway-inductive in some scenario and repressive in others. A recent review of the literature indicated that maturational status and dose/duration of exposure may explain some of the outcome variation. Therefore, we tested the effects of environmentally-relevant nitrate (0, 2, 5, 10, 25, 100 mg/L NO3-N) on fathead minnow juveniles using long-term (2 months) and short-term (4 days) aquatic exposures. We also tested the effects of a wide range of doses (0, 0.08, 0.5, 1, 2, 3, 5, 8, 10, 12, 15, 20, 30, 50, 75, 100, 200, 500 mg/L NO3-N) on fathead minnow embryo development, hatching, and early larval growth. Here, we report effects of nitrate on growth, hormone concentrations (estradiol 17β, testosterone, 11-ketotestosterone, insulin), plasma glucose, and gene expression in juveniles, and mortality, developmental defects, hatching rate, growth, heart rate, and thyroxine concentrations in larvae exposed from fertilization through 16 days post fertilization. These experiments are part of a larger effort to develop coherent nitrate dose-response curves for fathead minnows exposed to nitrate.

**TP004 Occurrence of Growth Promoters in Beef Cattle Operations and their Transport in Runoff from Associated Environments**

J.K. Challis, J. Cantin, University of Saskatchewan / Toxicology Centre; S. Sura, A. Curtis, K. Shade, Agriculture and Agri-Food Canada (AAFC) / Research; J. Giese, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; T.A. McAllister, Agriculture and Agri-Food Canada (AAFC) / Research; P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; F.J. Larney, Agriculture and Agri-Food Canada (AAFC) / Research

Occurrence of the synthetic hormones trenbolone acetate (TBA) and melengestrol acetate (MGA), TBA metabolites 17α-trenbolone (TB), 17β-TB and trenbolone, and beta-adrenergic agonist ractopamine (RAC) were assessed during a 220-day feeding trial. Pen floor manure (feces mixed with pen floor material) was subsequently used in a simulated rainfall experiment to assess the potential transport of these compounds in pen surface runoff. In cattle, TBA is metabolized and excreted primarily as 17α-TB (major) and 17β-TB (minor). Concentrations of the two metabolites measured up to 140 and 15 ng/g in feces and up to 50 and 5 ng/g in manure, respectively. MGA concentrations ranged from ≈10–40 ng/g in feces and manure. TBA and trenbolone were not detected. RAC, administered at high concentrations as a feed additive during the finishing stage before slaughter, was found at levels ranging from 1000–5000 ng/g. A portable rainfall simulator was used to apply water to a 1m2 area within each pen over 20-min rainfall periods. Runoff concentrations of MGA, 17α-TB, 17β-TB, and RAC ranged from 0.8-2.5, 2.0-7.5, 0.1-1.1, and 22-80 ng/L, corresponding to cumulative mass transport of 25, 66, 20, and 700 ng. Groundwater was collected from wells in feedlot alleys during the
Aquatic Toxicity Testing of “Difficult-to-Test” Substances - Meeting the Multi-Faceted Challenge

TP005 Dynamic Changes of Thallium Speciation and Toxicity to Freshwater Algae: Influences of Dissolved Organic Matter
K. Tsai, P. Chen, National Taiwan University / Department of Agricultural Chemistry

Thallium (Tl) is a trace metal widely used as a technology-critical element (TCE) in high technology industry nowadays. Due to its high toxicity to aquatic creatures, it is on the list of USEPA priority pollutants. Dissolved organic matter (DOM) is an important natural matrix in waters affecting metal species and toxicity. Although toxicities of monovalent and trivalent thallium (Tl⁺ and Tl³⁺) to freshwater algae have been investigated, their toxicities remain unclear in the presence of DOM. Besides, given the fact of fast and spontaneous reduction of Tl³⁺ to Tl⁺ (occurs within few hours), it is challenging to elucidate Tl³⁺ toxicity by long-term exposures (>= 72 h) in previous studies. In the present study, we will conduct flow cytometry-based algal bioassays for assessing acute (1-24 h) toxicities of Tl³⁺ and Tl⁺ to Microcystis aeruginosa and Pseudokirchneriella subcapitata in the presence of humic and fulvic acids (HA and FA) in culture medium. Time-course changes of thallium speciation will be monitored and analyzed by the high performance liquid chromatography-inductively coupled plasma-mass spectrometry. The toxicity endpoints including enzyme activity, reactive oxygen species, membrane permeability and potential will be evaluated using appropriate dyes. To characterize the binding of thallium and DOM, the spectra of Fourier transform infrared will also be obtained. The results of this study will provide insightful understanding in the toxicities of Tl³⁺ and Tl⁺ to freshwater algae, particularly with the presence of natural organic matters. The obtained information is also essential on the establishment of regulatory guideline to prevent TCEs contamination in aquatic ecosystems.

TP006 Determination of Persistent Organic Pollutants in Fish Tissues by Accelerated Solvent Extraction and GC-MS/MS
F. Galbiati, Thermo Fisher Scientific; L. Chiesa, G. Labella, R. Pavlovic, F. Arioli, S. Panseri, University of Milan; C. Shevlin, Thermo Fisher Scientific

Polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs) and polychlorinated diphenyl ethers (PBDEs) belong to a broad family of synthetic organic compounds known as halogenated hydrocarbons. The capacity of the halogenated hydrocarbons to bioaccumulate in fatty tissues and biomagnify up the food chain, in combination with their resistance to degradation and their toxicity, make this class of chemicals a serious threat to environmental and human health. Techniques such as Soxhlet and sonication are used for the extraction of halogenated hydrocarbons from food and environmental samples prior to their analytical determination. These techniques are, however, very labor intensive and suffer from high solvent consumption. Accelerated solvent extraction was developed to meet the new requirements of increased throughput and reduced solvent usage in sample preparation. With accelerated solvent extraction, extractions can be completed in very short periods of time and with minimal solvent as compared to conventional sample extraction techniques such as Soxhlet and sonication. Furthermore, interferences may be extracted along with desired analytes during those conventional extraction processes. These unwanted co-extractables can cause build up of nonvolatile materials on the GC injection port and the analytical column resulting in poor analytical results and high instrument maintenance costs. Additionally, challenges remain with high lipid content in which lipophilic pesticides may remain in the fatty layer even after the extraction. Recent advances using accelerated solvent extraction systems, as described in several publications, 1-19 include procedures for selective removal of interferences during sample extraction, thus combining extraction and purification into a single step. The method reported here is applicable for the determination of 29 halogenated hydrocarbons (6 PCBs, 16 OCPs, and 7 PBDEs) in fish tissues. The concentration ranges are 1-100 ng/g for PCBs, 0.5-10 ng/g for PBDEs, and 5-1000 ng/g for OCs.

TP007 The Challenges of Testing a Stereoisomeric Molecule in Support of an Ecological Risk Assessment of an Agrochemical
T. Carro, FMC Agricultural Solutions / Environmental Safety Assessment; J. Stry, J. Malin, L. Kong, FMC Agricultural Solutions

Stereoisomers are molecules that have the same molecular formula and bonded atoms sequence, while differing only in the 3D spatial arrangement of two or more atoms. In the agrochemical industry, a number of registered products and new development compounds contain stereogenic centers in their molecular structure. Ecotoxicity testing for the registration of pesticides requires an assessment of risk to non-target organisms through exposure in multiple matrices (e.g. exposures through diet, water, soil, etc.). When difficult-to-test substances such as stereoisomers are considered for registration, careful review of the proposed study designs are needed to develop a submission package that demonstrates acceptable risk to non-target organisms in the environment. The objective of this project is to develop a science-based approach for risk evaluation of stereoisomers while considering the following principles: 1) minimize, when reasonably possible, additional animal testing with stereoisomers; 2) acknowledge that when stereoisomers are present in an ecotoxicological matrix, they are inherently tested as part of the required regulatory study with the active substance; 3) consider experimental designs and models that thoroughly test stereoisomers without the need to conduct chiral synthesis and/or purifications. Through this project, study design challenges in ecotoxicology are identified, with a focus on issues that arise in specific matrices in routine laboratory study designs. Compound specific physical and chemical properties and behaviors in environmental fate studies are used to develop specific testing procedures with stereoisomeric agrochemicals. Further, a proposal for a tiered approach to the ecological risk evaluation of stereoisomers is introduced to demonstrate a strategy that can be implemented to support acceptable risk to non-target organisms in the environment.

Unraveling Complexity: Characterizing the Toxicity and Risk of Chemical Mixtures in the Environment

TP008 Can we predict synergic effect of chemicals to daphnids based on current knowledge of chemical mechanism of action?
H. Watanabe, R. Abe, National Institute for Environmental Studies / Center for Health and Environmental Risk Research; K. Hiki, H. Yamamoto, National Institute for Environmental Studies / Center for Health and Environmental Risk Research

Even though studies on mixture toxicity of chemicals to aquatic organisms has been increasing in recent years, there is no general answer yet on which chemical combinations might have more than additive toxicity in the environment. Among an infinite number of chemical combinations, one approach is combining substances according to their chemical mechanism of action. Here we investigated several binary mixtures of chemicals using a daphnid (Ceriodaphnia dubia) reproduction test. As chemicals with similar mechanism of action, heavy metals (Cu-Cd, Zn-Cd) and organophosphate insecticide (EPN-BPMC) were expected to follow concentration addition (CA) model, respectively; however, Cu-Cd and EPN-BPMC mixtures demonstrated more than additive toxicity based on isobolograms at 25% and 50% reproduction inhibition. Contraindication drug information also provides possible combination with synergic toxicity. An analgesic antipyretic, acetaminophen and...
antibiotic oxytetracycline were expected to show synergistic effects, but they followed CA model in daphnid reproduction. Antibiotic sulfamethoxazole was co-exposed with trimethoprim, which inhibits tetrahydrofolic synthesis pathway as well as sulfamethoxazole and possibly induce synergistic effects; however, isobolograms indicated less than additive toxicity. Based on chemical metabolism, toxicity of target chemical increases when its metabolizing enzyme is inhibited by other chemical. Polycyclic aromatic hydrocarbons (PAHs) are metabolized by CYP1A1 in vertebrate species, so co-exposure with CYP1A1 inhibitor, α-naphthoflavone (ANF) was expected to cause more than additive toxicity. However, pyrene-ANF and phenanthrene-ANF mixtures demonstrated additive and less-than additive toxicity, respectively. Similarly, isobole exposure of CYP2C9 target drug, ibuprofen and CYP2C9 inhibitor, sulfamethoxazole caused offset effect contrary to our expectation. Present study suggests that mixture toxicity prediction for daphnids based on general knowledge of chemical mechanism of action and metabolism pathway did not work well since most of the accumulative knowledge has been established for vertebrate species. Further understanding of chemical mechanism of action and metabolism pathway in the daphnids will be needed to obtain further insight into the question on which chemicals mixtures might cause synergic effect in the environment.

TP009 Determining the pre-impact biological condition of lakes influenced by a mixture of legacy mining contaminants near Yellowknife, NT

C. Cheney, University of Ottawa / Biology; K. Eccles, University of Toronto Mississauga / Department of Geography; L. Kimpe, J. Korosi, J.M. Blais, University of Ottawa / Biology

Natural resource extraction has supported the development of Canada’s far north, but in some cases, has also resulted in environmental contamination at a regional scale. Ore processing techniques used at mining operations in Yellowknife are responsible for the atmospheric release of approximately 20 000 tonnes of particulate arsenic trioxide, alongside a mixture of other heavy metal(loid)s. There is evidence that the rapid deposition of heavy metals in the surrounding area has caused ecological disturbances to aquatic food webs. This study examines lake sediment cores from 20 lakes within a 40 km radius of Yellowknife. Sediments were dated by 210Pb, 137Cs, and 226Ra, and the risk of a mixture of heavy metal(loids) to aquatic biota was assessed using emerging methods in palaeotoxicty. We found that sedimentary metal(loids) profiles show a peak in contaminant concentration during the height of mining operations, which decreases with distance from the city. Spatio-temporal analysis of lake sediments closest and downwind to the mine showed evidence that geogenic metal(loids) concentrations posed a risk to aquatic biota prior to the onset of mining operations. This risk increased substantially during the operation of gold mines in the region. Recently, the risk of some lakes has decreased. There is a notable positive trajectory towards recovery in the region, however our results indicate that aquatic ecosystems in Yellowknife continue to show lingering risk to aquatic biota despite termination of mining activities almost two decades earlier. <b>TP009</b>

TP010 Reducing Sample Preparation for Fine Particulate Matter Toxicology Studies: Re-suspension Solvent Selection

C. Roger, D. Barrett, Oregon State University / Department of Environmental and Molecular Toxicology; S. Simonich, Oregon State University / Depts of Chemistry and Environmental Molecular Toxicology; R.L. Tanguay, Oregon State University / Sinnhuber Aquatic Research Laboratory and the Environmental Molecular Toxicology

The underlying mechanisms of the well-established health effects from particulate matter exposures have yet to be discovered. Implementation of a model to study the mechanisms that is amenable to high-throughput screening (HTS) is essential due to the variability in human exposures. Zebrafish have been established for HTS as well as for research into particulate matter through developmental exposures. Here we explored various media for re-suspension of particulate matter in zebrafish exposures and assessed the compositional variability in particulate matter based on the re-suspension media used. The particulate matter, standard reference material 1649b (SRM1649b), selected was re-suspended into either DMSO, acetone, or methanol with both whole particle suspensions and the soluble fractions prepared. An aliquot of each preparation was used for chemical analysis of polycyclic aromatic hydrocarbons (PAHs, n=118) using GC-MS. A range of concentrations (0-200 μg/mL) of SRM1649b were tested in 5 day developmental exposures in zebrafish and mortality and morphological/behavioral changes were determined (n=32/treatment). Significant differences were observed between re-suspension solvents in the concentrations of individual compounds and classes of PAHs, with over two-fold differences in total PAH concentrations. Differences between the re-suspension solvents were also observed in behavioral and morphological changes in zebrafish at 5 days post fertilization. This work details the importance of vehicle selection when conducting particulate matter exposures and identifies the potential to select a vehicle that is amenable to both toxicity studies as well as for the initial extraction of particulate matter from a filter, reducing sample preparation and potential chemical losses.

TP011 The Effects of 17α-Ethinylestradiol (EE2) and Hydroxypropyl-β-Cyclodextrin (HPβCD) on the Heart Rate of Embryonic Japanese Medaka (Oryzias latipes)

J.C. Anderson, L. Beyger, Ontario Tech University / Faculty of Science; J. Guchardi, University of Ontario / Faculty of Science; D.A. Holdway, University of Ontario Institute of Technology / Science

Estrogen toxicity has been an area of priority in aquatic toxicology over the last 20 years. Recent evidence has indicated that a rapid, non-genomic, non-classical estrogen signaling pathway exists via the G protein coupled estrogen receptor (GPER). GPER is expressed in many biological systems, with roles in the cardiovascular system and metabolic pathways. The primary objective of this research was to investigate the effect of 17α-ethinylestradiol (EE2) on the heart rate of embryonic Japanese medaka (Oryzias latipes). A 5–20 % decrease in embryonic heart rate was observed in 120 and 144 hour post fertilization medaka embryos exposed to 0.1 ng/L, 1 ng/L, 10 ng/L, 100 ng/L, and 1000 ng/L EE2 (P≤0.05). This effect was attributed to the activation of GPER through the use of GPER and ERα and ERβ agonists and antagonist, highlighting a novel mode of action for EE2 toxicity. The secondary objective was to determine if the presence of the odour suppressant, hydroxypropyl-β-cyclodextrin (HPβCD), could alter the toxicity of EE2. HPβCD is an amphiphilic toroidal compound that can bind non-polar compounds such as fragrances and pharmaceuticals within a central cavity. The combination of EE2 and HPβCD in a 1:4 molar ratio (EE2:HPβCD) resulted in an embryonic heart rate that was significantly greater than EE2 alone at 120 and 144 hours post fertilization (P<0.05). EE2:HPβCD was also not significantly different from the control at 144 hours post fertilization, indicating that HPβCD reduced the effect of EE2 on embryonic heart rate (P>0.05). This research suggests that EE2 can cause a decrease in the heart rate of embryonic Japanese medaka through GPER activation, non-classical estrogen signaling, and this effect can be reduced by the presence of HPβCD.

Approaches for Understanding Diversity in Species Sensitivity to Chemicals

TP012 Standard Species Sensitivity Test on Species with Different Reproductive Strategies

L.M. Jackson, University of Cincinnati / Biology

Fish models are commonly used as indicator and test species contamination in aquatic environments. Although most model fish species are representative of many of the different fish species in the wild, there are still many species that remain underrepresented or unrepresented in environmental toxicology studies. This study aims to use varying reproductive strategies as the determining factor for conducting species sensitivity toxicity tests at different life stages. A comparison of sensitivities of Danio rerio, Pimephales promelas, Gambusia affinis,
and *Heterandria formosa* to the standard reference toxicants of NaCl, KCl, and CuSO4. Twenty-four-hour old fish and larve will be exposed to different concentrations of the reference toxicants as determined by LC50. Details of ongoing experiments and results will be presented at the SETAC National Meeting in Toronto, Canada.

**TP013** The verification of a benthic injury dose-response model for polychlorinated biphenyls

_E. Wirth_, NOAA / OR&R/ARD; _C. Rios_, New York University; _B.S. Shaddrix_, CSS, Inc. / NOAA / National Centers for Coastal Ocean Science; _P.L. Pennington_, NOAA / Office of Response and Restoration; _K. Finkelstein_, NOAA

While industrial inputs of polychlorinated biphenyls (PCBs) have long since ceased, environmental contamination related to PCBs is a continuing issue in coastal ecosystems. PCBs are hydrophobic and accumulate to high levels in sediments. In risk assessment, it is critical that an assessment of injury is measurable, but often these estimates are difficult to determine for benthic organisms. To better understand and predict these injuries, Finkelstein et al. (2017) developed a PCB dose-response benthic injury model based on historical laboratory toxicity data and equilibrium partitioning theory. The objective of this study was to assess whether the model would be appropriate for use in assessing damage to natural resources from exposure to PCBs. New acute aqueous toxicity data were generated and model response was compared. This research will address the application of this benthic injury model across multiple Arcorol mixtures using the same testing conditions and estuarine species. A series of acute, aqueous exposures of PCBs to the grass shrimp *Palaemonetes pugio*, the mysid *Americana bahia*, and the amphipod *Leptochirus plumulosus* will be conducted. It is expected that the validity of this model will be confirmed and that additional comparative toxicity data will decrease the predicted variability associated with using a compilation of literature values.

**TP014** Impact of salinity on the fitness of *Hyalella azteca*

_C. Fulton_, K.E. Huff Hartz, N.W. Fuller, Southern Illinois University, Carbondale / Zoology; _L. Kent_, Southern Illinois University / Zoology; _R.E. Connon_, University of California, Davis / Anatomy, Physiology & Cell Biology / School of Veterinary Medicine; _M.J. Lydy_, Southern Illinois University, Carbondale / Zoology

Global climate change continues to cause alterations in environmental stressors, such as changes in salinity, which are detrimental to aquatic ecosystem health. Furthermore, changes in temperatures and salinity may act synergistically with anthropogenic pollutants and exacerbate pre-existing threats to aquatic biota. This research aims to provide a robust assessment of the effects of the alterations in salinity on the fitness of the epibenthic amphipod *Hyalella azteca*. Full-life cycle bioassays have been conducted with *H. azteca* cultured under three different salinity conditions representing a gradient from freshwater control (0.2 ppt) to increased salinity due to salt-water intrusion (6.0 ppt). A two-fold reduction in the number of offspring produced was recorded in elevated salinity groups relative to control groups, suggesting *H. azteca* reproductive capacity may be diminished in future climate scenarios. Offspring of *H. azteca* cultured under elevated salinities were significantly larger than those from control groups, suggesting a life history modification towards the production of fewer, larger offspring as predicted by life-history theory. Conversely, the analysis of lipid content of *H. azteca* demonstrated no clear effect of salinity owing to high inter-individual variability. This study provides fundamental information about the fitness potential of *H. azteca* in a changing climate. In addition, this study further supports the need to consider the effects of global climate change when conducting risk assessment of contaminants of concern.

**TP015** Combining Omics Technologies and Environmental Epigenetics to Assess The Effects of Harmful Cyanobacteria on Japanese Medaka

_C. Goncalves Athanasio_, Ontario Tech University / Biosciences; _C. Flaherty_, Ontario Tech University; _D. Simmons_, Ontario Tech University / Faculty of Science

Harmful algal blooms (HABs) cause negative impacts on aquatic ecosystems and significant economic losses. HABs occur when populations of algae and cyanobacteria grow too fast, and can produce toxins that threaten drinking water sources, affect aquatic organisms, and the decomposition of the bloom can lead to hypoxic conditions. However, the specific mechanisms behind the toxic effects of harmful algae on fish remain unclear. In addition, little information is known about the potential long-term effects of biological toxins on the health of aquatic animals or on public health. Omics technologies, including proteomics and metabolomics, allow a global view of the molecular processes occurring in an individual, and a better understanding of the complex molecular mechanisms involved in aquatic organisms’ response to environmental pollutants. The analyses of epigenetic modifications combined to omics technologies would open novel possibilities to understand the complexity of the effects and to examine the historical exposure of an organism. Therefore, the goal of this study is to assess the impacts of HABs exposure on fish development and health using a combination of ‘omics and epigenetic approaches. We aim to assess the windows of susceptibility and the long-term effects by performing life cycle assays with the Japanese medaka (*Oryzias latipes*). Information about the effects of HABs on early life stages and physiological development in fish will inform decision makers, allowing them to create policy that will have positive consequences, and help to prevent deleterious effects on freshwater ecosystems.

**TP016** Transgenerational impacts of crude oil exposure on genome-wide gene expression in developing Gulf killifish embryos

_J. Park_, University of California, Davis / Environmental Toxicology; _C.D. Hess_, C.A. Brown, Louisiana State University / Department of Biological Sciences; _F. Galvez_, Louisiana State University / Dept of Biological Sciences; _A. Whitehead_, University of California, Davis / Environmental Toxicology

Growing research demonstrates that biological impacts of environmental toxicants can persist across several generations. One of the toxicants of concern is crude oil, which can originate from natural and anthropogenic causes, and can impact large geographic areas, and affect diverse species in sensitive habitats. Much research has sought to reveal impacts of oil exposure on development and physiology, including its underlying mechanisms. In contrast, relatively little is known of the biological impacts of oil exposure that persist across one or more generations. We characterized the developmental and transgenerational impacts of laboratory weathered crude oil exposure in Gulf killifish (*Fundulus grandis*) using transcriptomic and physiological endpoints. After exposing adult killifish to weathered crude oil and control conditions, we tested whether F1 and F2 descendants of exposed animals had altered gene expression and sensitivity to oil toxicity during embryogenesis. We found that parental oil exposure disrupted developmental gene expression patterns in offspring across multiple generations, and we identified molecular responses that are potentially involved in persistent transgenerational impacts of crude oil exposure.
Emerging Landscape for Toxicity Testing: WET Method Challenges and Refinements to Applied In Vitro Assays for Effluents

TP017 Reducing Acutely Toxic Effluent: Effectiveness of Environmental Monitoring and Compliance Regulations in Ontario
L. Kennedy, Ontario Ministry of the Environment, Conservation and Parks / Aquatic Toxicology Unit; T. Watson-Leung, Ministry of the Environment, Conservation and Parks / Aquatic Toxicology Unit; D.G. Poirier, Ontario Ministry of the Environment, Conservation, and Parks

It was not that long ago that over half of the water being released into the natural environment from many companies in Ontario, Canada would kill organisms exposed to it within a matter of hours or days. In 1987 the provincial government identified the need to control the discharge of toxic and persistent compounds and the Municipal/Industrial Strategy for Abatement (MISA) was implemented. The stated goal was to “stop pollution at its source.” Initially the program was comprised of comprehensive physical, chemical and toxicological monitoring of all discharges (process and cooling water) from almost 200 companies, representing 9 different industrial sectors. After analyzing data from thousands of samples and assisting the industries with identifying “best available technologies economically achievable” (BATEA) for removing toxicants from the effluent streams, the Ministry promulgated a series of Effluent Monitoring/ Effluent Limits Regulations under the Environmental Protection Act, 1990. The MISA program was instrumental in the significant reduction in acutely toxic discharges across all industrial sectors. Testing completed between 1989 and 1991 indicated that as many as 41% of all discharges caused acutely toxic effects. By 2015, this number had declined to 2%. However, the chronic monitoring data indicates that there is still potential for ecological harm. Some industrial sectors are still seeing almost 65% of their effluent samples causing reduced growth or reproduction in exposed organisms when compared to laboratory controls. This poster presents the industry specific acute and chronic toxicity data for over 26,000 samples collected over the past 30 years.

TP018 The Evaluation of Acute and Chronic Effluent Toxity and Permit Compliance Based on Endpoint Selection

Whole effluent toxicity (WET) testing is required for facilities in the United States which discharge treated wastewaters directly to surface waters as a requirement within the Natural Pollutant Discharge Elimination System permit. Both acute and/or chronic toxicity testing with aquatic organisms may be a requirement to determine if the wastewater discharge has the potential to cause an impact on the receiving waterbody. Current test methodologies have been developed and promulgated by a variety of regulatory and stakeholder organizations. Within the United States the specific requirements that result in a test meeting the facilities permit criteria vary from state to state. The most common endpoints utilized for permit compliance include the No Observed Effect Concentration (NOEC), Lowest Observed Effect Concentration (LOEC), median lethal concentration (LC50), and the 25 Percent Inhibition Concentration (IC25) which are generated from hypothesis testing. Additionally, some states have proposed to adopt USEPA’s Test of Significant Toxicity (TST), which evaluates the toxicity of a sample at a single effluent concentration. This review summarizes and discusses multiple case studies where the toxicity of the effluent samples was evaluated using all of the applicable test endpoints.

TP019 Evaluation of state-specific whole effluent toxicity testing implementation guidance and policy to improve whole effluent toxicity testing methods
N. Love, GEI Consultants, Inc.; S. Skigen-Caird, GEI Consultants, Inc. / Ecology; S. Pargee, GEI Consultants, Inc. / Ecological Division

Whole effluent toxicity (WET) testing methods are highly prescriptive when it comes to certain requirements such as test acceptability criteria and test conditions to control test variability and maintain consistency between tests and laboratories. However, there are some areas where WET methods are less prescriptive such as allowing options for different dilution water use, leaving decisions up to the regulatory authority to implement on a statewide-level or permit-by-permit basis. By allowing states flexibility, better decisions can be made to accommodate site-specific conditions that may require modified WET testing conditions. Even with the allowance for flexibility, there are some states who have not specified requirements in guidance or policy, leaving labs and dischargers to interpret the WET methods which can result in variability in WET test outcome. This lack of specific guidance can also lead to inconsistencies in interpretation of results, depending on the individual regulator reviewing the data. This analysis will focus on the different WET guidance and policy documents for a variety of states to evaluate areas where consistency exists, and where it does not or could benefit from enhanced clarity. By better understanding the differences in WET implementation across the country, WET methods could be improved by adding detail to WET method requirements.

TP020 A Whole Effluent Toxicity Conceptual Model - Applications to Causes of Toxicity, Ambient Conditions, and Method Refinements

Publicly-owned treatment works (POTWs) in the United States are required, through the National Pollutant Discharge Elimination System Program, to conduct periodic chronic whole effluent toxicity (WET) testing to determine if discharged effluent would impact aquatic life beneficial uses of the receiving water. As treatment levels and management practices have improved, observations of toxicity to organism survival has largely been replaced by intermittent and low magnitude effects to sublethal test endpoints (e.g., reproduction, growth). Given this trend over time, and in an effort to better focus POTW and regulatory resources on the reasonable protection of beneficial uses in the receiving water, the Central Valley Clean Water Association funded a comprehensive study of toxicity testing data from 66 POTWs in California from January 2011 through March 2017. The study characterized the frequency and magnitude of chronic toxicity, the efficacy of toxicity reduction/toxicity identification evaluations, documentation of potential sources of variability in sublethal test endpoints (e.g., reproduction, growth). This trend over time, and in an effort to better focus POTW and regulatory resources on the reasonable protection of beneficial uses in the receiving water, the Central Valley Clean Water Association funded a comprehensive study of toxicity testing data from 66 POTWs in California from January 2011 through March 2017. TP021 Application of Treatment to Minimize Pathogen Interference in Chronic Toxicity Testing with Ceriodaphnia dubia
B.C. Jorgenson, Pacific EcoRisk; N. Lynch, Pacific EcoRisk / Department of Chemistry; S.L. Clark, Pacific EcoRisk

The presence of pathogens contributing to chronic toxicity to Ceriodaphnia dubia/an efficient sample was investigated in this case study. A wastewater treatment plant effluent consistently demonstrated chronic toxicity to C. dubia/with an accompanying flat concentration response curve. An initial pathogen-focused toxicity identification evaluation (TIE) was performed. A single treatment was then selected for subsequent toxicity testing to be performed side-by-side with the baseline effluent treatment. The selected treatment successfully removed both toxicity and the flat concentration response curve.

TP022 LED light as an alternative to incandescent for Ceriodaphnia dubia culturing
J.L. Bouldin, Arkansas State University / Biological Sciences; R. Cooper, Arkansas State University

Incandescent light sales will be banned by 2020, so alternatives for use in culture organism light/dark cycles need to be investigated. Although they have a slightly higher up-front cost, LED lights last longer, are cheaper to operate over time, and produce less heat than incandescent lights, which is important for maintaining stable culture and test conditions. Over three distinct three-month periods, we tested for a difference in Ceriodaphnia dubia survival and fecundity, as well as neonate performance in reference toxicity tests (NaCl) from culture boards maintained with incandescent or LED lights with comparable light intensity. We compared survival, 14-d average total neonates, number of broods and days to third brood of 8 or more neonates, and number of days to first brood for culture boards. Endpoints for reference toxicity tests included NOEC, LOEC, and control group percent variation. We found no significant differences between any parameters tested, and conclude that LED lights at comparable light intensity are a viable alternative to incandescent for C. dubia cultures.

TP023 Impairment of the teleost stress response persists after weathered oil exposure
M.M. Alloy, M. Cartolano, R. Sundaram, A.X. Plotnikova, E.M. Milton, M. McDonald, RSMAS, University of Miami / Marine Biology and Ecology

Polycyclic aromatic hydrocarbons (PAHs) are a ubiquitous contaminant, closely associated with natural oil seeps, anthropogenic combustion, and oil spills. PAHs have been shown to impair the vertebrate stress response curve. That toadfish stimulated to elicit a stress response showed no significant impairment in mounting that response at the hypothalamic-pituitary level. However, these same individuals with elevated plasma ACTH levels showed significantly reduced plasma cortisol relative to controls. This cortisol response impairment remained after exposure had ceased long enough for CYP1A expression (a marker of PAH exposure) had reduced to levels not significantly different from controls. The amount of cholesterol in the liver and plasma will be determined.

TP024 Imaging of mitochondrial surface area and reactive oxygen species as a toxicity endpoint in the rainbow trout liver cells line, RTL-W1
O. Ulker, Ankara University / Department of Toxicology; J. Anadu, M. Minghetti, Oklahoma State University / Integrative Biology

Multiple endpoint cytotoxicity assays based on fluorescent dyes have been instrumental in advancing our knowledge of chemical mode of toxic action. For instance, Resazurin (the main active ingredient in the alamarBlue dye) has been shown to be a sensitive indirect indicator of cellular metabolic activity. In an attempt to find a more direct indicator of mitochondria toxicity, we have used a combination of commercially available dyes (MitoTracker and MitoSOX) to evaluate if cell imaging could be used as a sensitive toxicity endpoint. In addition, the dye H2DCFDA was used as an additional indicator of oxidative stress. To address this question the fish hepatic cell line RTL-W1 was exposed to AgNO3, CdCl2, azoxystrobin, and paraquat. Dose response curves were generated using a multiple endpoint cytotoxicity assay based on the dyes Alamar blue, CFDA-AM, and Neutral Red, which are indicators of metabolic activity, cell membrane and lysosomal integrity, respectively. Then, cells were exposed to the effective concentrations (EC) EC10, EC25, and EC50, and mitochondrial surface area was measured in cells stained with MitoTracker and MitoSOX. An automatic imaging reader was used to capture all images and measure the total mitochondrial surface area which was subsequently divided by the number of nuclei resulting in the average surface area per cell. Reactive oxygen species (ROS) were measured by fluorimetry in a parallel set of cells exposed to the same conditions but stained with H2DCFDA. RTL-W1 cells showed a reduced mitochondrial surface area after exposure to toxicants, however, the strongest effect was provoked by azoxystrobin, a known mitochondria inhibitor. The H2DCFDA ROS assay proved to be an appropriate tool to detect ROS formation as shown by the H2O2positive control results, which were significantly greater than the control. However, excluding azoxystrobin, which induced a mild reduction in ROS, none of the other chemicals tested were found to induce ROS at a significant level. In summary, these data show that measurement of mitochondria surface area can be used as a sensitive and specific endpoint of mitochondria toxicity.

TP025 The Qol fungicide trifloxystrobin inhibits oxidative respiration and induces deformity in zebrafish (Danio rerio)
C.L. Souder, University of Florida / Physiological Sciences; L. Yang, Institute of Hydrobiology / Chinese Academy of Sciences; T. Huang, Northeast Normal University / State Environmental Protection Key Laboratory of Wetland Ecology and Vegetation Restoration / School of Environment / Northeast Normal University; Y. Zhao, School of Environment / Northeast Normal University; C.J. Martyniuk, University of Florida / Physiological Sciences

Strobilurins (Qol inhibitors) are a relatively new class of agrochemical fungicide first discovered in the wood-rotting mushroom Strobilurus
tenacellus. These chemicals are applied to vegetables and fruits to protect against pathogenic fungi by inhibiting complex III of the electron transport chain. Trifloxystrobin received EPA registration in 1999 and is used in agriculture, and it can enter the aquatic environment, and can adversely affect organisms. However, data are scarce on how propiconazole may affect early developmental life stages. The objectives of this study were to evaluate the potential effects of trifloxystrobin during zebrafish development. Firstly, wildtype zebrafish (ABTu strain) embryos at ~6 hours post fertilization (hpf) were exposed to trifloxystrobin (0.25-2 µM) for 24 hours to evaluate the effects on oxidative respiration. Trifloxystrobin exposure at doses of 0.5 µM and higher induced basal respiration, maximal respiration, oligomycin-induced ATP linked respiration, spare capacity, and non-mitochondrial respiration, indicating compromised mitochondrial bioenergetics in zebrafish embryos. Embryonic exposure to trifloxystrobin (15-120 nM) for 144 h also induced developmental toxicity, most apparent at concentrations above 30 nM. Trifloxystrobin decreased hatch rate and increased malformation rates (pericardium edema and spinal lordosis). Survival rates up to 72 h did not differ among groups, but at 60 and 120 nM, larvae showed 100% mortality with 144 h exposure. A Visual Motor Response (VMR) test was used to measure larval fish exposed to the lowest concentration in the assay (15 and 30 nM), however the results showed no evidence of changes in locomotor activity. This study demonstrates that trifloxystrobin can disrupt mitochondrial bioenergetics in zebrafish embryos, and cause developmental toxicity at environmental relevant concentrations. Therefore, the potential risk of trifloxystrobin to aquatic organisms needs further attention.

TP026 Sub-lethal effects of propiconazole on zebrafish (Danio rerio) development, oxidative respiration, and larval locomotor activity

C.J. Souders, University of Florida / Physiological Sciences; P. Xavier, University of Florida / Department of Physiological Sciences / College of Veterinary Medicine; V. Perez-Rodrigues, U Florida / Physiological Sciences; N. Ector, U Florida; J. Zhang, U Florida / Henan Open Laboratory of Key Subjects of Environmental and Animal Products Safety / Henan University of Science and Technology; C.J. Martyniuk, University of Florida / Physiological Sciences

Propiconazole is a triazole fungicide used in agriculture. Via run-off, it can enter the aquatic environment, and can adversely affect organisms. However, data are scarce on how propiconazole may affect early developmental life stages of fish. The objectives of this study were to evaluate the potential sub-lethal effects of propiconazole during zebrafish development. Wildtype zebrafish (AB strain) embryos and larvae were exposed to propiconazole (0.1-100 µM) for up to 150 hours post fertilization (hpf) depending upon the endpoint measured. Propiconazole decreased survival and induced hypopigmentation in fish at 100 µM compared to the water and solvent controls. Pericardial edema was also noted in embryos and larvae (beginning at 2-3 dpf) exposed to 100 µM propiconazole. To visualize the effects of propiconazole on the circulatory system in more detail, we exposed transgenic zebrafish (globin-LCR:eGFP) to the fungicide. Hematopoietic changes were observed within 48 hours of exposure to 100 µM, and blood cells became diffuse, indicating pooling of blood in the pericardial region. We measured oxidative respiration in embryos as sufficient ATP is needed for development. Exposure to 100 µM propiconazole (~6-30 hpf) reduced basal respiration (~50%), oligomycin-induced ATP linked respiration (~70%), proton leak (~30%), and non-mitochondrial respiration (~50%), indicating compromised mitochondrial bioenergetics. A Visual Motor Response (VMR) test was used to measure larval fish exposed to propiconazole for a 6-day period and larval fish exposed to the highest concentration in the assay (10 µM) showed evidence of hypoactivity. This study demonstrates that propiconazole can induce hypopigmentation in zebrafish, disrupts mitochondrial bioenergetics, and alters locomotor activity. However, these sub-lethal responses were observed at concentrations above what is typically detected in the environment.

TP027 Mitochondrial dysfunction and gliotoxicity: Novel mechanisms of neuroendocrine disruption

C.L. Souders, University of Florida / Physiological Sciences; C. Wei, University of Florida / Department of Physiological Sciences / College of Veterinary Medicine; J. Schmidt, University of Florida / Physiological Sciences; D. Da Fonte, L. Xing, V. Trudeau, University of Ottawa / Biology; C.J. Martyniuk, University of Florida / Physiological Sciences

Mechanisms of neuroendocrine disruption can be many, and include neurohormone receptor agonism/antagonism, inhibition of neuropeptide synthesis/processing, and mitochondrial dysfunction. Radial glia (RGCs) are primary progenitor cells in the central nervous system that are capable of generating neurons and astrocytes. These cells are also the major cell type synthesizing neuroestrogens in fish, and the teleost brain has a high capacity to express aromatase which allows for remarkable neuroplasticity observed with teleosts. As neuroendocrine cells require ATP to synthesize, package, and release neuropeptides, we hypothesize that chemicals in the environment can act to impair mitochondrial bioenergetics of glial cells in the central nervous system. To test this, we isolated a mixed sex population of radial glial cells from goldfish (Carassius auratus) whole brain and measured metabolic function of the cells following a 24 hour exposure to fluazinam, a broad spectrum fungicide. Using immunohistochemistry and real-time PCR for glia and neuron-specific markers, we demonstrate that the radial glial culture was more than 95% pure, and that cells that expressed glial fibrillary acidic protein (GFAP) (i.e., RGCs) were significantly enriched in the culture compared to those synthesizing the neuronal markers myelin basic protein and growth associated protein 43, which were close to non-detectable in real-time PCR assays. Following a 24 hours exposure to three different doses of fluazinam, a mitochondrial stress test using the Seahorse XF24 Extracellular Flux Analyzer was conducted to assess metabolic function of the RGCs. Reduced maximum respiration and spare capacity of RGCs were observed compared to the control group with 25μM Fluazinam. Thus, fluazinam significantly decreased bioenergetics capacity of these neuroestrogen-producing cells. These studies demonstrate that the bioenergetics of RGCs are sensitive to environmental contaminants, and further studies are required to determine if such disruptions lead to functional impairment of the cells in vitro and in vivo.

TP028 Constructing Adverse Outcome Pathway Networks for Mitochondrial Dysfunction

D.A. Dreier, Syngenta Crop Protection, LLC / Environmental Safety; D.F. Mello, J.N. Meyer, Duke University / Nicholas School of the Environment; C.J. Martyniuk, University of Florida / Physiological Sciences

Mitochondria are key targets of many environmental contaminants, as specific chemicals can interact directly with mitochondrial proteins, lipids, and ribonucleic acids. These direct interactions serve as molecular initiating events (MIEs) that impede ATP production and other critical functions that mitochondria serve within the cell (e.g., calcium and metal homeostasis, apoptosis, immune signaling, redox balance). A limited but growing number of adverse outcome pathways (AOPs) have been proposed to associate mitochondrial dysfunction with effects at organismal and population levels. These pathways involve key events (KEs), such as altered membrane potential, mitochondrial fission/fusion, and mtDNA damage, among others. To illustrate the current state of the science for AOPs involving mitochondria (mtAOPs), we identified AOPs involving KEs for various hallmarks of mitochondrial dysfunction from the AOPWiki. Furthermore, we used these pathways to build an exploratory mtAOP network and identify the localization of mitochondrial KEs. Among 224 AOPs in the wiki, 29 included KEs related to mitochondrial dysfunction. In the mtAOP network, there were several cases where KEs for some form of mitochondrial interference or dysfunction also represented a MIE (e.g., KE 1260 “Direct mitochondrial inhibition”; KE 1446 “Increase, Uncoupling of oxidative phosphorylation”; KE 1481 “Inhibition of mitochondrial DNA polymerase gamma”), thus signifying direct mitochondrial toxicity. However, in most of the current mitochondrial AOPs, mitochondrial dysfunction was an intermediate KE linked...
to both upstream and downstream KEs. For example, KE 40 “Decrease, Mitochondrial ATP production” was a network hub associated with numerous pathways. In addition, the network was used to identify potential downstream consequences of mitochondrial dysfunction, including adverse outcomes for “parkinsonian motor deficits,” “growth inhibition,” “kidney toxicity,” “mortality,” and “reproduction decline.” Taken together, this organization indicates that the current state of knowledge identifies mitochondria as involved with multiple AOPs, primarily as an intermediate KE. Given the wide range of chemicals that affect mitochondria, and the centrality of energy production and signaling to ecologically important outcomes such as pathogen defense, homeostasis, growth, and reproduction, mitochondrial AOPs are expected to play a significant, if not central, role in environmental toxicology.

Canadian Oil Sands Part 1: Advances in Chemical Characterization, Reclamation and Monitoring Research

TP029 Analysis of Halogenated Polycyclic Aromatic Hydrocarbons in Sediment from the Alberta Oil Sands Region

With the third largest oil reserve in the world, the production of oil is a huge source of economic growth and development in Canada. The concern stemming from the industrial activity in the oil sands is that polycyclic aromatic compounds (PACs) will be deposited from the atmosphere and into lake ecosystems where they persist long after. Previously, halogenated polycyclic aromatic hydrocarbons (HPAHs) have been detected from the biological organisms from the Alberta oil sands region (AOSR). This study focused specifically on identifying HPAHs in lake sediments from AOSR. Our approach was to use one-step accelerated solvent extraction (ASE) for sample preparation and analysis by gas chromatography coupled with high-resolution time-of-flight mass spectrometry (GC-HRTOF-MS) for the identification and quantification of HPAHs.

TP030 Evaporative Emissions of Polycyclic Aromatic Compounds from Alberta’s Oil Sands Tailings Ponds Water

R. Robitaille, University of Toronto / Earth Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences; S. Bernstein, University of Toronto; A. Abdollahi, Trent University / Department of Chemistry; T. Harner, Environment and Climate Change Canada / Air Quality Research Division; A. Eng, Environment and Climate Change Canada / Atmospheric Science & Technology Directorate; H. Hung, Environment and Climate Change Canada / Air Quality Processes Research Section; M. Moradi, Environment Climate Change Canada; J. Parnis, D. Mackay, Trent University / Chemistry; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences

Polycyclic aromatic compounds (PACs) are semi volatile organic compounds emitted from Alberta’s oil sands tailing ponds (OSTPs). Their toxic effects via exposure and their ubiquity in our environment classify them as priority compounds for monitoring. These open-air OSTPs are known plume of OSPW-affected groundwater confirmed their diagnostic abilities. A secondary objective was to assess anthropogenic derived artificial sweeteners and per- and polyfluoroalkyl substances (PFASs) as potential tracers for OSPW. Despite the discovery of acylsulfane and PFAS in most OSPW samples, trace levels in groundwaters influenced by the Alberta McMurray bitumen background in groundwaters influenced by the Alberta McMurray formation. Improved sampling methods and quantitative analyses of two groups of mono-aromatic acids (Family A and B) were employed to analyze OSPW and bitumen-affected natural groundwaters for source discrimination. Both groups of mono-aromatic acids showed significant enrichment in OSPW, while ratios of O2-O4 containing heteroatomic ion classes of acid extractable organics (AEOs) did not exhibit diagnostic differences. Evaluating the mono-aromatic acids to track a known plume of OSPW-affected groundwater confirmed their diagnostic abilities. A secondary objective was to assess anthropogenic derived artificial sweeteners and per- and polyfluoroalkyl substances (PFASs) as potential tracers for OSPW. Despite the discovery of acylsulfane and PFAS in most OSPW samples, trace levels in groundwaters influenced by general anthropogenic activities preclude them as individual robust tracers. However, their inclusion with the other metrics employed in this study served to augment the tiered, weight of evidence methodology developed. This methodology was then used to confirm earlier findings of OSPW migrations into groundwater adjacent to the reclaimed pond at Tar Island Dyke, and reaching the Athabasca River system.

TP034 The Treatment of Oil Sands Process-Affected Water with the Kearl Treatment Wetland

A. Cancelli, Simon Fraser University / Resource and Environmental Management; F. Gobas, Simon Fraser University / Resource & Environmental Management; A. Bekele, Imperial Oil

Large volumes of oil sands process-affected water (OSPW) have been generated through mining operations and bitumen extraction in the atmosphere, allowing us to better understand their emissions and fate from oil producing locations. To do so, water samples taken from different OSTPs in the summers of 2016 and 2017 were analyzed for polycyclic aromatic hydrocarbons (PAHs) and alkylated-PAHs, and were screened for nitro and oxy-PAHs. An equilibrium chamber study was then devised to more appropriately determine the air-OSTP water partition coefficients for PACs. This chamber study setup used thin-film polymer-coated glass beads as passive samplers for fugacity measurements of PACs in air and water. We will be presenting the levels of PACs found in OSTP waters as well as the results of the chamber experiment using the complex mixture of OSTP waters. Furthermore, the newly determined partition coefficient values will be used to estimate the net emissions of PACs from Alberta’s OSTPs.
Canadian oil sands. While the industry has successfully reduced water requirements, treatment technologies are still needed to reduce the ecological footprint from bitumen extraction and mitigate the risks of OSPW in tailings ponds. Ongoing efforts have identified treatment wetlands as one viable technology with the potential to improve water quality of OSPW, which is currently subject to a zero-discharge policy. We have investigated the removal efficiency of a range of organic contaminants present in OSPW in a constructed treatment wetland at Imperial’s Kearl Oil Sands site. Polyethylene (PES) and polar organic chemical integrated samplers (POCIS) were used to measure freely dissolved concentrations of polycyclic aromatic hydrocarbons (PAHs) and naphthenic acids (NAs) in the OSPW within the wetland, respectively. In 2017, PES were deployed in the inlet and outlet of the KTW for two deployments (Jul. 21 - Aug. 29, and Aug. 29 - Sept. 29). In 2018, both PES and POCIS were deployed to measure changes to both PAH and NA freely dissolved water concentrations. The results show statistically significant (p < 0.05) reductions in dissolved concentration of PAHs as a result of wetland treatment during both 2017 deployments. The first deployment measured a mean reduction in concentration of 75.4% (SD 18.2%), and 82.4% for the concentration of S(19PAHs). The second deployment measured a mean reduction in concentration of 36.7% (SD 30.2%), and 57.0% for the concentration of S(25PAHs). The results from the 2018 investigations demonstrate the capacity for the Kearl Treatment Wetland to reduce concentrations of PAHs and NAs in OSPW. Higher concentration reductions were observed for NAs that are fully hydrogenated compared to their ionized counterparts within the same carbon group. Concentrations of SPAHs and SNAs declined 67% and 54%, respectively, over 28 days in the KTW. Our data indicate that treatment wetlands may be an effective tool to help treat OSPW. Using this empirical data, we have developed an environmental model that can be used to evaluate the fate of organic contaminants in treatment wetlands with the goal to evaluate the feasibility of these systems for specific wastewater challenges. The model also demonstrates the roles of different biogeochemical removal mechanisms of pollutants in the wetlands.

TP035 Fish Health in the Alberta Peace River Oil Sands Area
M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate, Aquatic Contaminants Research Division; G. Tetreault, M. Evans, Environment and Climate Change Canada / Water, Science and Technology Directorate; T. Clark, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants and Research Division; E. Ussery, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.G. Wynia, Environment and Climate Change Canada / Aquatic Contaminants Research Division
As part of the Canada-Alberta Oil Sands Monitoring Program (OSM), fish health within the Athabasca and Peace River watersheds was evaluated using methods developed for the Canadian Environmental Effects Monitoring program. Baseline fish health was assessed in both watersheds by collecting data over a three year period. Baseline data was evaluated for existing differences in fish health between sites sampled within each watershed and reference site variability was assessed in order to help make decisions when differences exist. The Athabasca River data has been assessed previously and this presentation will describe fish data from the Peace River collected from 2015-2017. Measurement endpoints include indicators of growth, reproduction and survival as well as indicators of fish exposure and contaminant levels. Data will provide a baseline against which future changes in fish populations will be judged and compared to. Information will be used to develop site-specific cumulative effects monitoring approaches and will contribute to the development of better predictive capabilities for oil sands environmental impact predictions. On the Peace River mainstem, longnose sucker have been selected as a large bodied sentinel species and trout perch as a small bodied sentinel species. Walleye are also being used for fish contaminant monitoring within the mainstem as they are consumed by resident populations. Design of the program is to look for effects, to confirm those effects, then to use developed critical effect sizes to make decisions on steps forward depending on the source of the change.

TP036 Laser ablation of White Sucker opercula to differentiate migratory and residency exposure to bitumen-derived chemicals from the Athabasca Watershed
T. Clark, Environment and Climate Change Canada / Water Science and Technology Directorate; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; K.R. Munkittrick, Wilfrid Laurier University / Biology
The Athabasca oil sands deposit, situated in the Lower Athabasca Region (LAR) of northern Alberta, Canada contains the province’s largest of 4 bitumen deposits, encompassing more than 42,000km². One major challenge in the LAR pertains to the differentiation between natural versus anthropogenic sources of potentially deleterious bitumen-derived substances. Over the last decade, the Canadian and Alberta governments have collaboratively developed and established a long-term Oil Sands Monitoring (OSM) Plan, with consideration of environmental concerns attributed to the potential impacts of oil sands surface mining operations on the Athabasca River watershed. The Athabasca River and its tributaries, as well as the Peace-Athabasca Delta and Lake Athabasca, are home to various large bodied migratory fish species. Many of these fish species are known to overwinter in Lake Athabasca and migrate up the Athabasca River to spawn and then reside for the duration of the open water months. With the potential for elevated inputs and concentrations of potentially toxic chemicals in the LAR aquatic receiving environment associated with increased oil sands development, pinpointing these sources is of primary interest. A component of OSM has investigated large bodied fish health since 2011, with White Sucker (Catosostomus commersoni) serving as the sentinel species due to its close interaction with the littoral zone. The five investigated LAR sites were chosen based on their proximity to industrial activities (upstream and downstream), as well as their proximity to the McMurray oil sands formation. One major challenge associated with assessing large bodied fish health at these designated sites has been the uncertainty of identifying exposure sites due to fish migration. As such, this study aims to utilize the opercula from White Sucker that were collected from each of the five LAR sites since 2011 to reconstruct residency, migration and fish life history. Laser ablation (LA-ICPMS) of the opercula will allow for quantification of elemental compositions found within growth annuli, which will then be used to differentiate between fish residencies and migrations.

TP037 Histopathological investigation of lake chub in a tributary adjacent to Athabasca oil sands activity
J. Cunningham, Environment and Climate Change Canada / Aquatic Contaminants and Research Division; E. Ussery, Environment and Climate Change Canada / Biological Sciences; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate, Aquatic Contaminants Research Division
The Athabasca River, which is a tributary to the Peace River, is adjacent to Athabasca oil sands activity in Northern Alberta, Canada. The Peace River is known for its polycyclic aromatic hydrocarbons (PAHs). Naturally occurring exposed bitumen beds combined with Oil Sands industry expansion, and associated surface mining activity in the region, contribute to PAH richness in the environment. Central to the industry expansion in the oil sands region is the Athabasca River. Numerous oil companies mine adjacent land for naturally occurring bitumen as well as utilize its waters in the petroleum extraction process. As a result, resident fish in the Athabasca and its tributaries may be exposed to either naturally occurring sources of bitumen or anthropogenically refined sources extracted through surface mining. Monitoring programs were developed ten years ago by both the Canadian and Alberta governments to investigate fish health in the lower Athabasca River and its tributaries. One such tributary is the Ells river located depending on the source of the change.
approximately 60 km north-east of Fort McMurray. The Ells serves as the predominant drinking water source for the First Nations community of Fort McKay, as well as representing an important food gathering location. As such, the health and productivity of this tributary is of high importance. Previous studies have reported a myriad of health effects in fish exposed to PAHs including altered visual acuity and reproductive effects. This study employs a histopathological examination of the effects of PAH exposure (both natural and anthropogenic) on various tissues of adult lake chub (*Couesius plumbeus*) at two sites in the Ells River. These sites were chosen to represent (a) naturally occurring PAH exposure from exposed bitumen beds as well as (b) a site more heavily impacted by anthropogenic activity. At each site, 20M and 20F wild fish were collected, euthanized and Gill, gonad, intestine, kidney and eye were all extracted and preserved for subsequent histological analysis. Tissues were embedded and slides were created and stained with Hematoxylin/Eosin for examination and comparison between sites. This work contributes to a larger, multi year, wild fish health monitoring program on the lower Athabasca River and its tributaries.

TP038 Characterization and Biodegradation of Oily Sludge using GCxGC TOFMS and its Toxicity Analysis using Triticum aestivum

P. Chand, Indian Institute of Technology Bombay / Center for Environmental Science and Engineering; S. Dutta, S. Mukherji, Indian Institute of Technology Bombay

Petrochemical industries produce large amounts of solid and liquid waste. Among the solid wastes, oily sludge is accumulated at the bottom of the crude oil storage tanks in oil refineries. Oily sludge cannot be directly dumped without any pre-treatment as it is highly toxic, mutagenic, and carcinogenic in nature therefore classified as priority environmental pollutants by the USEPA. The objective of this study was to characterize the oil and solids associated with the sludge and to test the feasibility of slurry phase biodegradation in presence and absence of coco-peat powder as an immobilizing agent, using indigenous microbes associated with the sludge. The oily sludge was found to contain 19-22% heavy oil when extracted using soxhlet extraction. The oil extract was further separated using column chromatography and was characterized in GCxGC TOFMS in 2D mode for aliphatic, aromatic and polar fraction. The individual fractions were processed using ChromaTOF software and the compounds were identified using their characteristic mass to charge ratio. The biodegradation studies were conducted in batch mode in mineral medium where residual oil was estimated using liquid-liquid extraction followed by column chromatography. The study was performed for a duration of 60 days where total petroleum hydrocarbon, maltene, asphaltene and CFU counts were measured periodically. It was found that the indigenous bacteria could degrade the oily sludge, where 49% degradation was seen in presence of coco-peat powder, where 76.1% removal of maltene and 8.3% asphaltene removal was observed. Biodegradation in absence of coco-peat powder was limited to only 36%, where 44.8% removal of maltene was seen while asphaltene removal was only 6.6%. The componentwise biodegradation of oily sludge were also compared using GCxGC TOFMS in 1D mode where n-alkanes ranging from pentadecane to Pentatriacontane and cycloalkanes ranging from Nonylcyclohexane to Octadecyclohexane were compared. It was observed that aliphatic fraction was highly biodegradable compared to other fraction whereas asphaltene fraction was least biodegradable because of their highly complex and large molecular structure. Phytotoxicity of oily sludge was also determined using *Triticum aestivum* where the plants were grown in pots at various concentrations (0-100%) and the root and shoot length were measured along with chlorophyll concentration, the IC50 was calculated using hill and was found to be 24.5%.

Canadian Oil Sands Part 2: Recent Advances in Toxicological Characterization of Oil Sands and Dilbit Chemicals

TP039 Ambient Concentrations and Total Deposition of Inorganic Sulfur, Inorganic Nitrogen and Base Cations in the Athabasca Oil Sands Region

E. Edgerton, ARA, Inc.

Trace gas, particulate matter and deposition data collected in the Athabasca Oil Sands Region (AOSR) from 2000-2017 were evaluated as part of a broad scientific programmatic review. Results showed significant spatial patterns and temporal trends across the region. Concentrations of reactive gases were highest near the center of surface oil sands production operations and decreased towards the edges of the monitoring domain by factors of 8, 20, 4 and 3 for sulphur dioxide (SO2), nitrogen dioxide (NO2), nitric acid (HNO3) and ammonia (NH3), respectively. 18 of 30 sites showed statistically significant ($p<0.05$) negative trends in SO2 concentrations suggesting an $\sim$40% decrease since 2000. In contrast, only 2 of 30 sites showed statistically significant temporal trends (1 positive, 1 negative) for NO2. NH3 data showed (i) marked and varied wildfire impacts, and (ii) exhibited very high seasonality, with low concentrations during winter and significantly higher values during the summer. Particulate matter (PM10) measurements were more limited, but also showed significant spatio-temporal variability. Comparison of PM10 and PM2.5 data showed that >80% of sulphate (SO42-) was in the PM2.5 fraction, while >60% of calcium (Ca2+), magnesium (Mg2+), sodium (Na+) and chloride (Cl-) were in the PM10-2.5 fraction. Ion balances of both PM10 and PM2.5 contained cation excesses at near-field oil sand sites, but PM2.5 samples at forest health sites >20km from surface production locations contained anion excesses. Monthly average concentrations of PM10 ions showed peak Ca2+ during March-April to November, but peak SO42-, NIH4+ and nitrate (NO3-) from November-March. Deposition estimates showed rapid declines as a function of distance to oil sand operations. Estimated total nitrogen (N) and total sulphur (S) deposition to forest health monitoring sites ranged from 2.0-5.7 kg ha-1a-1 and 2.1-14.0 kg ha-1a-1, respectively. Potential acid input (PAI) ranged from 0.46-0.79 keq ha-1a-1 and was mostly 0.1-0.2 keq ha-1a-1 throughout the domain, except for two clusters of sites near the center of oil sand operations.

TP040 The Impact of Atmospheric Acid Deposition on Tree Growth and Forest Understory Vegetation in the Athabasca Oil Sands Region

D. McIsaac, WBEA

Atmospheric acid deposition is of major concern in the Athabasca Oil Sands Region (AOSR) in northern Alberta, Canada, which is home to the third largest oil reserve in the world. After decades of oil sands production in the AOSR, the potential impact of deposition on forest health, including tree growth and understory biodiversity is still not clear. We evaluated the relationship of modelled atmospheric deposition of nitrogen (N), sulphur (S), base cations (BC), and derived potential acid inputs (PAI) from surface oil sands mining with: (1) the radial growth (i.e. basal area increment; BAI) of jack pine (*Pinus banksiana* Lamb.) trees using data from two decadal time periods, prior to (1957-1966) and during active oil sands development (2001-2010) in the AOSR; and (2) forest understory vegetation (abundance, diversity, and composition), which is an important component of forest biodiversity. BAI of jack pine trees varied with N, S, and BC deposition between the two time periods, and with site location relative to main emission sources. Growth was higher in areas close to the oil sands surface mining operations prior to and after oil sands development. This relationship held for the recent period with BAI positively related to atmospheric deposition, but the slope of this relationship was similar or slightly lower in the active period versus the non-active period. Understory vegetation; including vascular plant cover, richness, and diversity increased in relation to modelled atmospheric N and S deposition. There was limited correlation between soil pH or the BC:Al ratio (indicators of soil acidification) and BAI and understory vegetation.

Sulfur, Inorganic Nitrogen and Base Cations in the Athabasca Oil Sands Region

E. Edgerton, ARA, Inc.

Trace gas, particulate matter and deposition data collected in the Athabasca Oil Sands Region (AOSR) from 2000-2017 were evaluated as part of a broad scientific programmatic review. Results showed significant spatial patterns and temporal trends across the region. Concentrations of reactive gases were highest near the center of surface oil sands production operations and decreased towards the edges of the monitoring domain by factors of 8, 20, 4 and 3 for sulphur dioxide (SO2), nitrogen dioxide (NO2), nitric acid (HNO3) and ammonia (NH3), respectively. 18 of 30 sites showed statistically significant ($p<0.05$) negative trends in SO2 concentrations suggesting an $\sim$40% decrease since 2000. TP041 Epiphytic Lichen and Novel Geostatistical Approach to Evaluate Spatial and Temporal Changes in Atmospheric Deposition in Athabasca Oil Sands Region

**M. Landis, Integrated Atmospheric Solutions**

Temporal and spatial atmospheric deposition trends of elements to the boreal forest surrounding bitumen production operations in the Athabasca Oil Sands Region (AOSR), Alberta, Canada were investigated as part of a long-term lichen bioindicator study. The study focused on eight elements (sulfur, nitrogen, aluminum, calcium, iron, nickel, strontium, vanadium) that were previously identified as tracers for the major oil sand production sources. Samples of the in situ epiphytic lichen Hypogymnia physodes were collected in 2002, 2004, 2008, 2011, 2014, and 2017 within a ~150 km radius from the center of surface oil sand production operations in the AOSR. Site-specific time series analysis conducted at eight jack pine upland sites that were repeatedly sampled generally showed significant trends of increasing lichen concentrations for fugitive dust linked elements, particularly at near-field.

TP042 Effects of diluted bitumen exposure on repeat swimming performance and striated muscle of Atlantic salmon smolts

**T. Gillis, University of Guelph / Integrative Biology; S. Avey, University of Guelph / Integrative Biology; C. Kennedy, Missouri Department of Conservation / Department of Biological Sciences; A.P. Farrell, University of British Columbia / Zoology; S.L. Alderman, University of Guelph / Department of Integrative Biology**

Diluted bitumen (dilbit), a type of crude oil, is transported from Canada’s oil sands across the continent, increasing the potential for accidental spills. Due to the high viscosity of bitumen extracted from the Alberta oil sands, it must be diluted with natural gas condensates to form diluted bitumen (dilbit). Dilbit is mainly exported via extensive transcontinental pipeline networks, raising concern for potential leaks and spills into lakes and rivers located along transportation routes. Although major dilbit spills have occurred in the past and future spills are inevitable, there remain significant research gaps on the aquatic toxicity of dilbit. In the present study, whole-transcriptome sequencing was utilized to characterized molecular responses in liver of sub-adult fathead minnow (Pimephales promelas) exposed to 0, 3, 10, or 30% dilbit water-accommodated fractions (WAF) for 7 days. There was a total of 281, 469, and 307 significant differentially expressed transcripts (FDR-adjusted p ≤ 0.05) in the 3, 10, 30% WAF treatment groups, respectively. There was a marked skew towards downregulation of transcripts, with at least 94% of transcripts being downregulated in each WAF treatment. Furthermore, gene ontology analysis revealed many genes being involved in calcium ion binding, the renin-angiotensin system, the immune system, and the inositol trisphosphate signaling cascade. Alterations in gene expression following dilbit exposure were predicted to be linked to downstream cardiac and hepatic toxicity, including liver hyperplasia, heart failure, liver cirrhosis, and cardiac enlargement. Future studies will focus on metabolic physiological endpoints in fathead minnow to examine how changes in gene expression may affect organismal fitness. Through RNA sequencing, results from this research will elucidate the molecular mechanisms of dilbit toxicity and provide insight on potential impacts of dilbit spills on aquatic organisms. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).

TP043 Effects of weathered sediment-bound dilbit on the health of zebrafish embryos (Danio rerio)

**S. Everitt, University of Lethbridge / Biological Sciences; G.G. Pyle, University of Lethbridge; S. Wiseman, University of Lethbridge / Biology**

Due to the high viscosity of bitumen extracted from the Alberta oil sands, it must be diluted with natural gas condensates to form diluted bitumen (dilbit) to facilitate transportation through pipelines. Pipelines stemming from the oil sands span thousands of freshwater environments and pose a risk to aquatic organisms. If dilbit is spilled into or near a waterbody, environmental factors such as evaporation (weathering) and interaction with sediments can alter the fate of dilbit and its subsequent toxicity to aquatic organisms. Most studies of dilbit to date have focused on exposing fish to the water-accommodated fraction of fresh dilbit. Here, we present the first study that addresses the toxicity of weathered, sediment-bound dilbit to zebrafish embryos (Danio rerio). Zebrafish embryos were exposed to the water-soluble fraction of weathered sediment-bound dilbit from 30 minutes post-fertilization to five days post-fertilization. Exposed embryos showed increases of pericardial edema, yolk sac edema and incidences of uninflated swim bladder. There was no change in the abundances of transcripts related to oxidative stress (sod, gpx, gst, gelc), but wnt11--important for signaling in the Wnt pathway that has a role in swim bladder formation--was significantly down regulated. There was a concentration dependent induction of cyp1a, suggesting the embryos were exposed to polycyclic aromatic hydrocarbons that may have been responsible for the deformities. These results show that despite weathering and combination with sediment, water-soluble compounds remain bioavailable and negatively affect the early development of zebrafish.

TP044 Whole-transcriptome sequencing of sub-adult fathead minnow liver following water-accommodated conventional heavy crude oil exposure

**N.E. Andrzejczyk, University of California, Riverside / Department of Environmental Sciences; D. April, University of Saskatchewan / Veterinary Biomedical Sciences; V. Palace, IISD-Experimental Lakes Area; D.M. Janz, L.P. Weber, University of Saskatchewan / Veterinary Biomedical Sciences; D. Schlenk, University of California, Riverside / Environmental Sciences**

The Oil Sands region of Alberta, Canada has one of the largest known reserves of bitumen, containing an estimated 50 billion cubic meters of bitumen. Bitumen, a heavy type of crude oil, is mixed with natural gas condensate or synthetic oils to decrease viscosity for more efficient transport, thus forming diluted bitumen (dilbit). Dilbit is mainly exported via extensive transcontinental pipeline networks, raising concern for potential leaks and spills into lakes and rivers located along transportation routes. Although major dilbit spills have occurred in the past and future spills are inevitable, there remain significant research gaps on the aquatic toxicity of dilbit. In the present study, whole-transcriptome sequencing was utilized to characterized molecular responses in liver of sub-adult fathead minnow (Pimephales promelas) exposed to 0, 3, 10, or 30% dilbit water-accommodated fractions (WAF) for 7 days. There was a total of 281, 469, and 307 significant differentially expressed transcripts (FDR-adjusted p ≤ 0.05) in the 3, 10, 30% WAF treatment groups, respectively. There was a marked skew towards downregulation of transcripts, with at least 94% of transcripts being downregulated in each WAF treatment. Furthermore, gene ontology analysis revealed many genes being involved in calcium ion binding, the renin-angiotensin system, the immune system, and the inositol trisphosphate signaling cascade. Alterations in gene expression following dilbit exposure were predicted to be linked to downstream cardiac and hepatic toxicity, including liver hyperplasia, heart failure, liver cirrhosis, and cardiac enlargement. Future studies will focus on metabolic physiological endpoints in fathead minnow to examine how changes in gene expression may affect organismal fitness. Through RNA sequencing, results from this research will elucidate the molecular mechanisms of dilbit toxicity and provide insight on potential impacts of dilbit spills on aquatic organisms. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).
Environmental pH can change both the uptake of ionizable organic chemicals (IOCs) into exposed organisms and subsequent biological effects. Dissolved organic chemicals from oil sands process-affected water (OSPW) from Base Mine Lake has been previously demonstrated to bioconcentrate in fish, meaning any unintentional release of OSPW poses a risk to organisms in the surrounding water bodies, such as the Athabasca River. It has been shown that bioconcentration of these chemicals in fish correlated well with their partitioning to phospholipid-coated silica beads, thereby indicating that biodistribution is governed by partitioning into membrane lipids rather than storage lipids. It remains unclear, however, whether organic chemicals from fresh and treated OSPW would behave similarly. Furthermore, previous research using an in vitro screening assay was used to study the permeation of IOCs across an epithelium of cultured rainbow trout gill cells (RTgill-W1). It was found that a lower pH allows for greater permeability of the epithelium for acidic organics. The purpose of this study is to repeat those partitioning and in vitro assays with a broader range of OSPW samples at pH values representative of the Athabasca River during summer flow (approximately pH 7.5) and OSPW (approximately pH 8.5). Samples of OSPW from the operational inventories of several oil sands operators, along with samples from before and after Syncrude’s pilot treatment process are being characterized for their partitioning to phospholipids and permeation across gill epithelia. This study will support a better understanding of the impact of OSPW on the aquatic organisms in freshwater bodies surrounding the Athabasca Oil Sands Region and the effectiveness of Syncrude’s pilot treatment process to attenuate potential adverse effects of OSPW on aquatic organisms.

**TP046 Predicting Non-linear Adsorption of Naphthenic Acids (NAs) onto Carbonaceous Sorbents - Application of the Lognormal Langmuir (LNL) Isotherm Model**

C.W. Davis, ExxonMobil Biomedical Sciences, Inc.; A. Bekele, Imperial Oil; W. Zubot, Syncrude Canada, Ltd.; M. Gamal El-Din, University of Alberta / Civial and Environmental Engineering

Naphthenic acids (NAs), present in oil sands produced waters (OSPWs) from bitumen mining and processing in the Athabasca River Basin have been demonstrated to exert toxic effects on aquatic organisms in concentration ranges typical of raw produced water samples. Consequently, significant efforts have been made to evaluate methods for treating NA-containing OSPWs sufficiently such that direct release, or beneficial re-use is possible. Sorption to carbonaceous materials (i.e., GAC, Charcoal, etc...) has been widely used as an effective removal system for neutral organics in wastewater treatment systems. More recently, petroleum coke (PC) and other technical sorbents have been demonstrated to effectively remove NAs from OSPW samples in laboratory and pilot-scale systems. However, there are several key aspects of NA removal via PC that have yet to be addressed, most notably - the variable composition of NAs in OSPWs and how the interactions of the individual species with pet coke sorbents affects the overall removal capacity. The goal of this work is two-fold - First, a non-linear isotherm model, with a single chemical-specific parameter, is fit to a large set of adsorption isotherms (N = 69) for NAs onto several technical sorbents. This non-linear model (the LNL model) demonstrates excellent agreement with experimental adsorption data (RMSE = 0.203, N = 194) for PC, with a single total site density (qmax) and distribution of binding site energies (σκ), which are chemical-independent. The use of a non-linear isotherm model with a single chemical-specific parameter greatly simplifies the process of predicting sorptive behaviors for new chemicals, while addressing non-linear sorption of chemicals. Second, a model for predicting the observed LNL isotherm median Langmuir binding constants (the chemical-specific parameter) is presented which relies on only two chemical descriptors - the molecular weight (MW) and the excess molar refractivity (E) of a representative NA structure of a given carbon number (C) and hydrogen degeneracy (Z). While the RMS error for the model is larger than those previously observed for neutral organic compounds (RMSE = 1.51, N = 69), previous application to neutral organics has demonstrated lower overall errors in the predicted sorbed concentrations (q) relative to those of the binding constants themselves. This modeling approach represents a first attempt at deriving molecular-descriptor based models for the individual sorption of NA species onto carbonaceous sorbent materials.

**TP047 Assessing the toxicity of bitumen-derived chemicals in groundwater**

R. Frank, Environment and Climate Change Canada / Water Science and Technology Directorate; J.W. Roy, Environment and Climate Change Canada; A.J. Bartlett, Environment and Climate Change Canada / Water Science and Technology Directorate; J. Parrott, P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division; W. Norwood, Environment and Climate Change Canada; M.R. Rodrigues, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.E. Bauer, University of Waterloo / Biology; M. Rudy, S.D. Campbell, Environment and Climate Change Canada / Water Science and Technology Directorate; L. Brown, Environment and Climate Change Canada / ACRD: E. Holman, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M. Brown, Environment and Climate Change Canada / Water Science and Technology Directorate; L.E. Deeth, University of Guelph / Department of Mathematics and Statistics; G. Dixon, University of Waterloo / Biology; G. Bickerton, Environment and Climate Change Canada; M. Hevitt, Environment and Climate Change Canada / Water Science and Technology Directorate

Groundwater in the oil sands region near Fort McMurray, AB, Canada contains chemicals originating from natural bitumen and OSPW sources. While research is underway to better elucidate natural from anthropogenic sources of bitumen influence by using advanced separation and high resolution analytical methodologies, little is understood regarding the toxicity of these different source inputs. Significant dilution of these groundwater inputs often prevents detection of these bitumen- and OSPW-derived chemicals in surface waters of the Athabasca River watershed, further complicating investigations of the potential environmental impacts of tailings seepage. A multi-year investigation is underway to identify the primary toxic compounds/classes within these bitumen-influenced waters, and to determine if the drivers of toxicity are different between natural and OSPW sources. An initial investigation determined that whole groundwaters with bitumen influence from natural and OSPW sources were all toxic in fathead minnow embryo-larval assays and Hyalella azteca acute and chronic assays. Freshwater mussel (Lampsilis sp.) glochidia were also sensitive to some of the tested groundwaters. A follow-up investigation collected large volumes (>150L) each of these same groundwater sources with subsequent fractionation of the soluble organics using differences in polarity. Effects-directed analysis (EDA) of the generated fractions using acute assays with Vibrio fischeri, Daphnia magna, Ceriodaphnia dubia, Hyalella azteca, Hexagenia sp., Lampsilis sp., fathead minnow, and Japanese medaka indicated that toxicity varied by species and endpoint, however any observed toxicity was always associated with the fractions containing the least polar (i.e., O2 chemical species including naphthenic acids) and most polar (i.e., O4+ chemical species). Further iterations of chemical fractionation of the bioactive fractions are underway as part of this EDA investigation, using bioassays previously identified as sensitive to bitumen-derived organic mixtures. This work is intent on identifying the compound classes of interest within the soluble organic mixtures of bitumen-influenced waters, thereby providing critical information for the development of water monitoring programs and remediation initiatives in the oil sands region.
TP048 Effects-directed analysis of bioactive water soluble polar organic fractions from industrial and natural bitumen sources

M.R. Rodrigues, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R. Frank, A.J. Bartlett, Environment and Climate Change Canada / Water Science and Technology Directorate; L.E. Deeth, University of Guelph / Department of Mathematics and Statistics; M. Dunnin, Environment and Climate Change Canada; G. Dixon, University of Waterloo / Biology; M. Hewitt, Environment and Climate Change Canada / Water Science and Technology Directorate

Identification of the organic compounds of concern within bitumen-influenced waters is critical for effective monitoring and reclamation within Canada’s oil sands region. Effects-directed analysis (EDA) provides an effective tool to prioritize bioactive and unique compounds of interest in complex mixtures, allowing for chemical and toxicological characterization. Bioactive fractions from natural and industrial bitumen-influenced water sources subjected to a first tier EDA were further fractioned in a second tier using reverse phase high performance liquid chromatography (HPLC). Secondary fractions were analyzed using liquid chromatography-time-of-flight mass spectrometry (LC/TOF-MS), indicating successful fractionation was achieved, with fractions generated according to decreasing polarity. Toxicity was assessed using the Microtox(R) assay and Hyalella azteca due to sensitivities exhibited to the first tier EDA fractions. Here, the Microtox(R) and H. azteca assays were most sensitive to the polar organics of the primary fractions and secondary fraction recombinated treatments. To a lesser degree, they were also sensitive to the least polar secondary fractions isolated from the polar primary fractions. The lack of recoverable toxicity in the individual secondary fractions may indicate that there are interactive effects within the more complex mixtures of polar organics (e.g. primary and recombinated fractions) that lead to greater toxic potency than when the chemical components are separated into less complex mixtures. Methodological adjustments in secondary fraction preparations are required to advance this phase of the EDA.

TP049 Quantifying the accumulation of 13C-labelled phenanthrene in phytoplankton and transfer to corals using Cavity Ring Down Spectroscopy

A. Ashok, Red Sea Research Center; S. Kottuparambil, KAUST / Biological and Environmental Science and Engineering Division; L. Haj, A.P. Negri, Australian Institute of Marine Sciences; C.M. Duarte, S. Agusti, King Abdullah University of Science and Technology / Red Sea Research Center

While bioaccumulation of persistent pollutants is a serious concern, accumulation kinetics and pathways in aquatic organisms and their food chains are hardly quantified mostly due to methodological limitations. Polycyclic aromatic hydrocarbons (PAHs) are persistent, toxic and bioaccumulative organic pollutants. Here, we present a novel method to quantify the accumulation and uptake kinetics of a PAH, phenanthrene using stable isotope 13C-labeling and cavity ring down spectroscopy (CRDS). We demonstrated the efficiency of the method in a one-step experimental marine food-chain experiment using phytoplankton and corals. We first quantified accumulation of phenanthrene in the microalga, Dunaliella salina , demonstrating dose-dependent accumulation with a bio-concentration factor (BCF) of 2590 ± 787 L/kg dry weight. Subsequently, we quantified the uptake rates and accumulation of 13C-phenanthrene in tissues of the coral Acropora millepora via two exposure routes: (a) contaminated (13C-phenanthrene labeled) D. salina, (b) direct diffusive uptake from seawater. While uptake rate of 13C-phenanthrene in corals was faster through aqueous exposure than dietary exposure, passive diffusion showed larger variability and both routes exhibited similar accumulation levels. The developed method presents 13C-PAH labeling and analysis by cavity ring down mass spectroscopy as a promising tool to resolve uptake and transport of persistent organic pollutants with sensitivity, accuracy and detection levels similar to more complicated techniques based on IRMS or the use of radioactive traces which could be inherently toxic.

TP050 Factors Influencing the Field Bioaccumulation of Organic Contaminants in Bivalves

C. Xin, City University of Hong Kong; D. Kuo, City University of Hong Kong / Architecture and Civil Engineering

The biota-sediment accumulation factor (BSAF) model based on equilibrium partitioning theory (EqP) have been suggested as a simple tool to estimate bioaccumulation potential of contaminants in benthic ecosystems. High variability has been observed in field BSAF measurements and they may pose limitations to the applications of the BSAF model. To uncover factors behind such variability in field bioaccumulation, more than 3000 field BSAFs for 38 species of bivalves were collected from 49 peer-reviewed articles. Totally, 96 persistent organic contaminants (e.g., PCBs, PAHs, and organochlorine pesticides) were included. Results show that the variation in field BSAFs of bivalves can be 4-6 orders of magnitude for individual compounds. The mean, standard deviation, or interquartile range of BSAFs exhibited no significant correlation with hydrophobicity (KOW), organic carbon sorption coefficient (KOC), and black carbon sorption coefficient (KBC) for all contaminants (P>0.01). Temperature had no correlation with BSAFs for PCBs (N=105, P>0.01) and pesticides (N=43, P>0.01) and only a weak correlation for PAHs (N=171, R2=0.18, p< 0.01). The body size of bivalves shown no correlation with BSAFs for pesticides (N=291, P>0.01), a very weak correlation for PCBs (N=633, R2=0.02, p< 0.01), and a moderate correlation for PAHs (N=853, R2=0.50, p< 0.01). Narrowed variability in BSAFs was observed when the hydrodynamics of sampling sites was considered. For sites with standing water (e.g., lakes and lagoons), about 90% of BSAFs gather within +/-1 log unit of the theoretical BSAF in EqP model (log BSAF=0). For sites with unidirectional flowing water (e.g., rivers), over 80% of the log BSAFs are less than -1. The BSAFs for sites with complex hydrodynamic (e.g., intertidal zones and estuaries) are most variable, with log BSAF spanning a range from -4 to 2. This indicates the hydrodynamics may be a key factor influencing bioaccumulation of organic contaminants under field conditions.

TP051 Streamlining Freshwater Bioaccumulation Bioassays: Letting the Worms Do the Hard Work

G.R. Lotufo, US Army Corps of Engineers / Environmental Laboratory; N. Melby, T. Biber, US Army Engineer Research and Development Center

Laboratory bioaccumulation tests measure the movement of contaminants from field-collected or spiked sediment into the tissues of the test organism and adequately provide quantitative information concerning potential for exposure and trophic transfer at sites under investigation or at dredged material placement sites. For use with freshwater sediments, only bioaccumulation test method using the oligochaete Lumbricillus variegatus is currently standardized. The use of un-sieved sediment is recommended when investigating the bioaccumulation of contaminants from field-collected sediments. Sieving is only recommend when desirable to remove predatory organisms or large amounts of extraneous materials. At test termination, sediment is typically sieved through a fine-meshed screen sufficiently small to retain the oligochaetes. However, because sediment is typically used “as received” (without pre-test sieving), vegetative material (for example, live or decaying root fibers) and sand grains too large to pass through the sieve present in the sediment will collect on the sieve along with the test organisms. A large fraction of vegetative material typically results in labor-intensive and very time consuming effort to retrieve the organisms after sieving and may result in reduced recovered biomass. Recovery of oligochaetes is typically achieved by painstakingly pipetting organisms transferred to a shallow pan. We developed a “self-extraction” method to efficiently separate L. variegatus from the other materials retained on the sieve (“detritus”) during the process of washing the fine-grained test
Biomagnification of hydrophobic organic compounds (HOCs) increases in fish with increasing trophic levels, and plays an important role in affecting steady-state concentrations of HOCs in aquatic organisms. Effluent is the main source of contaminants of emerging concern, which may pose a threat to aquaculture. Effluent is the main source of contaminants of emerging concern (CECs, e.g., pharmaceuticals, personal care products). To assess the potential bioaccumulation, uptake and depuration of CECs on farmed fish, tilapia (Oreochromis mossambicus) was exposed to diltiazem and GenX at environmentally relevant concentrations. Results will be presented on the tissue and plasma bioconcentration values and projections. This work will provide aquaculturists with knowledge to make proactive management decisions regarding CECs in surface waters and potential fish bioaccumulation while improving our general understanding of human exposure to pollutants from nontraditional water use.

**TP054 Presence of bioaccessible legacy and current-use pesticides in Chinook salmon habitat in the Sacramento River watershed, California**

S. Anzalone, K.E. Huff Hartz, N.W. Fuller, Southern Illinois University, Carbondale / Zoology; D. Schlenk, University of California Riverside / Department of Environmental Sciences; S. Acuna, Metropolitan Water District of Southern California (MWD); M.J. Lydy, Southern Illinois University, Carbondale / Zoology

Juvenile Chinook salmon of the Sacramento River, California, face a variety of environmental stressors as they migrate to the Pacific Ocean. This includes exposure to anthropogenic pollutants, such as legacy and current-use pesticides, which were and are widely applied throughout the watershed. As hydrophobic compounds, these pesticides are often found in sediments of aquatic systems and have the potential to bioaccumulate in resident benthic invertebrates. Previous studies have demonstrated the ability of these contaminants to elicit adverse olfactory effects to fish. This study aims to investigate the potential for pesticide exposure via dietary routes in benthic food webs to juvenile Chinook residing in the Sacrament River channel and the Yolo Bypass, a corresponding floodplain that has been indicated as an important rearing habitat. Sediments were collected throughout the study area during both flooding and non-flooding conditions. Accelerated solvent extraction (ASE) was utilized to determine the total concentrations of pesticides present in the sediments, and the bioaccessible fraction was assessed using single point 24-h TENAX extractions. Both methods indicated higher concentrations of the legacy pollutants p,p'-DDE, p,p'-DDD and p,p'-DDT in the Cache Slough region of the Yolo Bypass than in the Sacramento River. Additionally, detectable concentrations of three current-use pyrethroid insecticides, bifenthrin, esfenvalerate and lambda-cyhalothrin, were found in Yolo Bypass and Lower Sacramento River regions, yet not detected in the Upper Sacramento River channel. These results indicate that Chinook salmon feeding in the benthos of the Sacramento River channel and Yolo Bypass floodplain are characterized by different pesticide exposure regimes, with Chinook residing in the floodplain potentially exposed to higher concentrations of legacy contaminated.

**TP055 Trophic dynamics of selenium along a gradient of exposure concentrations in a boreal lake ecosystem**

S. Graves, K. Liber, University of Saskatchewan / Toxicology Center; V. Palace, IIHSD-Experimental Lakes Area; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; L.E. Doig, University of Saskatchewan / Toxicology Centre; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences

Selenium (Se) is both an essential micronutrient and a contaminant of concern, and is of particular interest in mine-affected waterbodies in Canada. The objective of this research was to characterize the trophic dynamics of selenium along a gradient of exposure concentrations in a Canadian boreal lake ecosystem. From June 20 to August 22, 2018, six limnocorals (littoral, ~3000 L enclosures) were spiked with mean measured concentrations of 0.4, 0.8, 1.6, 3.1, 5.2 and 7.9 µg Se/L as selenium, with three untreated controls (background aqueous Se = 0.09 µg/L). Water, periphyton, phytoplankton, sediment, benthic macroinvertebrates, zooplankton and female finescale dace (added on day 21 of the experiment) were collected throughout and at the end of the experiment. Total selenium was measured in all matrices. Non-linear (polynomial) regressions and generalized additive models were used to determine the relationships between aquatic and biota Se. Preliminary results show significantly greater enrichment of Se by phytoplankton relative to periphyton, and taxonomic differences in accumulation of Se by invertebrates (Heptageniidae > Chironomidae > Zooplatkton). Variability in bioaccumulation of Se by fish and relationship with shifts in diet along the gradient of Se exposure concentrations will be discussed. This research provides new information on patterns of enrichment and trophic transfer of Se over a gradient of exposure concentrations and will aid in the prediction of Se exposure and risk assessment under similar environmental conditions.
TP056 Elevated blood metal levels and cyto genetic damage induced in rats exposed in situ to groundwater and air emissions at a municipal landfill, Nigeria

A.M. Gbadebo, University of Ibadan / Ecology and Environmental Biology Unit / Department of Zoology; O.A. Alabi, Federal University of Technology, Akure / Department of Biology; C.G. Alimba, A.A. Bakare, University of Ibadan / Department of Zoology

Solid waste landfills in developing nations have been known to be major source of environmental pollutants including heavy metals, thus, constituting ecological risk to exposed populations. This study herein investigated the levels of lead (Pb), cadmium (Cd), chromium (Cr) in blood and potential cytogenetic alterations in rats exposed in situ to underground water and ambient air emission from Olusosun landfill in Lagos, Nigeria. Male Wistar rats (5 rats/point/duration) were exposed at three different points to air emissions and underground water (via drinking) from the landfill for 4, 8, 12, 16, 20 and 24 weeks. Rats concurrently sited at 17.3 km from the landfill site served as control. Rats’ blood levels of Pb, Cd and Cr were measured after each exposure periods using atomic absorption spectrophotometer (AAS) and formation of bone marrow micronucleus and polychromatic erythrocyte/normochromatic erythrocytes (PCE/NCE) ratio were analysed. The strength of the linear relationship between blood metal levels and cytogenetic alterations were determined using Pearson’s correlation analysis. Blood levels (in mg/L) of Pb, Cd and Cr in the landfill exposed rats were significantly elevated (p < 0.05) compared to those of the corresponding control throughout each periods of exposure. Also, there was significant (p < 0.05) increase in the frequency of micronucleated polychromatic erythrocytes (MNPCNE) with significant (p < 0.05) decrease in PCE/NCE ratio at all points and periods of exposure compared to the control. No strong correlation (p > 0.05) was observed between blood metal levels and exposure periods; frequencies of MNPCNE; and PCE/NCE ratios respectively during the study periods. The concentrations (mg/L) of heavy metals such as Pb, Cd, Cr, Cu and Fe in the underground water were observed to be above permissible limit for drinking water. In situ exposure to underground water and air emissions at the landfill led to elevated blood levels of heavy metals in exposed rats. However, no strong correlation observed between blood metal levels and cytogenetic damage implies that other unanalyzed toxic agents present in the landfill compartments might have contributed either additively or synergistically with the metals in inducing the observed cytogenotoxicity in the erythropoietic stem cells. This finding is of ecological and health risk to animal and human populations who co-exist in the vicinity of major municipal waste dumping sites in developing countries.

TP057 Chromium, arsenic, and other elements of concern in fish from remote boreal lakes and rivers: drivers of variation

G.L. Lescord, Laurentian University / Boreal Ecology; T.A. Johnston, Ontario Ministry of Natural Resources; M. Heerschap, Laurentian University; C.M. O’Connor, M. Southee, Wildlife Conservation Society; B. Branfireun, University of Western Ontario / Department of Biology; R. Dyer, Ontario Ministry of Environment; J. Gunn, Laurentian University / Boreal Ecology

Eating fish has numerous health benefits, but it is also the dominant exposure pathway for contaminants to enter the human body. Across northern Ontario, Canada, various freshwater fish have elevated concentrations of chromium (Cr), arsenic (As), and mercury (Hg), which has invoked consumption limitations issued by the provincial government, a concern for people in remote First Nation communities who rely on such fish for subsistence. However, while piscine Hg concentrations have been well studied in this remote region, far less is known about As, Cr, or other elemental concentrations in boreal fish. In this study, we measured 11 elements (including Hg, As, and Cr) in 388 fish sampled from 17 river sites and 7 lakes across northern Ontario. All fish were also analyzed for stable carbon (δ13C), nitrogen (δ15N), and sulfur (δ34S) isotopes, which provide indications of fish diet and anadromy. Our aim was to determine the effect of: 1) trophic ecology; and 2) local abiotic characteristics (e.g., geology) on elemental concentrations. Overall, the concentrations of most elements were low, often below detection limits (e.g. lead) or advisory benchmarks (ABs) set by monitoring authorities (e.g., selenium). However, traces of Hg, As, and Cr were detected in most fish, sometimes at elevated concentrations that exceeded their respective ABs. Preliminary results show that Hg and As, but not Cr concentrations were related to fish size and trophic ecology (i.e., δ13C and δ15N), suggesting bioaccumulation of the former elements. Fish with elevated δ34S values, suggestive of anadromous behaviour, had lower Hg and higher Se concentrations; δ34S was not related to piscine As or Cr concentrations. On-going analyses include assessing the relationship between Cr, As, and Se concentrations in fish with proportions of various geologic features within delineated watershed (e.g., mafic intrusions, glacial till). Results from this study address current gaps in our understanding of As and Cr uptake in fish, and will be help refine consumption guidelines and future monitoring programs based in the “Ring of Fire” mining development region.

TP058 Exploratory methodology for hexavalent chromium determination in fish tissues

G.L. Lescord, Laurentian University / Boreal Ecology; A.S. Lock, Laurentian University / Perdue Central Analytical Facility (PCAF); C.M. O’Connor, Wildlife Conservation Society; J. Gunn, Laurentian University / Boreal Ecology

There is rising concern across the Canadian boreal ecozone regarding metals accumulation in commonly consumed freshwater fish. While there has been considerable effort to study and monitor mercury (Hg) concentrations in these fish, less work has examined the cycling of other metals. Recently, the Ontario Ministry of the Environment Conservation and Parks (OMCP) issued consumption limitations in various boreal riverine fish due to concentrations of chromium (Cr). However, these limits are based on monitoring total Cr concentrations, even though not all forms of these metals are toxic to humans or wildlife. The currently consumption advisories are, therefore, likely overestimating the risk to consumers, a major issue for remote aboriginal communities across northern Ontario because of their reliance on these fish for subsistence. In the environment, the majority of Cr exists either as benign and nutritionally essential form (trivalent Cr or Cr3) or in potentially toxic form (hexavalent Cr or Cr6). However, no method has been established to differentiate these forms of Cr in biotic samples because of the potential for oxidation throughout extraction procedures, particularly in low pH acidic techniques commonly used for total Cr analysis (e.g., EPA Method 3052). The goal of this project is to test two extraction techniques and validate findings using Speciated Isotope Dilution Mass Spectrometry (SIDMS, EPA Method 6800). Lab work is anticipated to begin in June 2019 and will test two types of extractions: (1) a microwave assisted extraction (MAE) using methanol and water (20, 50, 80, and 100% v/v) and, (2) direct measurement of Cr6 using an alkaline digestion with MAE (i.e., EPA Method 3060A) and subsequent Cr3 measurement on residual tissue using total procedures (i.e., EPA Method 3052). Extracts from both approaches will be analyzed using ion chromatography coupled with inductively coupled plasma mass spectrometry (IC-ICP-MS) at Laurentian University. We plan to validate the method with the most promising results using SIDMS, during which each Cr species is “labeled” with an isotopically enriched spike in the corresponding species form. The inter-conversions that occurs between species after spiking can be traceable and corrected for by back calculation. Results from this work will be help refine consumption guidelines and future monitoring programs based in the “Ring of Fire” mining development region and beyond.
TP059 Validation of Toxicological Interpretation of Diffusive Gradients in Thin-films in Marine Waters Impacted by Copper

J.E. Strivens, Pacific Northwest National Laboratory / Coastal Sciences; G. Rosen, NIWC Pacific / Energy and Environmental Sustainability; N. Hayman, NIWC Pacific (Naval Information Warfare Center Pacific) / Energy and Environmental Sustainability; A. Myers-Pigg, Pacific Northwest National Laboratory / Coastal Sciences

As part of the ambient monitoring program being conducted for the Puget Sound Naval Shipyard & Intermediate Maintenance Facility at Naval Base Kitsap in Sinclair and Dyes inlets of the Puget Sound, receiving waters of the Inlets are routinely monitored for trace metals and toxicity to assess water quality status, track progress in achieving water quality goals, and demonstrate protection of aquatic life. In 2016, aqueous metals bioavailability tracking, using diffusive gradients in thin-films (DGT) passive samplers was incorporated into the monitoring program. Eight subsequent in situ campaigns have recorded labile (CDGT) Cd, Cu, Ni, Pb, and Zn at twelve stations. A current obstacle to regulatory acceptability of CDGT data is validation of an uptake response that reliably mimics that of aquatic organisms. Towards reconciliation of CDGT Cu and natural ligands in respect to toxicity, ex situ studies in 2018 quantified DGT lability of Cu in Sequim Bay seawater at varying dissolved organic carbon (DOC) concentrations (as Suvannee River natural organic matter), while simultaneously determining and modeling biota correlation (as EC50 values of Mytilus galloprovincialis [Mediterranean mussel] larvae). Embryo-larval development tests, using Mytilus, were selected as they are among the most sensitive saltwater bioassays used for aquatic life criteria development and are the basis for the current EPA Criterion Maximum Concentration of Cu in seawater. In the current study, Mytilus larvae Cu EC50s in seawater from five ecological communities with diverse DOC quality, were assessed against the previous model, and the toxicological protection provided by Cu-DOC binding is discussed in terms of fluorescence characterization.

TP060 Trophodynamics and parabolic behaviors of polycyclic aromatic hydrocarbons in an urbanized Lake food web, Shanghai

A. Qadeer, L. Min, East China Normal University / School of Geographical Sciences

Understanding the trophic movement and trophic magnification factor (TMF) of polycyclic aromatic hydrocarbons (PAHs) is an important criterion to assess their fate and potential effects in an aquatic ecosystem. This study investigated concentrations and trophodynamics of 16 priority PAHs in food webwb (food web comprising whole bodies) and food webm (food web containing only muscles) of total 14 species. TMF values of PAHs in food webm ranged from 0.34 for pyrene to 0.68 for phenanthrene compared to TMF values of food webwb ranged from 0.34 for pyrene to 0.74 for fluorene. Because of two opposing scientific views for biomagnification and biodilution of PAHs in the food web, albeit based on a rather limited number of studies, our study investigated that there is parabolic behavior of most of the PAHs. Concentrations of PAHs in the red-eared terrapin (Trachemys scripta elegans) were biodiluted which showed that this species metabolises such compounds. Hepatobiliary system (such as gall bladder and liver) in the whole body considered to have higher bioaccumulation potential of organic compounds than extrahepatic tissue (muscles).

TP061 Bioaccumulation prediction of persistent organic pollutant in freshwater mussel using passive sampling

N. Lombard, M. Bokare, University of Maryland, Baltimore County / Chemical, Biochemical and Environmental Engineering; T. Stephen, University of Maryland Baltimore County; J. Damond, University of Maryland, Baltimore county / Department of Chemical, Biochemical, and Environmental Engineering; R. Harrison, University of Maryland / Department of Environmental Science and Technology; L.T. Yonkos, University of Maryland / Environmental Science and Technology; A.E. Pinkney, US Fish and Wildlife Service / Chesapeake Bay Field Office; D. Murali, Department of Energy and Environment; U. Ghosh, University of Maryland, Baltimore County / Chemical, Biochemical, and Environmental Engineering

Accurate prediction of persistent organic pollutant (POP) uptake in benthic organisms is critical for bioaccumulation prediction higher in the food web. The case of freshwater mussel such as Elliptio complanata is of particular interest due to their biology. They live in sediment and consequently are exposed to porewater concentration but filter feed on particles and plankton that are in equilibrium with the water column. In this study, we tested the passive sampling approach as a tool to predict POP bioaccumulation in E. complanata and estimate the relative contribution of water and porewater in POP uptake into E. complanata. We used polyethylene (PE) sheets as passive sampler to measure the freely dissolved water column and porewater concentrations. PE were co-deployed with caged mussels for a period of 2-3 months in summer in several streams of the Anacostia watershed. Our analysis was targeted on 119 PCB congeners, 34 PAHs and several organochlorine pesticides. Lipid, protein and carbohydrate content in mussel were also measured. Streams selected had a wide range of POP concentration from below to above EPA water quality criteria for the protection of human health. Various scenarios were observed with water column being the source, the sink, or at equilibrium with the sediment porewater, depending on the streams and pollutants considered. Equilibrium partitioning-based models were first tested using water column concentration measured and various partitioning coefficient to lipid (Klip) reported in the literature. Results showed reasonable agreement within a factor of 2 to 10 between predicted and measured concentrations depending on the Klip value used. Models were further refined to include nonlipid organic matter but did not show significant improvement in the predictions. Additionally, the fractional contribution of pore water to bioaccumulation is being estimated for E. complanata for one site and used in the model for the remaining sites. By linking water concentrations to uptake in freshwater organism, it is possible to estimate load reductions necessary to achieve a target concentration in tissue for the protection of human health.

TP062 Spatial and temporal trends in cyclic volatile methylsiloxanes in top predatory fish in Canadian lakes

T. McDaniel, D.J. McGoldrick, Environment and Climate Change Canada / Water Quality Monitoring and Surveillance; J. Kim, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; M. Clark, Environment and Climate Change Canada; J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting; R.M. Seston, Hyla Environmental Consulting, LLC / Toxicology, Environmental Research & Consulting; E. Burresi, Environment and Climate Change Canada / National Laboratory for Environmental Testing

Organosiloxanes are high production volume chemicals and are common components of many personal care products, cosmetics, as well as many other materials such as dry-cleaning solvents and industrial cleaning fluids. Due to their usage patterns and physiochemical properties, the majority of releases to the environment are through solid and water waste streams where they bind to aquatic sediments or volatilize to air. Cyclic volatile methylsiloxanes (cVMS) such as octamethylocyclohexasiloxane (D4), decamethylocyclopentasiloxane (D5), and dodecamethylocyclohexasiloxane (D6) have been detected in different compartments of the aquatic environment including water, sediment, and biota. Concentrations of D4,
D5 and D6 in whole-body homogenates of top predator fish, lake trout and walleye, from sites across Canada were measured as part of Environment and Climate Change Canada’s (ECCC) National Fish Contaminants Monitoring Program. Due to the volatile nature and ubiquitous presence of cVMS in personal care products, contamination during laboratory processing can be a concern. To address this, a background study on the laboratory pre-processing of samples was conducted to determine the optimal processing procedures. Additionally, a multi-year collaborative study between ECCC and the Global Silicone Council adds validity to this dataset by allowing for an inter-laboratory comparison of cVMS concentration data. The objectives of this study were to assess spatial trends of cVMS in predatory fish from sites across Canada, conduct an interlaboratory comparison of trends in cVMS concentrations in lake trout collected from Niagara on the Lake in Lake Ontario and incorporate appropriate QCs during sample processing to facilitate quantification of contamination and subsequent background correction of sample concentrations.

TP063 Determination of Oxybenzone, Clofibrate, and Sulfamethoxazole in Water, Sediment, and Fish from Galveston Bay and Clear Creek Areas

S.O. Atilologe, Texas Southern University / Environmental and Interdisciplinary Sciences; J. Turner, Texas Southern University; P.K. Relangi, M.A. Yakubu, Texas Southern University / Department of Environmental & Interdisciplinary Science

Environmental chemical contaminants have been of major concern as they can cause adverse health effects in single or multiple forms — even at trace levels. They are derived from different activities; and they include pesticides, personal care products, pharmaceuticals, and byproducts of various industrial processes. The contaminants often referred to as contaminants of emerging concern (CEC) are of growing awareness and concern because of their possibilities of interacting with biological systems to cause serious health issues. CEC are used daily and are continuously released into the environment via various waste streams. Galveston Bay and Clear Creek receive waters from several sources including runoffs which may contain a significant number/concentration of contaminants with a high possibility of human exposure. The potential adverse effects of the contaminants on humans, human environment, and the ecosystem can range from acute to chronic and are of significant importance. This study analyzed the presence of selected CEC: oxybenzone, sulfamethoxazole, and clofibrate in the water, sediment, and fish samples from the Galveston Bay and Clear Creek areas. Samples were collected from the identified locations, extracted using standard protocols, and analyzed using high-performance liquid chromatography coupled with an ultraviolet/visible detector. Results quantified, and bioaccumulation calculated. The results showed the presence of the contaminants in the samples analyzed. The concentration of oxybenzone in water and sediment samples were 1.85 ± 0.82 and 1.30 ± 1.55 ppm respectively. Oxybenzone in fish tissues/organs was 38.49 ± 14.64 ppm, this is 2.081% and 2.961% its concentration in water and sediment samples. Clofibrate was detected at a concentration of 0.45 ± 0.31 and 2.28 ± 3.76 ppm in water and sediment samples. Its concentration of 7.76 ± 2.46 ppm found in fish tissues/organs is 17 and 3 times more than the levels in water and sediment. Sulfamethoxazole was below detection limits. Thus, the results revealed that oxybenzone and clofibrate are present in the locations analyzed and they bioaccumulate in fish tissues/organs with a high probability of biomagnification in higher animals. Oxybenzone has a higher bioaccumulative capacity and may produce more toxic interactions. The data from this research is an impetus for the continuous monitoring of the levels of CEC in the Galveston/Clear Creek areas bodies of water and the aquatic environment.

TP064 Influence of dissolved organochlorines on bioaccumulation in San Diego Bay, California

A.N. Parks, Southern California Coastal Water Research Project / Toxicology; W. Lao, E. Wenger, Southern California Coastal Water Research Project; K.A. Maruya, Southern California Coastal Water Research Project / Chemistry; C. Stransky, Wood Environment & Infrastructure Solutions, Inc. / Aquatic Sciences and Toxicology; J. Leather, Space and Naval Warfare Systems Center; J. Carilli, SPAWAR Systems Center Pacific / Environmental Sciences; S. Bay, Southern California Coastal Water Research Project

San Diego Bay is a natural embayment used for both recreation and industry and comprises a large working waterfront as well as several military facilities. Previous studies and ongoing monitoring programs in this region have identified elevated levels of PCBs and other organochlorines in both sediment and biota samples. However, the influence of dissolved organochlorine concentrations in the water column, due to flux from sediment or other sources, to bioaccumulation has not been characterized. Quantification of the site-specific influence of sediment and water column contamination on food web contamination is a critical component of establishing effective sediment cleanup targets and assessing regulatory attainment. The purpose of this study was to evaluate the specific contributions of sediment organochlorines, including pesticides and PCBs, to the water column via flux and transport mechanisms, and relate these data to spatial and temporal variations in biota concentrations and bioaccumulation model estimates. Samples were collected at 10 stations within San Diego Bay that represented a large range of sediment contaminant concentrations. Organochlorine concentrations in sediment grabs, mid-depth water column passive samplers, sediment-water interface passive samplers, and biota (zooplankton and fish) were measured in Spring and Fall 2018. These data were used to evaluate the distribution of organochlorines from the sediment through the water column, and examine the correspondence with measured and predicted biota concentrations. Sediment porewater and bulk sediment concentrations were highest at stations 1, 3, and 5, with a clear gradient in concentration between the sediment porewater concentration to the mid-water depth dissolved concentration. Highest tissue PCB concentrations were present in all the fish species sampled (shiner perch, topsmelt, and spotted sand bass), and were found at stations 1 and 8 during both sampling events, as well as station 7 in Spring 2018 and station 3 in Fall 2018. The highest concentrations were frequently found in both North and Central San Diego Bay. A site-specific bioaccumulation model will be used to determine expected biota concentrations and investigate the relative influence of sediment and water column matrices on food web contamination.

TP065 Evaluation of published bioaccumulation data for per- and polyfluoroalkyl substances across aquatic species

L.P. Burkhard, US Environmental Protection Agency / ORD/NHEERL / Mid-Continent Ecology Division; C. Elomen, US Environmental Protection Agency / Office of Research and Development

Per- and polyfluoroalkyl substances (PFAS) are a group of man-made chemicals of concern across the globe, and some of the PFAS chemicals are known to be bioaccumulative in aquatic and avian species. A literature search for bioaccumulation information for PFAS compounds has been done, and the reported bioconcentration factors (BCFs), bioaccumulation factors (BAFs), biota-sediment accumulation factors (BSAFs), biomagnification factors (BMFs), and trophic magnification factors (TMFs) have been assembled and evaluated for quality. The quality evaluation involved assigning a low, medium, or high-quality ranking to the studies based upon criteria such as “Were the measurements for BCFs performed according the OECD 305 protocol?”, “Were uptake and elimination rates measured?”, “Were adequate numbers of field samples collected to obtain representative samples for biota and water phases?”, and “Were field samples co-located in space and time?” From this dataset, we will present information on the aquatic species with measured bioaccumulation metrics and on chemical subgroups within the PFAS universe with measured bioaccumulation data. From these data, we will identify
gaps and limitations in bioaccumulation information for PFAS chemicals and develop some initial estimates on the variability of BCFs and BAFs sorted by organism trophic level. This abstract does not necessarily reflect USEPA policy.

**TP067 Antidepressants in the sea: Washed away or taken up? Quantifying Fluoxetine and Venlafaxine in cuttlefish and crabs**

A. Chabenet, Normandie University, University of Le Havre; N. Hucher, Normandie University / University of Le Havre; J. Raynert, S. Olivier; T. Monsinjon, Normandie University, University of Le Havre / UMR-I 02 INERIS-URCA-ULH Environmental Stress and Aquatic Biomonitoring (SEBIO); C. Bellanger, Normandie University, University of Caen / UMR 6552, Rennes 1-CNRS Animal and Human Ethology (EhoS); T. Knigge, Normandie University, University of Le Havre / UMR-I 02 INERIS-URCA-ULH Environmental Stress and Aquatic Biomonitoring (SEBIO)

Prescriptions of antidepressants are still on the rise worldwide, and their excretion may result in a potential contamination of the aquatic compartments. Indeed, antidepressant residues such as fluoxetine (FLX) and venlafaxine (VEN) are currently detected at low concentrations, from ng.L⁻¹ to µg.L⁻¹. Due to bioaccumulation, however, the toxicity of these micropollutants is not necessarily represented by their concentration in the water body. Furthermore, these compounds conceived to treat depressive or anxiety disorders are worrisome because they can trigger neurobiological changes through targeting the serotonergic system of non-target organisms, such as marine invertebrates. Indeed, juvenile shore crabs and cuttlefish, which are particularly vulnerable to predators, thrive in the intertidal zone and coastal water. To study the effects of antidepressants at environmental concentrations, juvenile cuttlefish and crabs were exposed during 30 days to fluoxetine alone or in mixture with venlafaxine (i.e., 2.5 ng.L⁻¹ and 5 ng.L⁻¹). Behavioural test results showed an effect of the antidepressant on predation and camouflage. Now we investigate if VEN or FLX are bioaccumulated in these juvenile organisms at environmentally realistic concentrations. A former method from Robert et al. (2017) was updated to allow detecting and quantifying the two antidepressants at very low concentrations (pg.mg⁻¹). QuESChERS method was used for extraction and chemical analysis was done via LC-MS-MS.

**TP068 Can we say something about the bioaccumulation potential of molecules sharing the same chemical formula without knowing their exact structures?**

Z. Zhang, University of Toronto, Scarborough / Physical and Environmental Science; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

Non-target analysis (NTA) is rapidly gaining popularity as a screening-level analytical technique. Based on high-resolution mass spectrometry, it enables swift acquisition of thousands of mass spectra, thereby allowing for the detection of a wide array of chemical contaminants and their metabolites in environmental and biological samples. Oftentimes, it is relatively easier to obtain the chemical formula, i.e., the numbers of each type of atom in a molecule, but more demanding and time-consuming to elucidate their exact chemical structures one by one. Therefore, we need to prioritize the chemical formulae that are most likely to be “troublesome” (e.g., bioaccumulative) and hence need further elucidation of their exact structures. In this presentation, we will present a model-based method to automatize the prioritization of thousands of chemical formulae based on bioaccumulation potential, e.g., to what extent a chemical can be biomagnified along a food chain. In the meanwhile, we will establish how variable the bioaccumulation potential can be for isomers sharing the same chemical formula. For each of the chemical formulae detected in environmental samples (e.g., sediment), the approach makes it possible to enumerate a range of plausible isomers by extraction from the ChemSpider database or random generation from the Molgen model. The model predicts their partition coefficients between octanol, water and air using poly-parameter linear free energy relationship (pLFER) and the biotransformation half-life in biota using the automated Iterative Fragment Selection (IFS) algorithm. These parameters allow us to evaluate the bioaccumulation potential of individual isomers. Chemical formulae are ranked based on the number (or percentage) of isomers that are identified to be bioaccumulative. We found that the water/air (KAW) and octanol/air (KOA) partition coefficients predicted for one chemical formula can span over more than six orders of magnitude whereas the octanol/water (KOW) partition coefficient is much less variable. The biotransformation rate constants predicted for one chemical formula in both fish and humans span around two orders of magnitude. This work is the first effort that seeks to characterize environmental chemical bioaccumulation potential while by-passing the need for converting mass formulae to structure. It could direct future NTA studies to formulae that are predicted to have environmentally undesirable properties.

**TP069 Avoiding bias in human health and ecological risk assessments by using censored regression methods to develop tissue bioaccumulation models**

S.A. Roark, J. Gondek, A. Wilson Fallon, Jacobs Engineering Group Inc. / Global Environmental Services

The approach to handling left-censored results (i.e., non-detects) in co-located tissue and soil data sets, which are used to develop bioaccumulation regressions for predicting tissue concentrations from soil concentrations, may lead to unintended bias in risk estimates. Risk assessments for humans and upper trophic level wildlife frequently require estimates of contaminant concentrations in food or prey tissue. Ordinary least squares linear regression may be used to estimate food or prey tissue concentrations from environmental media concentrations if enough co-located data are available. If there are non-detects in the tissue, soil, or both, a decision about how to handle non-detects in the regression is needed. Despite the availability of censored regression methods, common practices have been to exclude the non-detects or substitute proxies for non-detects (e.g., using detection limit or one-half detection limit values). Censored regression methods, which estimate the regression using, for example, maximum likelihood estimates, account for the uncertainty about the actual values of the censored data. To explore the consequences of the selected approach, we evaluated the magnitude of bias that could be introduced into human or wildlife risk assessment by exclusion or substitution approaches. The outcomes of simplified upper trophic level wildlife risk estimates using various approaches to handling non-detects were compared using simulated data sets across a range of detection limits (i.e., proportions of censoring), regression slopes, and standard deviations. Monte Carlo simulations were used to develop confidence bounds on wildlife exposure and risk estimates under various scenarios. As expected, in data sets with few non-detects (e.g., < 5%), the approach to handling non-detects had little effect on the risk assessment outcome. However, when non-detects represented a substantial portion of the results (e.g., >25%) the approach to handling non-detects resulted in substantial bias. In our simulations, censored regression methods consistently yielded more accurate results (based on slope and intercept comparisons) than exclusion or substitution approaches. The magnitude of bias introduced by substitution methods and the accuracy of censored regression approaches depended not only on the proportion of non-detects in the data, but also on the slope and relative variability of the tissue-to-soil relationship.

**TP070 Quantifying Primary Sources of Variability in Laboratory Bioaccumulation Tests**

Bioaccumulation tests are a critical component of regulatory dredging evaluations. Standard bioaccumulation tests conducted in accordance with procedures outlined in the Ocean Testing Manual (OTM) and the...
Inland Testing Manual (ITM) utilize *Macoma nasuta* (a clam), *Alitta virens* (a polychaete) for marine tests and the oligochaete *Lumbricus variegatus* for freshwater tests. Tests are designed to detect statistical differences in tissue residues of dredged and reference sediment exposed test organisms. However simple statistical differences may not equate to biologically relevant differences, therefore it is important to understand the role of variability associated with test design (laboratory exposure and tissue chemistry) and provide guidance to ensure appropriate expenditure of resources for additional analysis only when biologically relevant differences have been established. While many labs have demonstrated capability to conduct bioaccumulation tests and many labs have demonstrated capability to quantify tissue residues, the interlaboratory variability associated with conducting exposures and quantifying resulting tissue residues in 28-day bioaccumulation tests has never been addressed. To quantify variability of laboratory bioaccumulation tests, the USACE-ERDC, the USGS-CERC and two commercial bioassay laboratories (EA and EcoAnalyt) participated in an interlaboratory evaluation. Marine (*M. nasuta* and *A. virens*) and freshwater (*L. variegatus*) species were exposed in standard 28-day bioaccumulation tests to marine and freshwater sediment, respectively, contaminated with low levels of PCBs (1-2ppm total PCBs) [LGRC(1)]. At test termination all participating labs provided resulting tissues to ERDC’s lab for analysis to enable quantification of exposure variability. In a separate, parallel experiment, the ERDC conducted a second set of 28-day *M. nasuta* and *A. virens* bioaccumulation tests utilizing the same marine sediment and exposure conditions and provided splits of the resulting tissue composite to ERDC’s in-house lab and three commercial analytical laboratories for purposes of quantifying analytical variability. Evaluation of variability associated with both exposure and tissue analysis will be summarized and the implications for determining biologically relevant differences in 28-day bioaccumulation tests discussed.

**TP071 Towards an improved understanding of the bioaccumulation and trophic transfer of microplastic particles**

*T. Gouin, TG Environmental Research / Safety and Environmental Assurance Centre*

Observations of microplastic particles (MPs) in the environment and their detection in the stomachs and intestines of aquatic organisms have been reported since the early 1970’s. Given that the size of MPs is in the same size range of the particles and prey ingested by suspension-feeding invertebrates, an argument has been proposed regarding the potential of microplastic to be consumed by organisms low in the food-web, which could then facilitate transport of MPs to higher trophic-level organisms. Whereas several studies continue to report microplastic in the gastrointestinal tract (GIT) of various species, strong evidence for a bioaccumulation process remains poorly understood for this methodologically challenging group of materials and there currently exists no systematic review that has been conducted to assess the issue related to the bioaccumulation of microplastic. The ingestion of particles of varying sizes for aquatic organisms can vary from species to species and is strongly influenced by physiological and behavioural traits that are related to the size of the organism and its feeding strategy. Consequently, some species may be susceptible to ingesting and accumulating MPs, however, there currently exists limited mechanistic understanding related to the potential of MPs to bioaccumulate. The bioaccumulation potential of MPs thus represents a concern to regulators assessing the environmental risks of MPs, as their bioaccumulation may result in internal levels that can impact both individuals and populations. The objective of this presentation is to summarize observations obtained from a critical review of the literature related to the biological uptake and bioaccumulation of MPs reported over the last 50 years in both aquatic and terrestrial species at all levels of biological organization. The critical review includes an assessment of the quality of the data associated with studies reporting biological uptake and bioaccumulation, a summary of trends with respect to size and types of MPs reported, guidance with respect to monitoring of species most sensitive to ingesting MPs and the potential for trophic transfer.

**Adverse Effects of Chemicals on the Microbiome**

**TP072 Unveiling the endangered St. Laurence Estuary beluga’s skin microbiome and its potential utility in halogenated flame retardant exposure monitoring**

*B. Jia, R. Lo, Simon Fraser University / Molecular Biology and Biochemistry; M.J. Allison, J.M. Round, C.C. Helbing, University of Victoria / Biochemistry & Microbiology; J. Verreault, University of Quebec, Montreal / Sciences Biologiques; F. Brinkman, Simon Fraser University / Molecular Biology and Biochemistry*

Multiple sources of contaminants (e.g. wastewater effluent, industry runoff) represent toxicological hazards to coastal organisms including marine mammals. Persistent and bioaccumulative chemicals such as polybrominated diphenyl ethers (PBDEs) are at high levels in the blubber of St. Lawrence Estuary belugas, posing a continuous threat to an already endangered population. Current beluga contaminant monitoring relies on skin biopsies, a highly invasive procedure that is challenging for the study of marine mammal populations. Skin microbiome analyses represent an innovative and non-destructive biomarker approach to monitor environmental toxicants and animal health. Presented here is a beluga skin microbiome analysis aimed to investigate the beluga skin microbiome communities, understand the relationship between biopsy contaminant concentrations of halogenated flame retardants and the skin microbiome and, to identify potential biomarkers for early detection of altered ecosystem health. Biopsy samples were collected from the dorsal regions of adult belugas and analyzed for the concentrations of 35 PBDEs and 13 emerging halogenated flame retardants. The skin microbiome was obtained by swabbing the beluga skin, extracting bacterial DNA collected, and performing 16S amplicon-based DNA sequence analysis. A total of 117 samples, including skin swabs, sea water controls and sequencing controls, were sequenced using Illumina MiSeq technology, and amplicon sequence variants identified and assigned to a taxonomy profile using Qiime2. Further metadata analysis, including contamination-microbiome differential abundance analysis, was initiated using the taxonomic profiles of the skin microbiomes, sample metadata, and contaminant metadata. Skin microbiome analysis revealed that belugas have their own distinct skin microbiome, which differs from the surrounding seawater. There were no significant differences between the skin microbiome of male and female belugas nor at different geographic regions within the estuary. However, notably, we identified several bacterial taxa at the phylum and genus level that were strongly correlated with concentrations of certain contaminants. These warrant further investigation as potential biomarkers. Results to date do suggest a potential utility of skin microbiome analysis for non-invasive monitoring of contaminants in belugas that warrants further study as a tool to aid investigation of such species at risk.

**TP073 The Binding of Antidepressants to Analogous Transporters on Neurons and Bacterial Cells, What Might this Mean for Gut Microbiota?**

*A. Weber, A. DeBofsky, University of Saskatchewan / Toxicology Centre; M. Sniatyński, J. Rubin, University of Saskatchewan / Department of Veterinary Microbiology; J.K. Challis, University of Saskatchewan / Toxicology Centre; M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences*

Pharmaceuticals such as serotonin reuptake inhibitors (SSRIs) can be found downstream of wastewater treatment plants. Studies are continuously being conducted to elucidate the impacts these contaminants may have on aquatic organisms. With recent understandings of a microbiome-gut-brain axis and the ability of bacteria to synthesize and transport biogenic amines, such as serotonin, it is useful to understand how SSRIs may also influence the relationship between aquatic organisms and their gut microbiomes. Inhibition of bacterial growth cultured from the gut of *P. promelas* when exposed to fluoxetine, a common SSRI, has been
observed. In order to better understand the mechanisms of inhibition, we propose to first assess if these bacteria hold the sodium symporters: uptake-2 plasma membrane monoamine transporter (PMAT) and the organic cation transporter (OAT), encoded within the same solute carrier gene family as the serotonin reuptake transporter (SERT) found on neurons and other host organism cells. This study will be conducted using five bacteria species cultured from the gut of *P. promelas*, and a fluorescence-based assay consisting of fluorophores that mimic serotonin which can be taken up into the cells specifically by OAT and/or PMAT. If fluorescence is observed, it can be acknowledged that the bacteria cells carry the applicable sodium symporters. Furthermore, an exposure of the same bacterial species to fluoxetine and the fluorophores will be performed to identify whether fluoxetine is binding to OAT and/or PMAT resulting in inhibition of growth. This study should allow for identification of sodium symporters on the bacteria cells being investigated and determine if fluoxetine is impeding growth of the bacteria by binding to these transporters. This preliminary data is crucial in understanding how the SSRI, fluoxetine, may cause dysbiosis of gut microbial communities, potentially influencing fish homeostasis. For further insight into how fluoxetine effects the intestinal microbiome, future research will be conducted to identify perturbations of the gut microbiome of *P. promelas* due to fluoxetine exposure in vivo.

**TP074 The sub-chronic effects of polycyclic aromatic hydrocarbons (PAHs) on the sheephead minnow gut-microbiome and foraging behavior**

*M. Wigren, M.S. Sepulveda, Purdue University / Department of Forestry and Natural Resources; T.A. Johnson, Purdue University / Animal Sciences; R.J. Griffitt, University of Southern Mississippi / Coastal Sciences*

The microbiome plays a key symbiotic role in maintaining host health and aids in acquiring nutrients, supporting development and immune function, and modulating behavior, therefore protecting the host from opportunistic pathogens and other environmental stressors. Microbial communities can vary in species composition and have functionally different roles depending on their location within the host. However, more research is needed to elucidate the potential impact of environmental pollutants on microbial communities and how they can mediate toxicity to the host. Recent studies have shown that contaminants can change the composition and function of vertebrate microbiomes with some evidence showing a shift towards species that are capable of degrading specific chemicals. The Deepwater Horizon disaster that occurred in April 2010 was the second largest oil spill in history and had catastrophic effects on several ecologically important fish species in the Gulf of Mexico. This study aims to determine if exposure to weathered oil will affect the abundance and composition of fish gut-associated microbiomes as well as foraging behavior. We accomplished this by sequencing the gut microbiome of a native Gulf estuarine species, the sheephead minnow (Cyprinodon variegatus). Fish were exposed to oil within HEWAF (High Energy Water Accommodated Fraction) over a 7-day period and whole gastrointestinal tracts were sampled for microbiome analyses. Fish also underwent a foraging behavioral assay to determine feeding efficiency before and after the 7-day exposures. We predict that microbes involved in degrading polycyclic aromatic hydrocarbons (PAHs) will increase in abundance, and that foraging behavior will become less efficient, potentially due to microbiome dysbiosis.

**TP075 Soil Acidiﬁcation Accelerates Nitrogen Loss via Anaerobic Ammonium Oxidation Coupled With Ferric Reduction**

*D. Ma, Tongji University; H. Gao, Tongji University / College of Environmental Science and Engineering; X. Lu, Peking University*

Long-term application of nitrogen fertilizer in agricultural leads to gradual acidification of soil, but nitrogen loss in acidified soil has less attention. Anaerobic ammonium oxidation coupled to iron reduction (Feammox) is a recently discovered pathway contributing to nitrogen loss in various ecosystems such as paddy soils. However, little is known about the Feammox under soil acidification in an agricultural ecosystem. Meanwhile, the specific approach of Feammox is still not clear. Here, Feammox has been demonstrated in the red clay of Southwest China using 15N isotopic tracing technique, and mechanisms of Feammox under acidic conditions have been clarified. Results showed that the potential N losses linked with Feammox was 0.94 ± 0.08 mg N kg⁻¹ d⁻¹ and Feammox accounts for 86.2% of total N losses under acidic conditions. This rate was significantly higher than that at higher pH values treatments. Microbiological data suggested that a significant increase in the abundance of *Clostridium* and *Acidimicrobiaceae* under acidic conditions which possibly involved in ammonia oxidation and NOX⁻ reduction. Based on the results of the prediction of abundance of functional gene contents, the functional categories of nitrate and nitrite reduction or transfer were significantly higher under acidic conditions. Ammonia may firstly be oxidized into NO2⁻ by microbial and then reduced to N2 by Fe(II) by reduct reaction and it could be the mechanism of Feammox under low pH conditions. Overall, this study evaluated the potential rate of N loss via Feammox and demonstrated Feammox made an important contribution to N loss in acidic soils.

**TP076 Sub-chronic dietary exposure to the organochlorine pesticide dieldrin alters the gut microbiome of zebrafish (Danio rerio)**

*H. Qing, Inner Mongolia University / Inner Mongolia Key Laboratory of Environmental Pollution Control & Waste Resource Reuse / School of Ecology and Environment; O. Adamovsky, Masaryk University, RECETOX / RECETOX; J. Boyda, U Florida / Department of Physiological Sciences, College of Veterinary Medicine; J. Schmidt, University of Florida / Physiological Sciences; M. Kozuch, University of Florida / Center of Environmental and Human Toxicology; S.L. Craft, P. Ginn, University of Florida / Department of Comparative, Diagnostic and Population Medicine / College of Veterinary Medicine; J.H. Bisesi, University of Florida / Environmental and Global Health; C.-J. Martyniuk, University of Florida / Physiological Sciences*

The gastrointestinal (GI) system is the first line of defence for dietary exposures to environmental contaminants. Long-term ingestion of chemicals can lead to GI pathology and an altered microbiome. This is important as gut dysbiosis is significantly associated with animal and human disease. The organochlorine pesticide dieldrin is a legacy environmental contaminant, accumulating in tissues of organisms. Dieldrin is lipophilic and bioaccumulates up through trophic levels, resulting in significant dietary exposures. The objectives of this study were to determine how environmentally relevant levels of dieldrin affected gut morphology and its microbiome in zebrafish. Adult male zebrafish (AbTu strain) beginning at 5 months of age were fed a measured amount of pelleted feed of either control or dieldrin (measured at 16 ng/g and 163.5 ng/g dry weight). Zebrafish in the three experimental groups did not show any difference in weight gain over 4 months. Body burden levels of zebrafish at the end of the exposure were 10.8 ng/g and 18.32 ng/g wet weight (10x and 20x above background levels). Dietary exposure to dieldrin did not induce any notable gut pathology. The gut content was extracted from males in each group and 16S rRNA sequencing conducted, followed by QIIME analysis pipeline. Interestingly, dieldrin fed to fish at 16 ng/g lowered the abundance of Firmicutes, bacteria involved in energy resorption, and one that is common to many disease states (e.g. diabetes, obesity). Detailed evaluation on class level revealed a decrease in Clostridia (class of Firmicutes), Betaproteobacteria and Verrucomicrobiae species following dieldrin treatment. Changes in the abundance of these microorganisms are observed in many human diseases. Approaches are ongoing to annotate the observed changes in microbiome composition with predicted effect on bacterial bioactive metabolites. This study demonstrates that low dose exposure to dieldrin can dysregulate the microbiome-host axis, however the long-term impacts of gut dysbiosis on fish health remain unknown.
TP077 Impacts of emerging short-chain PFASs on fatty acid metabolism and the microbiome

C.A. Ng, S.J. Haig, University of Pittsburgh / Civil & Environmental Engineering; S. Wendell, University of Pittsburgh / Pharmacology & Chemical Biology; J.C. DeWitt, East Carolina University / Pharmacology & Toxicology

There is growing concern over long-term chronic exposure to per- and polyfluorinated alkyl substances (PFASs), a group of >4000 chemicals widely used in consumer and industrial products. PFASs have become ubiquitous contaminants in drinking water and food, and are associated with increases in serum total cholesterol in adults, reduced birth weight, and decreased antibody response to vaccination in children. A leading hypothesis for why PFASs are bioavailable and interact with many biological targets is that they mimic endogenous fatty acids and hence may interfere with their metabolism. This study is investigating, at a mechanistic level, how PFASs interact with the gut microbiome and its role in fatty acid metabolism. We hypothesize PFASs may disrupt lipid metabolism by interfering with the processing of essential short-chain fatty acids (SCFA) or by disrupting the gut microbiome. To test this hypothesis, we have leveraged a suite of innovative molecular tools, including lipidomics, droplet digital PCR (ddPCR), and 16S rRNA sequencing, using the mouse as a model organism. Male and female C57BL/6 inbred mice have been exposed to several short-chain perfluorinated alkyl ethers and one short-chain perfluoroalkyl acid. The chemical structures of these short-chain acids suggest they may compete with or inhibit short-chain fatty acids produced by gut bacteria such as butyrate, a 4-carbon fatty acid with key neuroprotective and nutritional roles. In this talk we will present initial results from our integrative analysis of how PFAS exposure changes the composition of the gut microbial community using ddPCR and sequencing. We will also discuss the use of liquid chromatography high resolution mass spectrometry (LC-HRMS) to probe differences in microbiome function with PFAS exposure, including how we can probe the extent to which PFASs participate in and alter fatty acid metabolism pathways. This study seeks to establish, for the first time, PFAS-microbiome interactions in adult mice and also develop novel lipidomic methods to trace impacts on fatty acid metabolism, focusing on PFASs of unknown toxicity and of high relevance to ongoing drinking water contamination.

TP078 Evaluating the viability of microbial viability assays for the microbiome of the built environment

L. Wang, Y. Yan, K. Thompson, T. Hsu, C. DuLong, Harvard University / T.H. Chan School of Public Health / Department of Biostatistics; H. Vlamakis, Broad Institute of MIT and Harvard / T.H. Chan School of Public Health, Department of Biostatistics; C. Huttenhower, Harvard University / T.H. Chan School of Public Health, Department of Biostatistics

The microbiomes of built environments are a major route by which humans are exposed to both commensal and pathogenic microbes. Despite growing interest in these microbiomes, elucidation of their community structures and mechanisms of transmission to humans are challenged by an inability to distinguish viable microbes from relic DNA. Previous studies have used pre-treatment of samples with propidium monoazide (PMA) coupled with downstream molecular profiling (e.g. qPCR or DNA sequencing) to attempt to characterize the viable fraction of a microbial community. While these studies have met with some success, most have focused entirely on synthetic communities and failed to validate their read-outs. Here, we describe our ongoing efforts to rigorously benchmark “PMA-seq” (PMA treatment followed by 16S rDNA amplicon sequencing) as a screen for microbial viability in a combination of synthetic and natural microbial communities. Our first validation experiment focused on synthetic mixtures of living and heat-killed Escherichia coli and Streptococcus sanguinis. Here, we were able to successfully reconstruct the communities of live/dead E. coli and S. sanguinis using PMA-seq. Next, to test the effects of biomass and sample diversity on PMA-seq, we sampled communities of variable initial biomass (computer mice and screens, soil, and saliva) and combined them with known mixtures of living and dead E. coli as internal controls. These trials demonstrated sub-optimal performance, especially at high biomass, suggesting that further protocol tuning is needed. Once this is complete, we will apply PMA-seq to unspiked environmental samples from the Boston subway system (seats, grips, and ticketing touchscreens) to identify and quantify living microbes in that environment. This is the first study to employ a comprehensive evaluation of the performance of PMA-treatment to test the viability of microbes in built environments. In the future we will conduct additional testing of PMA-seq on high biomass and diverse communities of microbes, as detailed above. Further work will plan to expand our work to include other methodologies used in human research to distinguish active vs. dormant microbes, such as RNA-seq. Detection of viable microbes within a community will allow for further elucidation of interactions between different microbes and with the ecosystem/host, potentially furthering our knowledge of the interplay between the environment and human health.

Toxicity Beyond PAHs: New Insights Into Effects of Weathered Oil After Spills

L.A. Kristofco, Chevron; T. Patterson, Chevron Energy Technology Company; C. Espino Devine, Chevron; R. Mohler, Chevron Energy Technology Company; N. Sihota, R. Magaw, Chevron Energy Technology Company; D.A. Zemo, Zemo & Associates; K. O’Reilly, Exponent, Inc.; S. Ahn, Exponent / Environmental and Earth Science

Thousands of petroleum hydrocarbon compounds are present in mixtures in petroleum releases and this presents challenges for attributing hazard (toxicity) at spill sites. Non-targeted GCxGC-MS analyses of historically impacted groundwater have tentatively identified more than 1,000 unique polar metabolites that include acids/esters, alcohols, phenols, ketones, and aldehydes. Our goal was to better elucidate the toxicity attributable to petroleum biodegradation metabolites in groundwater at petroleum release sites. The potential aquatic toxicity of biodegradation metabolites was thus investigated in three ways. 1) Individual components’ toxicity was estimated through the development of a relative ranking system. Here, metabolites chemically identified in groundwater plumes were grouped into 5 families (i.e. alcohol) and 22 classes (i.e. alkyl alcohol), and searched for in reference dose (RfD) databases. Resulting RfDs were compared to regulatory guidance thresholds and ranked (i.e. low, moderate, high). Chemical families corresponding to higher degradation tended to have lower risk rankings. 2) In vitro tests were run on groundwater samples. Eight (8) groundwater samples that represented upgradient (local background conditions) and downgradient (intending to contain metabolites but not hydrocarbons) groundwater were collected and submitted to a laboratory for chronic aquatic toxicity tests as well as in vitro genotoxicity and endocrine assays. Chronic aquatic toxicity bioassays included EPA method 1000 (Pimephales promelas; survival and growth) and EPA Method 1002 (Ceriodaphnia dubia; survival and reproduction). No consistent changes between upgradient and downgradient samples for aquatic toxicity, genotoxicity, or estrogen receptor activity were observed. 3) In vivo bioassay results were complimented by computational toxicology approaches. Similar to the risk ranking, ecotoxicological data was pulled from the European Union’s chemical registration database (QSAR Toolbox 4.2 software; OASIS LMS) for identified metabolites. The literature query yielded empirical studies on invertebrate and vertebrate aquatic toxicity data that suggests decreasing aquatic toxicity along the hydrocarbon degradation pathway and with decreasing alkyl chain length. Finally, the bioaccumulation potential of various compounds along the degradation pathway were modeled to better understand the potential risk of accumulation up the food chain.
TP080 Modeling Analysis of the Importance of Photo-oxidation to Oil Weathering, Water Column Exposure and Aquatic Toxicity
D.P. French-McCay, A. Dissanayake, RPS Ocean Science

Oil weathering and fate processes (evaporation, photo-oxidation, dispersion by turbulence and dispersant use, dissolution, biodegradation, sedimentation) modify the chemical composition of floating oil, affecting aquatic exposure and toxicity in surface waters. During periods of calm winds, evaporation quickly removes the volatiles and semi-volatiles in the original spilled oil, leading to little water column exposure and toxicity. However, during windy periods much more oil is entrained, increasing dissolution and exposure of surface water biota to PAHs and other semi-volatile and semi-soluble compounds. Photo-oxidation changes the composition of the surface oil, creating polar products that dissolve more readily than their precursors during these entrainment events, as well as during calm periods. This implies that photo-oxidation may increase the effects of oil on surface water biota over and above the known effects of photo-oxidation of PAH toxicity on clear-bodied organisms. However, the balance of formation rates of photo-oxidized products with dissolution, physical dispersion and biodegradation determines the degree of exposure and their effects on biota. Modeling analyses using pseudo-components representing the fate of various hydrocarbon groups and oxidation products, along with toxicokinetic modeling of narcotic effects, demonstrates the relative importance of photo-oxidation products in contributing to exposure and toxicity, as compared to compounds originating in the oil and photo-enhanced toxicity from PAHs.

TP082 Ten years Biomarker Monitoring Following the M/V Hebei Spirit Oil Spill in Korea -Biochemical Responses in Pelagic and Benthic fish
J. Jung, M. Kim, U. Yim, S. Ha, J. An, Korea Institute of Ocean Science and Technology / Risk Assessment Research Center; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group

After the M/V Hebei Spirit oil spill incident (7th December, 2007) in the west coast of Korea, contamination of biliary PAH metabolite and hepatic biomarkers in a pelagic and a benthic fish was monitored for ten years. Concentrations of 16 PAHs and alkylated PAHs in fish muscle were highest (22.0 ng/g d.w. for 16 PAHs and 284 ng/g d.w. for alkylated PAHs) at 5 days after the spill and then decreased rapidly to background levels at 11 months after the spill. Elevated levels of biliary PAH metabolites and EROD activity were found in fish collected from areas affected by the oil spill immediately after the spill. Biochemical responses based on hepatoxidation (CYP1A mRNA, CYP1A protein, and EROD) showed a significant relationship with the concentrations of biliary PAH metabolites in resident fish. The biochemical responses of pelagic and benthic fish to petrogenic PAHs exposure resulting from the HSOS were generally similar to those observed following other large oil spills. The physiological recovery of resident benthic fish was slower than that of pelagic fish. The slower recovery of benthic fish is possibly due to feeding habits on contaminated benthic organisms.

TP083 The biodegradation of dispersed oil does not induce toxicity
R. Prince, Stonybrook Apiary; B. Hedgemoth, ExxonMobil Biomedical Sciences, Inc. / Toxicology and Environment Science Division; A. Redman, ExxonMobil Petroleum and Chemical / Toxicology and Environment Science Division; J. Butler, ExxonMobil Biomedical Sciences, Inc. / Environmental Toxicology and Chemistry Laboratory

The acute toxicity of dispersed oil is well understood, and oil dilutes to levels below those of acute concern within hours of dispersion whether oil is dispersed by high energy waves or with lower energy turbulence in the presence of chemical dispersants. Nevertheless, concern has been raised that the subsequent biodegradation of the dispersed oil might increase the acute toxicity by generating and releasing toxic by-products. We show here, using Americamysis bahia as the test species, that this does not occur. In the 16 days after dispersion, the indigenous microorganisms in seawater collected from the New Jersey shore removed 78% of the detectable hydrocarbons in a lightly weathered light oil. Sequential 96hr acute toxicity tests during this process showed no mortality.

TP084 The effects of the Deep Water Horizon oil spill on marine algae - A comparison of species sensitivity to field-collected source oil
K.A. Softechek, Smithers Viscient, LLC / Ecotoxicology

Limited algal toxicity data have been generated with crude or weathered oils as part of oil spill response and impact assessment activities. Smithers conducted a series of toxicity tests using four standard microalgae and one macroalga species: Dunaliella tertiolecta, Skeletonema costatum, Isochrysis galbana, and Thalassiosira pseudonana, and Ectocarpus siliculosus. Eight toxicity tests with Dunaliella and Skeletonema, and four each for Isochrysis, Thalassiosira, and Ectocarpus were conducted with field-collected source and weathered oil samples collected during the Deepwater Horizon (DWH) MC252 Spill of National Significance. A portion of the data was evaluated to compare the sensitivity of the five algal species tested to one of the field-collected source oil samples from the Gulf of Mexico after the DWH oil spill. As crude oils are mixtures of poorly water soluble hydrocarbons, exposures of weathered oil water-accommodated fractions (WAFs) were conducted at nominal loading concentrations of 100, 50, 25, 13, and 6.3% of a 1000 mg/L or 1.0 mL/L(oil) solution. Exposure solution samples were collected at the beginning and end of each exposure or renewal period for chemical analysis of volatile organic compounds (VOCs), parent and alkylated polycyclic aromatic hydrocarbons (PAHs), and saturated hydrocarbon compounds (SHCs). The toxicity of the oil sample was determined and evaluated on the basis of No-Observed Effect Concentration (NOEC) values based on average specific growth rates. The results of the toxicity tests were determined based on the nominal loading percent WAF based on the dissolved sum of toxic unit (ΣTUs) of the whole oil.

TP085 The Freshwater Oil Spill Remediation Study (FOReSt) - Examining minimally invasive remediation methods for oil spills
V. Palace, IISD-Experimental Lakes Area; G.T. Tony, L.E. Peters, University of Manitoba / Department of Chemistry; M.L. Hanson, University of Manitoba / Department of Environment and Geography; V.S. Langlois, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; J.E. Smith, University of Calgary / Ecosystem and Public Health; C.W. Greer, National Research Council Canada / Energy, Mining and Environment; T. Shanoff, Stantec Consulting, Ltd.

Potential environmental impacts of oil spills are a concern for the Canadian public and the oil industry. There is also uncertainty on the part of regulators and the scientific community on which methods are best to employ when cleaning up oil spills in different environments. Improving the clean-up procedures, and demonstrating their effectiveness under realistic field situations is required. In 2018, the International Institute for Sustainable Development-Experimental Lakes Area (IISD-ELA) began a collaborative program to examine the fate and behaviour of diluted bitumen (dibit) and conventional heavy crude oil in the freshwater shoreline environment. In 2018, model oil spills in contained shoreline environments (15 X 2.5m) were used to quantify the efficiency of immediate product recovery and then to compare degradation via Monitored Natural Recovery (MNR) of residual oil constituents. Basal degradation rates of residual (i.e., after initial clean-up) weathered conventional crude and dibit were determined by assessing concentrations of oil constituents in water, sediment, and soil, including polycyclic aromatic compounds (PAHs) and their alkylated analogues (alkyl-PAHs). Microbial community shifts appeared to respond to the presence of oil and potential impacts of residual oil were evaluated at multiple trophic levels over a period of 16 weeks. Degradation trajectories were significantly different for dibit and conventional heavy crude oil in the low energy shoreline environments. Results form the 2018 pilot study were used to design a larger study being performed in 2019 that focuses on comparing the efficacy of oil removal using nutrient additions, a shoreline cleaner, and engineered floating wetlands relative to natural attenuation.
TP086 The toxicity of oil photo-products from Macondo oil to Gulf killifish embryos

F. Galvez, Louisiana State University / Dept of Biological Sciences; C. Aeppli, Bigelow Laboratory for Ocean Sciences; C. Ward, Woods Hole Oceanographic Institute; C. Campbell, C. Hess, Louisiana State University / Biological Sciences

Oil spill risk is assessed solely on a limited number of measured compounds, usually the polycyclic aromatic hydrocarbons (PAHs). However, research on the Deepwater Horizon Incident suggests that solar radiation transformed over 50% of the mass of the PAHs in surface slick oil into photo-products within weeks of the spill. Current research is attempting to advance the scientific understanding of oil photo-product risks by producing comprehensive data on the bioavailability and dose-dependent toxicity of these compounds. Using a solar simulator, laboratory-weathered Macondo oil (i.e., dark control) was irradiated. This light-exposed oil (i.e., total irradiated oil) was separated on a silica gel into a saturated aromatic fraction and a polar fraction. The dark control, the total irradiated oil, and the saturated aromatic and polar fractions of the total irradiated oil were exposed to Gulf killifish embryos to assess the bioavailability and toxicity of each fraction. Preliminary work attempted to develop an oil exposure regime that generated large volumes of oily water of each oil fraction for continuous-flow exposures. Based on these preliminary experiments, a custom-dosing regime was developed consisting first of the generation of oily-water effluents prepared by passing brackish water through oily gravel contained in a glass desorption column at 4 °C. Following collection of the oily effluents from the glass columns, these oily waters were then used as stocks to create serially-diluted concentrations for use in toxicity testing on Gulf killifish embryos. Water chemistry was characterized using a two-dimensional gas chromatography method to identify and quantify oxygenated PAHs, carboxylic acids, and ketones from their parent compounds. We also used a solid-phase microextraction method to determine the bioaccumulation potential of each oil type. Finally, we evaluated biological responses and toxicity of these oily fractions in Gulf killifish over a 21-day exposure period. Results from this study will be used to examine the importance of photo-products with respect to exposure and toxicity to aquatic biota.

TP087 Toxicity Assessment of Hydrocarbon and Polar Components of Groundwater Plumes at a Terrestrial Crude Oil Spill Site

Nearly forty years after an oil pipeline rupture spilled 1.7 million liters of light crude into the adjacent sandy soil near Bemidji, Minnesota, groundwater contamination of the underlying aquifer continues to be evaluated. Biogeochemical processes and hydrologic transport of the parent petroleum hydrocarbons and their more soluble transformation products at this site have been the focus of extensive research since the time of the spill. The objective of this study was to provide an initial evaluation of potential toxicity of petroleum hydrocarbons and their polar metabolites currently found in groundwater at the site. Groundwater sampling included six wells along a gradient of hydrocarbon and polar metabolite contamination; ranging from a background reference well to hydrocarbon-dominated contamination to metabolite-dominated contamination. Toxicological characterizations included cell-based (aryl hydrocarbon receptor, AhR) transactivation assays and fathead minnow embryo developmental assays. Endpoints evaluated in the embryo assays included total body length, pericardial area, blood circulation, hatching rate, and survival. This array of sublethal endpoints allows for targeted assessment of toxicity. Dose-response relationships were generated for the cell-based assays and the in vivo embryo developmental assays. In vitro potency estimates indicated AhR activity in the metabolite portion of the plume, as well as in the hydrocarbon portion of the oil plume.

TP088 Toxicity of Gasoline, Diesel and Weathered Diesel Related Petroleum Hydrocarbons to Freshwater and Marine Organisms

The purpose of this study was to determine environmental effects-based concentrations of total petroleum hydrocarbons for assessing the impacts of fresh gasoline and fresh or weathered diesel in the freshwater and marine environments. The study was conducted by the Washington State Department of Ecology (Ecology) and Nautilus Environmental to determine the no-observed effects concentration (NOEC) and lowest-observed effects concentration (LOEC) of gasoline (C7-C12), diesel (C10-C24) and weathered diesel, in addition to IC25 and IC50 endpoints, using aquatic toxicity bioassays. This presentation compares results obtained with weathered diesel in groundwater from a contaminated site with previous results obtained with fresh gasoline and diesel. In separate experiments, hydrocarbons within either the diesel or gasoline range were spiked into toxicity test solutions and weathered diesel in contaminated groundwa- ter was obtained from a well-characterised site in Washington State. Petroleum mixtures were tested with two freshwater and two marine organisms. Freshwater organisms were the fathead minnow (Pimephales promelas) and a cladoceran (Ceriodaphnia dubia). Topsmelt (Atherinops affinis) and the echinoderm, purple sea urchin (Strongylocentrotus purpuratus) were the marine species tested. Tests were conducted according to USEPA test methods and Ecology’s whole effluent toxicity (WET) guidance document or “Canary Book” (Marshall, R., 2016). Publication No. WQ-R-95-80. Aquatic toxicity tests were conducted at Nautilus Environmental in Burnaby, BC. Hydrocarbon concentrations in toxicity test solutions were measured using Northwest Total Petroleum Hydrocarbon - Gasoline/Diesel (NWTPH-Gx and NWTPH-Dx) Methods at the Manchester Environmental Laboratory, Port Orchard, WA. Gasoline caused similar toxicity between topsmelt, fathead minnow and Ceriodaphnia, which were more sensitive than the echinoderm. The most sensitive endpoint for gasoline was fathead minnow biomass IC25 1.5 (1.2 - 1.7) mg gasoline/L with NOEC 1.0 and LOEC 2.1 mg gasoline/L. Diesel was generally more toxic than gasoline to all test organisms. The order of toxicity from most to least for diesel was as follows: echinoderm < cladoceran > topsmelt > fathead minnow. The most sensitive endpoints for diesel were: the cladoceran IC25 reproduction, 0.17 (0.16 - 0.19) mg diesel/L with NOEC 0.15, and LOEC 0.22 mg diesel/L. With the weathered diesel tests, this pattern changed. The fish became the more sensitive organisms, and the invertebrates were relatively insensitive to the groundwater concentrations of weathered diesel that we tested. All test organisms were generally less sensitive to the weathered diesel compared with fresh diesel. This may indicate that volatile compounds present in the fresh diesel may be responsible for greater toxicity to the organisms and in particular, the invertebrate species.

TP089 Weathering reduces the partitioning of hydrocarbons from oil trapped in river sediments but not the bioavailability of polycyclic aromatic compounds

J. Adams, Queen’s University / School of Environmental Studies; R.S. Brown, Queen’s University / Department of Chemistry; P.V. Hodson, Queen’s University / School of Environmental Studies

Oil spilled in rapidly flowing and turbulent rivers will be dispersed in the water column and may be entrained into bed sediments by hyporheic flows associated with pressure gradients caused by variable riverbed forms. Once filtered by bed sediments, hydrocarbons in trapped oil will partition into interstitial waters that support the development of fish eggs deposited in gravel by spawning salmon and other fish species, causing a risk of toxicity and recruitment failure due to components such as polycyclic aromatic hydrocarbons (PAHs). However, the extent of gravel contamination decreases as oil viscosity increases. Highly viscous heavy
New and Existing Chemical Contaminants in Changing Arctic and Antarctic Environments

TP090 Persistent Organic Pollutants (POPs) and Emerging Chemicals of Arctic Concern in Canadian Arctic Air
H. Hung, F. Wong, H. Dryfhout-Clark, Environment and Climate Change Canada / Air Quality Processes Research Section; E. Barresi, Environment and Climate Change Canada / National Laboratory for Environmental Testing; E. Sverko, Harbin Institute of Technology; P. Fellin, AirZone One, Ltd.

Canada's Northern Contaminants Program (NCP) monitors for persistent organic pollutants (POPs) and other Chemicals of Emerging Arctic Concern (CEAC) in air at the High Arctic station of Alert, Nunavut (82°30'N, 62°20'W) since 1992. Air samples were screened for emerging contaminants, including halogenated flame retardants (HFRs), neutral and ionic per- and polyfluoroalkyl substances (PFASs) and other CEAC, to assess the long-range transport potential (LRTTP) of these compounds in support of chemical control initiatives. Temporal trends of POPs, HFRs and PFASs in the air are derived up to 2016 to better understand and evaluate the effectiveness of national and international regulations. Most legacy POPs are showing declining trends in Arctic air. POPs that are recently listed under the Stockholm Convention have started to show declining tendency in air. However, a time lag in declining trends for recently-regulated chemicals is observed. Many HFRs, which are used as replacement chemicals for polybrominated diphenyl ethers (PBDEs), are frequently detectable in Arctic air. The current study will explore the various factors affecting atmospheric levels of POPs and CEAC in Arctic air including chemical control regulations, source changes and effects of climate change.

TP091 Organotin contamination in the Arctic and subArctic environment
J.R. Kucklick, National Institute of Standards and Technology / Chemical Sciences Division; M. Ellisor, O2SI Smart Solutions an LGC Standards Company

The occurrence of organotins (OTs), particularly tributyl tin (TBT), in the marine environment has been widely studied in many regions across the globe. Research and monitoring in areas with high ship traffic, where historically TBT was used in antifouling coatings, has linked certain OTs with biological impacts particularly in invertebrates. In the Arctic and Subarctic, OTs are of continued concern as they are still widely used despite TBT being restricted from use on most marine vessels. The highest OT concentrations found in Arctic fauna are in regions associated with human activity especially marine transportation. There is an overall trend of declining butyl tin (BT) concentrations in Arctic fauna especially moluscs which are the subject of a limited number of long-term monitoring studies. The incidence of imposex has likewise generally declined in moluscs in response to declining TBT concentrations. There are a number of knowledge gaps in OT occurrence and transport in the Arctic that warrant continued monitoring. OTs, in particular octyl tins, are heavily used in the production of plastic, hence leaching from plastic may be an unrecognized source to Arctic regions. This review also found several studies reporting volatile tin species in the atmosphere suggesting atmospheric transport of volatile tins to the Arctic is possible. Relative to other more well known persistent organic pollutants, there are few reports of OTs in marine mammals and temporal tend studies are needed to define trends in BTs and search for the occurrence of other tin species.

TP092 Understanding the long-range transport of Perfluoroalkyl Substances (PFAS) using a High Arctic ice core
D. Persaud, York University / Chemistry; A. Criscitiello, University of Alberta; I. Lehnherr, University of Toronto Mississauga / Department of Geography; C. Spencer, Environment and Climate Change Canada / Water Science Technology Directorate; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; C. Young, York University / Department of Chemistry

Poly- and perfluoroalkyl substances (PFAS) are extremely persistent and bioaccumulative compounds that are distributed ubiquitously in the environment. They can be formed from the atmospheric oxidation of volatile precursor compounds or directly transported in their acidic form through the atmosphere and oceans to remote locations. Ice caps are commonly used to study temporal trends of contaminant since these elevated locations are expected to receive deposition solely from the atmosphere where they preserve a record of contamination. To improve our understanding of long-range transport (LRT) mechanisms to the High Arctic, a 15-meter ice core representing an accumulation period of forty-eight (48) years (1968-2016) was collected from the ice field adjacent to Mt. Oxford on northern Ellesmere Island, Nunavut, Canada at an exact location of 84.2°N, 73.8°W. Samples were concentrated using solid phase extraction (SPE) and analyzed by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Ion chromatography-mass spectrometry (IC-MS) analysis will also be performed on sub-samples to determine major ions. Both perfluorocarboxylic acids (PFCAs) and perfluoroalkyl sulfonic acids (PFSA) are present in the ice core with interannual variations. This data will be compared to an ice core collected at 75.2°N, 82.7°W (Devon Island Ice Cap, Devon Island, Nunavut, Canada) to confirm our previous findings. The current ice core provides ten (10) additional years of deposition record and is located at a higher latitude close to suspected emission sources.

This data will be used to better understand transport mechanisms, pollutant sources and production changes of PFAS.

TP093 Using Ice and Sediment Cores to Quantify Climate-Warming Induced Inputs of Legacy Mercury to Lake Hazen, Nunavut
D. Lemire, University of Toronto Mississauga / Geography and Planning; I. Lehnherr, University of Toronto Mississauga / Department of Geography; C. Young, York University / Department of Chemistry; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; A. Criscitiello, University of Alberta / Earth and Atmospheric Sciences; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; S. Varty, University of Toronto Mississauga

Mercury (Hg) emitted from anthropogenic sources can undergo long-range atmospheric transport to the Arctic where it may cause health concerns for Arctic wildlife and indigenous people. Many sediment records do not show a clear decline in Hg deposition despite estimates that Hg emissions from anthropogenic sources have recently stabilized or declined, suggesting that Hg is being remobilized in catchments and delaying the recovery of lakes following emission reductions. To date there is little data on whether the input of legacy Hg increases Hg accumulation in lakes. We hypothesize that the climate-warming induced melting of glaciers may be remobilizing legacy Hg from glaciated watersheds into downstream lakes, providing an important subsidy of Hg in addition to modern Hg inputs. To test this hypothesis, we will compare Hg accumulation rates through time measured in an ice core and sediments cores collected from the Lake Hazen watershed, Nunavut, Canada. By comparing ice and sediment core data, we can determine
TP094 Disentangle local and remote contamination in fjord ecosystem of the high Arctic: The Kongsfjorden (Svalbard, Norway) as model system

Arctic fjord ecosystems are linked intimately to the dynamics of sea/ice, input of glacial melting water and it is reasonable that these complex interactions may be perturbed by global warming, ocean acidification, loss of sea-ice, and human impact on local and global scale. The impact of human activities on the marine ecosystems involves the continuous release of hundreds of thousands of legacy and emerging substances, and despite of several studies on the influence of legacy substances, there is only little knowledge on new threats related to local release of pollutants. The aim of this study is the comprehension of the contaminant dynamics in the Kongsfjorden and to disentangle the role of point-sources and its seasonality respect to the material released into the water column after ice melt. The results obtained within three sampling cruise carried out in Kongsfjorden (Ny-Ålesund, Svalbard, 79° N 12° E) in two different seasons (June 2016, March 2017 and July 2018) is shown. This fjord is a high-latitude (sub)-Arctic fjord, influenced by both the Atlantic water masses of the WSC (West Spitsbergen Current) and the Arctic-type coastal waters as well as a glacial input of melt water. The experimental design was drawn up to sample seawater (surface and bottom) and fine grained sediment along the main axis of the fjord in order to evaluate the dynamics of “old POPs” and “new” emerging contaminants: PCBs; PAHs; nonylphenols (NPs); bisphenol A (BPA), CUPs, PFAAs together with the determination of sediment texture, Organic C, total N, C/N ratio, δ13C and biogenic silica. In summer, the concentrations measured in seawater varied from 2.9 to 40.4 ng/L for PAHs, from 0.13 to 1.5 pg/L for PCBs and from 0.15 to 2.5 ng/L for PFAAs. Values found in winter were not significantly lower than the summer ones: the absence of solar irradiation and the lower temperature probably inhibited the degradation of these POPs, competing with the greater anthropogenic pressure and the ice melting inputs occurring in the spring-summer period. The statistical analysis on PCBs data supported the additive effect of season and distance from the glacier, but not their interaction: PCBs were higher in June than in March and decreased with increasing distance from the glacier in both sampling seasons. This trend highlights the release of POPs from melting glaciers acting as secondary sources of legacy pollutants.
Island, Hudson Bay and Ungava/Labrador. These regions were characterized by environmental parameters such as ice coverage, air temperature, precipitation and climate indices (i.e., Arctic, North Atlantic and Pacific/ North American Oscillations) through time. Results indicated that liver mercury concentrations were higher in seals collected from the western locations. Mercury and selenium concentrations in liver increased with age of seals, in a site-specific manner, to about 15 years of age. Temporal trends of mercury in liver increased significantly in seals from the Central Arctic and the Hudson Bay (4.7%, p < 0.05); other trends (Beaufort Sea, Hudson Bay, Ungava/Labrador) were not significant. Hepatic selenium concentrations increased with age of animals, however results indicated that exposure of seals to selenium decreased over the period of 1997-2017. The decreasing selenium trend was significant in seals from Ungava/ Labrador (-3.1%, p < 0.0001). Relationships of contaminants with climate parameters will be discussed.

**TP097 Environmental sources and trophic transfer of PFAS to the sub-Arctic ringed seal foodweb of Lake Melville, northern Labrador, Canada**

_D. Xiong_, University of Toronto / Geography; _I. Lehnherr_, University of Toronto, Mississauga / Department of Geography; _A.O. De Silva_, Environment and Climate Change Canada / Water Science and Technology Directorate; _J.L. Kirk_, Environment and Climate Change Canada / Aquatic Contaminants Research Division; _Y. Sun_, South China Sea Institute of Oceanology / Chinese Academy of Sciences / Aquatic Contaminants Research Division; _D.C. Muir_, Environment and Climate Change Canada / Aquatic Contaminants Research Division; _E.M. Sunderland_, Harvard University / Harvard John A. Paulson School of Engineering and Applied Sciences; _M. Li_, Harvard University / School of Public Health; _X. Wang_, Environment and Climate Change Canada / Aquatic Contaminants Research Division; _A. Gleason_, Environment and Climate Change Canada; _C. Spencer_, Environment and Climate Change Canada / Water Science Technology Directorate; _M. Williamson_, Environment and Climate Change Canada; _T. Sheldon_, _R. Laing_, _L. Pijogg_, Nunatsiavut Government

Perfluoroalkyl substances (PFAS) are synthetic organic compounds that are highly persistent. Among these, perfluoroalkyl sulfonates (PFASs) and perfluoroalkyl carboxylates (PFCAs) have been shown to bioaccumulate in terrestrial and aquatic organisms. The ringed seal (Phoca hispida) is a semi-enclosed estuarine fjord located in northern Labrador eastern Canada, has not been previously evaluated for PFAS. Local sources of PFAS in the Lake Melville region are a military base in terrestrial and aquatic environments. The ringed seal (Phoca hispida) is a semi-enclosed estuarine fjord located in northern Labrador eastern Canada, has not been previously evaluated for PFAS. Local sources of PFAS in the Lake Melville region are a military base and airport and distant sources are PFAS delivered through atmospheric deposition and ocean circulation. We hypothesize that PFAS may be released from sediments into the water column through land disturbances related to climate change and development. Thus PFAS monitoring is warranted to determine exposure to Indigenous people feeding on ringed seals, fish, and other traditional country foods. The objectives of this research are to identify environmental sources of PFAS and assess their bioaccumulation in the Lake Melville food web. Biota and water samples were collected between 2013-2018 with seal samples provided by hunters during the local harvests. Liver and muscle of seals and fish, water, plankton, and other invertebrates were extracted then analyzed for a suite of PFCAs and PFASs using liquid chromatography tandem mass spectrometry. The total PFAS corresponded to 5.9 ± 1.5 ng/g dry weight (dw) for plankton >500 μm and 4.8 ± 1.6 ng/g dw. for plankton in the 153-500 μm size. In fish muscle, the total PFAS corresponded to 2.3 ± 0.3 ng/g wet weight (ww) in flatfish and 1.5 ± 0.6 ng/g ww. in cod. Seals liver in 2017 corresponded to 68 ± 12 ng/g ww. The predominant PFAS in ringed seal liver were each negatively correlated with body length, negatively correlated with C-13 stable isotopes, and positively correlated with N-15 stable isotopes, suggesting that increasing trophic position and greater freshwater/terrestrial feeding strategies were associated with higher PFAS burdens in seals. Evaluating trophic biomagnification factors (TMF) of PFAS requires consideration of different approaches compared to traditional hydrophobic organic contaminants. PFAS differ in that their measurements are commonly in liver, that they are lipophobic and bind to proteins, and the lack of practicability in sampling large marine mammals on a whole body basis. In this research, various TMF assessments are considered. This study is the first to investigate PFASs in the ringed seal food web in Labrador.

**TP098 Accumulation of PBDEs in Harp (Pagophilus groenlandicus) and Hooded Seals (Cystophora cristata) from the Northwestern Atlantic**

_B. Soulen_, University of North Texas; _B. Venables_, University of North Texas / Biology / Advanced Environmental Research Institute; _D.W. Johnston_, Duke University Nicholas School of the Environment / Duke Marine Lab; _L. Sheppard_, _G. Stenson_, Fisheries and Oceans Canada / Northwest Atlantic Fisheries Centre (NWAFC), Newfoundland and Labrador Region / Marine Mammal Section; _A.P. Roberts_, University of North Texas / Biological Sciences / Advanced Environmental Research Institute

Polybrominated diphenyl ethers (PBDEs) are highly lipophilic components of bromanized flame retardants that are environmentally persistent and bioaccumulative. PBDEs are taken up from the gastrointestinal tract and accumulate mainly in fat depots and liver tissues. Seal species inhabiting Arctic and sub-Arctic regions can have upwards of 30% of their body mass composed of blubber. When those blubber stores mobilized for energy, stored toxicants are also released into circulation. Most studies reporting accumulation of PBDEs in seals have focused on harbor and grey seals with few examining harp and hooded seals. In this study, PBDEs were analyzed in blubber from stranded harp and hooded seals sampled along the northeast coast of the U.S. (1999-2010). A PBDE congener profile was determined for each individual. The results show that both species of seals are accumulating PBDEs with BDE-47 being the dominant congener. Mean ZPBDE concentrations in harp seal were 70.55 ± 33.59 ng/g ww and for hooded seals 94.28 ± 42.65 ng/g ww. The results of this study are consistent with previous studies reporting a decrease in bioaccumulation with an increase in bromination. For both species, BDE-47 represented the highest percentage of the ZPBDEs, composing over 50% of the ZPBDEs in harp seals. When compared to stranding condition code, animals found alive had overall higher PBDE concentrations than those found in a state of moderate decomposition. This difference could be due to decreased blubber levels in the decomposed animals or potential degradation of the compounds in the blubber. Almost all seals used in this study were yearlings which is the most likely age class to strand. Yearling seals are at a crucial stage of development, especially of their immune system, which can be impacted by high levels of contaminants like PBDEs and increase the susceptibility to disease. Thus, serum samples were also collected from harp and hooded seals (2017-2018) for analysis of PBDEs, metabolites, and RNA to indicate changes in gene expression related to PBDE exposure.

**TP099 Temporal trend of perfluoroalkyl substances and current-use pesticides in penguin eggs from the Ross Sea (Antarctica)**

PFASs and CUPs have been detected in most ecosystems, including those in remote areas. They are long-range transported and can reach the polar regions. Antarctica and the Southern Ocean show extreme climate; due to the low temperatures and winter darkness, contaminants degrade very slowly; moreover, they can be trapped in snow and ice and eventually released during summer melting. When in the seawater, they can enter trophic webs and bioaccumulate mostly in predators that feed directly or indirectly on the cryopelagic community. PFASs include thousands of chemicals but the compounds usually detected in the environment belong to the class of perfluoroalkyl acids (PFAsAs), such as perfluorooctanesulfonic acid (PFOS), and perfluorooctanoic acid (PFOA). The Stockholm Convention has recently restricted the production and use of PFOS;
however, it is still manufactured and used in various industrial processes in China. CUPs such as dacthal, chlorpyrifos and endosulfan are, or have been, high production volume chemicals i.e N1000 t/y globally. Unhatched eggs are very useful non-destructive samples already successfully used to determine chemical levels. Unhatched eggs of Adelie penguin (Pygoscelis adeliae) (n = 18) were collected at Edmonston Point (74° 21’S, 165° 08’E) (Ross Sea, East Antarctica) during the XVII (2001/02) and the XXX (2014/2015) and the XIV (2018/2019) Italian Expeditions, in the framework of the Italian Antarctic Research Programme (PNRA). The general aims were to assess the PFAA and CUP bioaccumulation in penguin eggs, to assess their transfer to the chick embryo, and to evaluate a temporal trend. On-line SPE-HPLC-MS revealed the occurrence of 12 PFAAs in eggs and chick embryos. PFOS and PFOA were detected in all samples collected in 2001, with concentrations ranging 0.3–0.53 ng g⁻¹ wet weight (wt) in eggs (mean value: 0.42 ng g⁻¹ wet wt) and 0.05–0.08 ng g⁻¹ wet wt (mean value: 0.07 ng g⁻¹ wet wt) in chick embryos. Lower levels were detected in 2015 samples, with mean values of 0.3 and 0.005 ng g⁻¹ wet wt of PFOS and PFOA, respectively. This decreasing trend was not observed for PFHxA, PFNA, PFDA, PFUnA, PFDoDA, PFTrDA, PFTeDA concentrations. PFHxA showed the highest levels in the egg samples collected in 2015 (mean value: 0.8 ng g⁻¹ wet wt), confirming an ongoing input of these compounds from long-range transport and/or local sources.

**TP100** Trophic and fitness correlates of Hg and POP exposure in incubating female Antarctic petrels

A. Carravieri, University of Liverpool; N.A. Warner, Norwegian Institute for Air Research / Fram Centre; A. Tarroux, Norwegian Institute for Marine Research / Fram Centre; P. Bustamante, University of La Rochelle / Littoral ENvironnement et Sociétés LIENSs; S. Descamps, Norwegian Polar Institute / Fram Centre

Increasing environmental perturbations threaten Antarctic wildlife, with some populations showing demographic declines. Yet, our understanding of the drivers and effects of exposure to toxic contaminants such as mercury (Hg) and persistent organic pollutants (POPs) in Antarctic wildlife is still limited. The Antarctic petrel is one of the least known Antarctic species, with poor documentation about contaminant exposure and effects on its physiology and fitness. Here we measured Hg and 14 POPs in blood cells and plasma, respectively, of 30 female Antarctic petrels from Svarthamaren (Antarctica) during the early incubating period. We recorded female and egg morphometrics, and monitored the nests until chicks were approx. 20 days old. Carbon (δ13C) and nitrogen (δ15N) stable isotopes measured in the females’ blood cells served as proxies of feeding habitat and trophic position, respectively, during spring (pre-laying period). The aim of this study was 1) to document POP concentrations in blood for the first time in this species, and characterise its trophic drivers; and 2) test the effect of female blood Hg and POP concentrations on i) female and egg morphometrics, ii) hatching success, iii) chick survival and body condition. Blood Hg burdens (mean±SD, 2.4±1.03 µg/g dry weight) were three-fold higher than those previously documented in the same population, and were related to the female spring trophic position. PCB concentrations were very low when compared to other Polar seabirds. By contrast HCB (1.02±0.36 ng/g wet weight, ww), Mirex (0.72±0.35 ng/g ww) and 4,4’-DDE (1.02±1.49 ng/g ww), were present at burdens comparable to those of ecologically-similar Antarctic seabirds (i.e. snow petrels). POP concentrations showed no clear relationship with either spring feeding habitat or trophic position. Two non-exclusive factors could explain this: 1) POP exposure is homogeneous over females’ feeding habitat in spring; 2) intrinsic factors such as differential POP mobilisation from internal pools to blood and into the egg during its formation overcome trophic drivers in explaining plasma POP concentrations in incubating females. Preliminary analyses showed no strong associations between female blood Hg and POP residues with their egg and fitness parameters. Yet, HCB and Mirex burdens were inversely related to the females’ body condition. Future monitoring is warranted to test Hg and POP long-term effects in this Antarctic petrel population.

**Microplastics in the Environment: Transport, Fate and Ecological Effects**

**TP101** Different microplastics can influence structure and function of sediment microbial communities

M. Seeley, Virginia Institute of Marine Science / Aquatic Health Sciences; B. Song, Virginia Institute of Marine Science / Biological Sciences; R.C. Hale, College of William & Mary / Aquatic Health Sciences

Plastics are now ubiquitous in freshwater, coastal and open ocean environments. Sediments therein have been discovered to be major sink for microplastic. While plastic polymer type has been reported to influence the composition of floating plastic biofilm communities, studies to date have not investigated the effects of different microplastics on sediment microbial communities or sediment biochemical activities. Here, we present the results of a sediment microcosm experiment established with microplastics (50-300 µm) of different petroleum-based polymers (polyethylene [PE], polyvinyl chloride [PVC] and polyurethane foam [PUF]) and one bio-polymer (polylactic acid [PLA]). We characterized the sediment bacterial compositions and functional gene abundances after 7 and 16 days incubation using 16S MiSeq and quantitative polymerase chain reaction (qPCR) analyses, respectively. Nitrogen cycling was also evaluated by measuring dissolved inorganic N fluxes and denitrification rates (calculated via sediment slurry incubation experiments using a 15N isotope pairing technique). We observed that bacterial community compositions differed significantly between the biopolymer, petroleum-based polymers and non-amended sediment, with PVC being the most distinctly unique community. Nitrification gene abundances and inorganic N fluxes revealed that nitrification was highest in the biopolymer (PLA) and PUF, and lowest in PVC treatments. Correspondingly, denitrification rates were inhibited in PVC, but highest in PLA and PUF. Both denitrification and nitrification activities were higher in PE, PUF and PLA treatments than the non-amended control. This suggests that: (1) microplastics may enhance sedimentary nitrogen cycling processes and (2) sediment microbial communities may have the capacity to use plastics as carbon substrate. Overall, our study shows that the environmental presence of different microplastics may alter the structure and function of sediment microbial communities. This underlines the need for greater evaluation of the consequences of plastic contamination to sediment microbial ecosystems and biogeochemical cycling.

**TP102** An Assessment of Plastic Ingestion in Black sea bass, Centropristis striata: A Lab and Field Study

J. Joseph, C. Stienbarger, University of North Carolina, Wilmington / Biology and Marine Biology; S. Athey, University of Toronto / Earth Sciences; B. Monteleone, University of North Carolina, Wilmington / Department of Chemistry and Biochemistry; A. Andrydu, NC State University / Department of Chemical and Biomolecular Engineering; W. Watanabe, University of North Carolina, Wilmington / Center for Marine Science; P. Seaton, University of North Carolina, Wilmington / Department of Chemistry and Biochemistry; A.R. Taylor, University of North Carolina, Wilmington / Department of Biology and Marine Biology; S.M. Brander, Oregon State University / Environmental and Molecular Toxicology

The accumulation of microplastics (granules of plastic < 5mm in one dimension) in oceans is one of the major environmental concerns of our age. Due to their large specific surface area and hydrophobic properties, microplastics can absorb numerous organic pollutants. Intake of microplastics by marine organisms may therefore result in introducing toxicants to the organism itself and to the food chain, possibly leading to their bioaccumulation. Though a number of marine organisms have been found to ingest microplastics, few studies have been performed on commercial fishery species such as black sea bass (Centropristis striata), an important fishery off the East coast of the United States. To understand the plastic ingestion in black sea bass and subsequent transfer of associated pollutants, studies were conducted both in field and laboratory. The
results from field study showed three macroplastics, which are currently being analyzed through u-FTIR. Additionally, in the lab we conducted pellet feeding experiments to investigate the possibility of transfer of organic pollutants from microplastics to fish tissue. PVC pellets were spiked with bis (2-ethylhexyl) phthalate (DEHP) and allowed to grow biofilm. Pellets were fed to late juvenile sea bass and we recorded 78% pellet ingestion and did not find any significant difference in ingestion (after 12 h) for biofilm vs. no biofilm or 0% phthalate vs. 10% phthalate. 20 % the total ingested pellets were recovered from the GI tracts after 120 hrs and these pellets were analyzed to determine loss of phthalate. Our results showed no significant difference in phthalate levels in control vs. recovered pellets. However, tissue analysis is required to draw any conclusions on the pollutant transfer to organism. Liver analysis will be performed with LC/MS/MS to verify any accumulation of DEHP and its metabolite MEHP. We anticipate that our results from both field and lab experiments will contribute to the current knowledge on the plastic pollution in C. striata and will inform fishery management about the potential concerns regarding human consumption of black sea bass that have ingested plastics.

TP103 Non-targeted analysis of leachables in plastic fragments and microplastics collected in beach sediments

S. Bayen, S. Reino, L. Liu, McGill University / Food Science and Agricultural Chemistry

Plastic fragments, microplastics and other plastic litters have been detected in aquatic systems globally. In particular, plastic particles have been reported in shellfish and in the gut content of fish. Recent studies suggest the potential role of plastics as vectors of chemical pollutants. Standardized methods are urgently needed to identify and quantify the chemicals which can leach from these materials (leachables). To date though, chemical migration studies focused on characterizing known chemicals, an approach referred to as targeted analysis. However, very few tools are available to assess the migration of “unexpected” or “unknown” chemicals. This approach, also called non-targeted analysis, has recently been developed for food contact materials, including plastics. There are however no standard non-targeted methods applicable to the study of plastic fragments and microplastics. In this study, a non-targeted approach was developed to study leachables from plastic fragments and microplastics collected in beach sediments in Martinique, a French island located in the Caribbean. The plastic particles were extracted with methanol and analyzed using liquid chromatography coupled to time-of-flight mass spectrometry (LC-QToF-MS). Several hundreds of molecular features were detected in the extracts. Several of these features were successfully identified based on the accurate mass of parent ion, isotopic patterns, retention time and multiple MS/MS fragment ions with matching abundance ratio.

TP104 Vertical distribution of microplastics and their presence in marine snow in offshore waters of South Korea

S. Eo, Y. Song, Korea Institute of Ocean Science and Technology; S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs research group; G. Han, Korea Institute of Ocean Science and Technology; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group

Microplastics can be vertically transported by physical mixing as well as biological interaction. There is, however, still limited in situ observation data in vertical profile and characteristics of microplastics in offshore areas. In this study, the vertical distribution of microplastics larger than 20 μm was evaluated at 14 stations in offshore waters of Yellow Sea and South Sea of Republic of Korea. Each seawater sample of 100 L was collected at four to six vertical layers from surface (1 m below sea surface) to bottom (1 m above sea floor) based on the presence of thermocline and water depth. In addition, the presence of microplastics in marine snow was determined in the mid-column samples. Every single particle was identified and confirmed with micro-FT-IR spectroscopy after density separation with lithium metatungstate solution and wet peroxide oxidation. The abundance of microplastic was in the range of 15-2080 particles/m³. The average microplastic abundances in the surface (295 ± 488 particles/m³) and bottom (316 ± 477 particles/m³) were higher than mid-column (124 ± 108 particles/m³), but they were not significantly different each other (Kruskal-Wallis test, p > 0.05). The highest microplastic abundance was found in bottom water among the vertical layers at 7 out of 14 stations surveyed, in surface water at 5 stations and in mid-column at 3 stations. At 9 of 13 stations except for one station that had no thermocline, the microplastic abundance in the upper thermocline was higher than that in lower thermocline layer, respectively. The abundance of microplastic increased by decreasing size, showed the peak in between 50 and 100 μm and then decreased < 50 μm in all layers. Fragment was the most abundant shape in all layers, accounting for 81% in surface, 86% in mid-column and 84% in bottom waters. In all samples, 33 different types of polymers were identified by micro-FTIR spectroscopy. While polypropylene that was less dense than seawater was the most dominant type in the surface water (24%), alkyd that was denser than seawater was the most dominant type in the mid-column (24%) and bottom (26%) waters. Among 1863 marine snow examined, 63 (3.4%) contained microplastics. The microplastics in marine snow form accounted for 0-37.5% (average of 9.3%) of the total microplastics in the water sample of the sampling layer.

TP105 From Your Laundry To The Lake: Blue Jeans As A Source Of Anthropogenic Microfibers To The Aquatic Environment

S. Athey, J. Adams, University of Toronto / Earth Sciences; L. Erdle, University of Toronto / Department of Ecology & Evolutionary Biology; P.A. Helm, Ontario Ministry of the Environment, Conservation and Parks / Environmental Monitoring and Reporting Branch; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; S. Finkenstein, University of Toronto / Earth Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences

Originally designed as work-wear in the 17th century, blue (denim) jeans have become a modern fashion staple within the last 70 years with 450 million pairs of jeans sold per year in the US alone. Cotton is the most common material used in the production of denim textiles, including blue jeans. Although cotton fibers are classified as a ‘natural’ fiber, and therefore assumed to be an environmentally friendly material compared to synthetics, cotton can often contain additives and dyes that could influence its persistence and toxicity in the aquatic environment. During washing, frictional forces can cause the loss of microfibers and associated chemical additives from cotton materials to outgoing wastewater. Wastewater treatment plants (WWTPs) are known conduits of microfibers to the aquatic environment. We hypothesize (1) blue jeans are a major contributor of cotton microfibers to WWTPs and (2) that WWTP effluent is a conduit for cotton/cellulose microfibers to enter the aquatic environment. To investigate blue jean washing as a source of microfibers to wastewater, we washed triplicate pairs of Levi Strauss & Co. straight-legged, dark-wash blue jeans (98-100% cotton). Three treatments included: new distressed, new, and used jeans. Microfibers were chemically characterized using Raman spectroscopy. Results show that a single pair of blue jeans shed approximately 2,840 fibers per L, 90% of which were cellulose and/or contained indigo dyes. This release rate of ~100,000 fibers per pair of new jeans compares to 1,900 per new fleece jacket. To determine if WWTP effluent is a conduit for cellulose/cotton fibers to enter the aquatic environment, three replicate 24-h composite samples of final effluent were collected for microplastics and microfiber analysis from two WWTPs in southwestern Ontario. Approximately 90% of particles in the effluent samples were microfibers with 70% of the microfibers consisting of cellulose and/or indigo dyes. The chemical make-up of fibers found in WWTP effluent corresponds in morphology and spectral signal with those released from washing blue jeans, indicating blue jeans may be a source of microfibers to the aquatic environment. Scalled up, our results suggest that approximately 0.7 - 5.7 billion cellulose microfibers per day are discharged to Lake Ontario via each sampled WWTP.
TP106 Analysis of polymer additives in fish exposed to two microplastic fiber types
A.M. Lewie, L. Ferguson, Duke University / Civil and Environmental Engineering; L. Hu, Normal University Shanghai; M. Chernick, D.E. Hinton, Duke University / Nicholas School of the Environment

Microplastic particles derived from synthetic polymers are ubiquitous environmental pollutants. Most synthetic polymers utilize a suite of chemical additives and dyes to enhance the functionality and coloring of the material. Common polymer additives, including plasticizers, antioxidants, and dyes, are of environmental concern due to their role as suspected endocrine disruptors and/or mutagens. Microplastic fibers are the dominant particle type found in many environmental samples, including gut content recovered from organisms. We hypothesize that microplastic fibers may act as a delivery mechanism for chemical additives to aquatic organisms that ingest or are otherwise exposed to them. We have designed laboratory-based exposure experiments to test this hypothesis. In these experiments, green polyester and clear polypropylene fibers were used in a 21-day exposure with Japanese Medaka mating pairs. Both fibers were sourced from a Chinese fabric store. We applied a non-targeted mass spectrometry approach to identify relevant additives in the fibers that may be absorbed by fish after fiber ingestion. A custom, curated database of known organic polymer additives and dyes was used in concert with liquid chromatography-high resolution Orbitrap mass spectrometry (LC-HR/MS) to analyze organic extracts and tank water leachates of the fibers. Specifically, 6-day freshwater leachates and ethyl acetate solvent extracts of transparent polypropylene and green polyester fibers were analyzed. Based on library matching and/or computational mass spectrometry evidence, tentative identification of several known polymer additives was obtained. Multiple plasticizers (Dibutyl phthalate), textile dyes (C. Disperse Blue 60), antioxidants (Irganox 1010), and surfactants (PEGn) have been tentatively identified in both the organic extract and tank water leachate of the fibers. Fish exposed to microplastic fibers were carefully dissected and sectioned by tissue type: gills, gut, gonads, and liver. The tissue types, plus feces and embryos were extracted and analyzed by LC-HR/MS for detection of plastic additives identified in the respective fiber types. Results will be discussed in context of novel additive identifications and potential for uptake and accumulation in microfiber-exposed fish.

TP107 Investigating the effects of microplastics and their associated chemicals to fathead minnows at multiple levels of biological organization
K. Bucci, M. Bayoumi, University of Toronto / Department of Ecology and Evolutionary Biology; K. Stevack, University of Guelph / School of Environmental Sciences; T. Watson-Leung, Ministry of the Environment, Conservation and Parks / Aquatic Toxicology Unit; C.M. Rochman, University of Toronto / Department of Ecology and Evolutionary Biology

Due to the pervasiveness of microplastics (plastic < 5 mm) in aquatic environments, the public, scientists, and decision-makers often ask whether microplastics pose an ecological threat. However, investigation into the effects of microplastics to aquatic organisms is often conducted using simplistic scenarios that do not capture the reality of microplastics as a complex contaminant. These studies generally investigate effects by exposing low trophic-level species to extremely high concentrations of pristine microplastics. The goal of my project is to investigate how environmentally relevant concentrations and types of microplastics affect fathead minnows at multiple levels of biological organization. Fathead minnows were exposed to fragments of virgin polyethylene and polyethylene collected from the shore of Lake Ontario at two concentrations: 100 and 2400 particles per L. The exposure began at the egg stage, 24 hours post-fertilization, and will last until all breeding groups from the control treatment have laid at least 1000 eggs (5-7 months). Throughout this experiment, I will be investigating effects at the suborganismal-level (e.g. histopathology, gene expression), the individual-level (e.g. survival, length, body condition), and the population level (e.g. reproductive success, sex characteristics). I will also be quantifying length, deformities, and epigenetic effects in offspring. Results to date will be presented at this conference.

TP108 Municipal sewage sludge as a source of microplastics in the environment
C. Rolsky, V. Kelkar, R.U. Halden, Arizona State University / Biodesign Center for Environmental Security

Wastewater treatment plants are known to contribute to microplastic (MP) pollution in freshwater and terrestrial environments, but studies on MP abundance in sludge are scarce. We aimed to provide an initial estimate of mass loads of MPs in sludge by compiling literature (n = 7) reported particle counts and dimensional data and then converting these into units of MPs mass per sludge mass. Conversion factors used were informed by the average weight of plastic beads, particles, pellets, films, and fibers. Data on MP abundance were found to be inconsistent with respect to analytical methods and quantification units used. Polymer types present in sludge were identified in 57% of studies. The average weight ± standard deviation in units of mg by MP class was 1.5 ± 0.5 for fibers, 12 ± 4 for particles, 55 ± 1 for fragments, 0.3 ± 0.1 for films, 13 ± 1 for plastic pellets and 3.4 ± 0.1 for microbeads. Based on the weights obtained, the mass loadings of MPs in sludge in units of mass per mass of dry weight sludge were highest for China followed by the United States, Finland, the Netherlands, and Sweden. Mass loading data underscore the significance of the MP pollution problem and found significant geospatial variation worldwide.

TP109 Trophic transfer and depuration of 6 μm virgin fluorescent-label polystyrene microplastics in Daphnia magna and Pimephales promelas
A. Elizalde Velazquez, Texas Tech University / ENTX; A. Carcano, J. Crago, Texas Tech University / Department of Environmental Toxicology The Institute of Environmental and Human Health TIEHH; J.E. Canas-Carrell, Texas Tech University / Environmental Toxicology

Small size, appealing color and buoyancy promote ingestion of microplastics by aquatic organisms. Occurrence and reports of plastic debris in the gastrointestinal (GI) tract of fish has been well documented in scientific literature increasing attention on human health due to a probable exposure to microplastics through the consumption of contaminated fish. However little is known about the behavior of microplastics in organisms of higher trophic levels after ingestion of prey species that had accumulated microplastics. Most of the available research regarding microplastic toxicity has focused on marine aquatic organisms through direct feedings or waterborne exposures at the individual level. Food chains from invertebrates to vertebrates have not been investigated in depth with regard to the transfer of microplastics. The freshwater zooplankton Daphnia magna and the freshwater teleost fish Pimephales promelas are well-known model species used in standard toxicological studies and ecological risk assessments, and provide a simple model for food chain transfer and facilitate the evaluation and comparison of data among different studies. The aim of this study was to assess the trophic transfer of two concentrations (2000 part/mL and 20 part/mL) of 6μm virgin fluorescent-label polystyrene (PS) microplastics between Daphnia magna and Pimephales promelas, as well as to investigate the depuration rates of the plastic particles within the bodies of both species. Epifluorescence microscope was used to determine and count the number of particles within the organs of both species. Bioaccumulation factor (BCF) were calculated for Daphnia magna and their values ranged between 0.026-0.033, bioaccumulation factor (BAF) were calculated for Pimephales promelas and their values ranged between 0.094-0.205. Along the 5 days of exposure, microplastics were only found within the GI tract of both species; no translocation to other organs or tissues was observed in this study. 96h after exposure all microplastic particles were depurated from the GI tract of both species when they were moved to fresh media and fed. Based on the low estimated values of BCF and BAF for both species, the quick depuration rates and the null translocation of microplastics to organs and tissues other than
the GI tract, we conclude that microplastics have a very low probability of bioconcentrating and further bioaccumulating under environmental conditions.

**TP110 Removal of microplastic from wastewater effluent using an electrocoagulation process**

D. Elkhathit, University of Rhode Island / Environmental Engineering; E. Carissimi, Federal University of Santa Maria; V. Oyanedel-Craver, University of Rhode Island

The main goal of this study was to evaluate the use of electrocoagulation (EC) to enhance the removal of microplastics from wastewater effluents. EC has been applied for the treatment of wastewater from a variety of industries (petrochemical, textile, tannery, dairy, and food processing) and has proven to remove pollutants such as pharmaceuticals and heavy metals. Microplastics (MPs, plastics fragment smaller than 5 mm) detected in marine and freshwater environments can have negative impacts on ecological and human health. The effluents of wastewater treatment plants (WWTPs) have been identified as one of the major sources of MPs released into the environment. Due to their size and density, MPs are not completely removed during conventional wastewater treatment processes. However, scarce information is available about alternatives for the enhancement of MPs removal from wastewater effluents. EC is the electrochemical dissolution of metal electrodes into metal ions that aggregates with suspended particles and adsorb dissolved contaminants. The agglomerates formed during EC can either settle and be removed through filtration; or float due to the hydrogen microbubbles released at the cathode and move the flocs upward, which can be removed by overflow or skimmed from the surface. In this study, we assessed the removal of MP using both synthetic and real wastewater effluent collected from a local utility. The experiments were performed in batch reactors, and parameters such as current density, pH, and electrolysis time were varied to determine the most effective operational conditions. Removal efficiencies in synthetic wastewater obtained ranged between 98% and 99% using initial pH between 4 and 7 and applying current densities of 2.88 mA/cm² and 8.07 mA/cm², respectively. However, the lowest operating costs were obtained using the current density of 2.88 mA/cm² with initial pH of 4 since it requires low energy use. For real wastewater effluent, EC process removed 96.5% of MPs, 92.2% of COD, and 88.8% of fecal coliform colonies using the best conditions found for synthetic wastewater. In conclusion, the applicability of EC process proves to efficiently remove MPs from the effluent at municipal WWTPs, reducing the impacts of these discharges in the receiving natural waters, and consequently fewer negative impacts on the ecosystem and public health.

**TP111 Polyethylene and polystyrene microplastics uptake by immune cells of Atlantic salmon (Salmo salar L.)**

L. Abrikissa Garcia, Y. Park, V. Kiron, P.A. Olsvik, Nord University / Faculty of Biosciences and Aquaculture

The ubiquitous presence of microplastics in the marine environment is a recent but increasing concern worldwide. Microplastics are ingested accidentally by the marine fauna or enter indirectly through the food chain. They can accumulate in several cells and tissues, and affect the normal biological functions of the organism, including their defence mechanisms. However, there are still many uncertainties about the immune cells response to microplastics. The degree of uptake in cells, responses to environmental relevant concentrations, or if differences exist in the response of immune cells from different organs are points that remain unclear. Moreover, very little is known about the toxicity of different polymer types. This study aimed to shed light on the physical impact of microplastics on immune cells from Atlantic salmon. We isolated immune cells from head kidney, blood and intestine and exposed them to green fluorescent polyethylene microparticles (1-5 pm) and red fluorescent polystyrene microbeads (2.1 pm). Cells were exposed to three microplastic treatments (polyethylene, polystyrene or a mix of both) and to three concentrations termed high (50 mg/L), medium (5 mg/L) and low (0.05 mg/L), the latter being an environmental concentration. After incubating the cells for 1, 24 or 48 h, mortality and microplastic uptake were analysed by image flowcytometry. Our study is the first to use image flowcytometry for microplastic exposure experiments. Using this method, we were able to determine the lethal concentration of microplastics uptake by immune cells in fish. It is also the first study to use environmental relevant microplastic concentrations in an exposure experiment. We found that, even at this low concentration, the immune cells from Atlantic salmon ingested microplastic particles. We also observed that immune cells responded differentially depending on the types of polymers. Polyethylene was generally more phagocytosed by Atlantic salmon immune cells than polystyrene. Polyethylene might thus have a stronger impact on the immune system of the fish. This study provides new information about the impact of microplastics on aquatic animals at the cellular level. Furthermore, image flowcytometry can be applied to other species to increase our overall knowledge of the effect of microplastics in the environment.

**TP112 Microplastics in the Delaware Bay: Distribution and direct effects on major zooplankton**

A. Internicola, J. Cohen, University of Delaware

Plastic debris is an emerging pollutant of growing concern. The most abundant form of plastic marine pollutants consists of pieces smaller than 5 mm, referred to as microplastic marine debris (MPMD). Despite studies on the effects of MPMD on marine organisms, there has yet to be a systematic investigation on the impact of MPMD at the population, community, and ecosystem level. Coastal systems are a hotspot for the accumulation of MPMD and may serve as an important link between land-derived waste and MPMD in the open ocean, yet to date, the extent of the potential hazards of MPMD are unknown in the Delaware Bay; a well-mixed temperate estuary with extensive urban land use in parts of the watershed. The two primary objectives of this research are: 1) to assess the physiological effects of MPMD on *Acartia tonsa*, a common calanoid copepod in the Delaware Bay; and 2) to quantify the distribution and types of MPMD in the Delaware Bay. Copepods were exposed to various concentrations of microbeads and fibers over a 24-hour period to determine the lethal concentration of MPMD and over the lifetime of the organism to determine the effects of MPMD on growth and development. Neuston tows were taken at 16 stations in the Delaware Bay from tidal freshwater to the coastal ocean outside the bay mouth. A representative 1% subsample of the total MPMD collected was taken for Fourier-transform infrared analyses and plastic formulation was identified by comparing the spectra collected to known spectra. The highest concentrations of MPMD occurred upstream, near the estuarine turbidity maximum zone and areas of urban land use. The majority of MPMD consisted of fragments and filaments with the most commonly identified formulations being polyethylene and acrylonitrile-butadiene-styrene irrespective of plastic type. Studying this coastal ecosystem will provide valuable insight on the fate of land-derived MPMD as well as predictions on what impacts MPMD may have on major zooplankton in the Delaware Bay as this may have bottom up effects on higher trophic levels.

**TP113 Assessing the presence and concentrations of microplastics in the gizzards, intestines, and feces of Virginia waterfowl**

T. Bustamante, University of Mary Washington; T. Duong, University of Mary Washington / Earth and Environmental Sciences; R. Gunraj, A. Dolby, University of Mary Washington; T.E. Frankel, University of Mary Washington / Earth and Environmental Sciences; J. Asper, University of Mary Washington; B. Odhiambo, University of Mary Washington / Earth and Environmental Sciences

Microplastics have become a ubiquitous water pollutant. While a substantial amount of research on their impacts on marine ecosystems has been conducted, the effect of microplastics on freshwater food webs remains poorly understood. Previous studies that have attempted to assess microplastic contamination in freshwater waterfowl via fecal analyses have failed to provide strong confirmation of microplastics ingestion due to concerns regarding the contamination of those samples with exogenous
plastic particles. In this study, we assessed the presence and concentrations of microplastic particles in the gizzard and intestines of the Canada Goose (Branta canadensis), the Ring-necked Duck (Aythya collaris), the Long-tailed Duck (Clangula hyemalis), and the Bufflehead (Bucephala albeola), hunted in the Piedmont and Coastal Plain of Virginia and donated by hunters. Fecal samples from B. canadensis were also collected from nearby areas and examined for differences in microplastic contamination. Gizzard samples were processed by rinsing with deionized water over a set of stacked sieves. Fecal and intestinal samples were assessed in a similar manner, but included an initial oxidation step to disaggregate any organic matter. Plastics were identified under a dissecting microscope. Microplastic particles collected from each of these samples will be quantified in terms of abundance by source (primary or secondary), location, and polymer type using infrared spectroscopy. While this study is still ongoing, results so far have revealed the presence of secondary microplastic fibers in fecal samples. We expect to find microplastic particles in most of our gastrointestinal tract samples, which will provide firm evidence that freshwater birds consume microplastics. We also expect to find evidence of greater microplastic consumption in resident geese taken from suburbanizing areas of the Piedmont than in migratory geese collected from Coastal Plain sites. Additionally, we also expect higher concentrations of microplastics in fecal samples around urban areas and along rivers downstream from wastewater treatment plants. This study will contribute to a more thorough understanding of microplastic ingestion patterns in eastern North American waterfowl.

**TP114 Exploring the Importance of Microplastic as a Vector of Metals to Suspension Feeders**

*C. Bruno, City University of New York / Environmental Science; W.G. Wallace, The Graduate Center / City University of New York / Earth & Environmental Science*

Microplastic (MP) in the oceans was first recorded in the early 1970’s. We now know that MPs are found in all of the world’s oceans, at every trophic level, from surface to seafloor. Some MPs are similar in size to suspended sediment particles and algae and, as such, they may be inadvertently ingested by marine filter feeders. When ingested, MP may serve as a vector of adsorbed pollutants. Metals, such as Cadmium (Cd), readily adsorb to the surface of plastic particles, ingestion therefore represents a pathway for plastic and associated toxins to enter, and then be transferred within, the food web. Even though MP is ubiquitous in aquatic systems, comparatively little is known about its interactions with organisms and the environment. Assessing how marine invertebrates are affected by the ingestion of MP is important in understanding how MP enters the marine food web and affects ecosystems overall. Furthermore, it is critical to understand how associated toxins may be transferred to higher trophic levels via these food webs, and potentially affect human health. This study aims to answer the following question: Do MPs serve as a vector of toxic metals, specifically Cd, when consumed by a model marine zooplankton, *Artemia salina*? It is hypothesized that MP will act as a vector of Cd to *A. salina* when ingested. In order to answer this question *A. salina* were fed polystyrene MP particles (5.7-8.9 μm) saturated with Cd-109 or a mixture of saturated MP particles and algae. Subsequent to feeding, *A. salina* were allowed to depurate and were radioanalyzed every 30 minutes for 2 hours. Preliminary results suggest that *A. salina* assimilate greater amounts of Cd associated with MP particles when fed a mixture of algae and MP compared to when fed MP alone. This research is the first of its kind to bridge the gap between what is understood about metal sorption kinetics to what is unknown about how microplastics act as a vector of toxic metals to marine filter feeders and how those interactions may affect ecosystems.

**TP115 Drivers of microplastic pollution – Do seabirds significantly contribute microplastics to the environments around breeding colonies**

*M. Bourlanges, Carleton University / Geography and Environmental Studies; J. Provencher, Environment and Climate Change Canada / Canadian Wildlife Service; B.M. Braune, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M.L. Mallory, Acadia University / Biology Department; C. Geoffroy, Acadia University; A. Kopalie, Nattivak Hunters and Trapper’s Organization; J. Vermaire, Carleton University / Geography and Environmental Studies*

The presence and persistence of microplastics in the environment is becoming increasingly recognized, however, understanding the distribution and various drivers of microplastics within different environmental systems is less studied. Seabirds have been identified as a possible bi-vector of plastic pollution in the marine environment, however, the role of animals as vectors for microplastic pollution has yet to be fully examined. We examined two species of seabirds known to ingest plastics (Northern fulmars [Fulmarus glacialis] and thick-billed murres [Uria lomvia]) as potential significant vectors for the transport of microplastics in and around breeding colonies. With the guidance of local Inuit hunters from Qikiqtaaluk National Wildlife Area, Nunavut. The water and sediment samples were collected along a transect away from the bird colony. We expected to find a higher concentration of seabird guano in water and sediment samples resulting in the accumulation of microplastics in the environment at sites closer to the breeding colony. The results from these samples will indicate whether seabird are significant drivers and concentrators of microplastics in the coastal environment.

**TP116 Occurrence of fine microplastics in seawater from Japanese tropical area and their partitioning between seawater and beach sand**

*Y. Kameda, Chiba Institute of Technology / Creative Engineering*

Microplastics (MPs) greater than 20 μm were measured in surface water and beach sand from Japanese tropical area, Okinawa. These MPs were collected and measured by a novel developed methods with Fourier transform infrared microscopy (μFTIR) shown in poster MO279. The samples were collected at three sites where their contamination properties are much different. The concentrations of MPs were 380 p/m3 in Azama beach, 260 p/m2 in tropical beach and 660 p/m2 in Mibaru beach, respectively. Principal polymer type was PE, but the numbers of their types were 3 in Azama beach, 6 in tropical beach and 7 in Mibaru beach, respectively. Their polymer profiles were different among sampling sites but profiles were more complicated at annual average COD concentration in sea water were higher. Size distributions of numbers of MPs showed that MPs in Azama beach was the largest, and Mibual beach was the smallest though MPs size distributions were smaller than those in effluent from wastewater treatment plants. These results indicated that size distribution of MPs and numbers of polymer types were influenced by MPs released from land, but MPs concentration were not because of micronizing by UV radiation and ocean wave. The most predominant polymer in beach sand was PE, which is similar to that in sea water. But the size distribution of MPs in sand was smaller than 100 μm. Moreover, PE- MPs concentration in sand had good relationship to that in sea water. These indicated that smaller PE- MPs might be trapped and accumulated in beach sand.

**TP117 Microplastics loading estimation and their daily variation on urban areas to sewage treatment plants in Japan**

*Y. Kameda, E. Fujita, Chiba Institute of Technology / Creative Engineering*

Microplastics (MPs) greater than 20 μm were measured in wastewater from residential areas to sewage treatment plants (STPs) at 19 STPs in Japan in order to estimate MPs loading in Japan. Daily variations of MPs concentration and polymer types in wastewater were also investigated. These MPs were analyzed by a Fourier transform infrared microscopy (μFTIR) with the automatic mapping system as well as microscope.
counting method. MPs concentrations by microscope counting were remarkably lower than those by μFTIR method because there were many clear small particles which couldn’t be identified. These results indicated that microscope counting was much difficult to measure MPs though the daily variations of spheres, fibers and films were associated with human activities such as taking bath, and washing dishes and clothes. MPs concentrations by μFTIR were 4180, 2400, 2160 and 2460 p/L at 7, 9, 18 and 21 o’clock, respectively. The median diameters in 4 daily samples were approximately 50 μm. The predominant polymer was Nylon (polyamid) and the compositions were different among 4 daily samples. In Japan, many kitchen tools were made of nylon or nylon-coating. It could peel off during cooking. In this poster, we will reveal the MPs loads and their removal ratios to STPs. These data will be important parameters to simulate MPs concentration in surface water in rivers and lakes.

TP118 Occurrence of fine microplastics in surface water from a river contaminated by sewage treatment plant effluent in Japan
Y. Kameda, E. Fujita, Chiba Institute of Technology / Creative Engineering

Microplastics (MPs) greater than 20 μm were measured in surface water from a Japanese urban river contaminated by effluent from many wastewater treatment plants. These MPs were collected and measured by a novel developed method using Fourier transform infrared microscopy (μFTIR) with the automatic mapping system. The concentration of MPs increased with the current. The highest concentration was 1471 p/m³ at the river mouth. This concentration was approximately 300 times higher than that from previous study where MPs greater than 335 μm were measured. Particle size distribution of MPs showed that 98.8 % particles were those less than 335 μm and that the median diameter was about 100 μm. The size distribution of MPs surface area also could be revealed that MPs smaller than 335 μm accounted for from 42.7% to 82.8% to all surface area of MPs. Major polymer types detected were PP, PE, PET, PS and PMMA except the river mouth sampling site. On the other hand, Nylon, PVA, ABS-resin and PU-resin were detected at only the river mouth. According to the large decrease of HHCB concentration in surface water, sea water was mixed at the river mouth. Therefore these 4 polymers may be more dominant in sea water at Tokyo Bay. These results indicated that general analysis methods for MPs by picking and FTIR underestimate MPs concentration in surface water remarkably and this analysis technique will be one of the most powerful tool to measure MPs. It also indicated that small MPs were dominant in surface water and they were very important for ecological risk assessment.

TP119 Prediction of polyethylene microplastic concentration originated from face wash products and lip products in surface water by AIST-SHANEL model
Y. Kameda, E. Fujita, Chiba Institute of Technology / Creative Engineering

The concentrations of polyethylene microplastics (PE-MPs) originated from facial wash products and lip products were simulated in surface water in Tsurumi river by AIST-SHANEL model. AIST-SHANEL was established by National institute of Advanced Industrial Science and Technology in Japan. This model can estimate chemical concentrations over 109 Class a river systems in Japan for risk assessment. It can also estimate monthly exposure concentration in a 1 km mesh with emission, climatic, geographical, sewage and industrial statistics in river systems. Almost all of facial wash products do not contain MPs now. Lip products contain remarkably high concentration of PE-MPs smaller than 10 μm in a diameter. In order to predict their concentrations, their net national consumptions, PE-MPs concentrations in each product and their removal rates in sewage treatment plants were used as input data. Predicted concentration of PE-MPs from facial wash products was compared to those observed by Fourier transform infrared microscopy with the automatic mapping system. The results indicated that maximum concentration of PE-MPs from facial wash along the river was 2.3 p/m³ and the contribution to all PE-MPs observed was 12%. It suggested that voluntary regulation of PE-MPs in facial wash products was effective to their reduction in river water. On the other hand, it also demonstrated that other countermeasures were needed for PE-MPs reduction in water. PE-MPs concentration from lip products were estimated that it ranged from 6,000 to 11,000 p/m³. Unfortunately, it was difficult to measure these small MPs by FTIR. Further researches are needed to confirm their occurrence, characteristics and environmental behavior.

TP120 An International research about environmental behaviors of fine microplastics along Kuroshio current ( Western Pacific ocean )
Y. Kameda, E. Fujita, Chiba Institute of Technology / Creative Engineering

Western Pacific ocean is considered to be one of the areas with the highest concentration of microplastics (MPs) in the world. Asian countries must investigate their occurrences, characteristics, sources and environmental behaviors. To understand their behavior, international researches by Asian researchers are needed by using one precision analysis method. This presentation will introduce this dream team research. In our research, an automatic analysis method are used to measure MPs larger than 20 μm in a diameter in surface water and other environmental media. By using these methods, the occurrence in environment such as their concentration, polymer profiles and their size distributions can be revealed along Kuroshio current which begins from Marshall island, Philippines, East China sea, Taiwan and flows northeastward past Japan. The samples are now being collected from open sea, coastal areas, beach sands and aquatic organisms around Japan, Taiwan, China, East China sea, small islands around the equator and northern and Australia. This presentation will also present some research data. This project will be a first action to monitor various pollutants in the western Pacific ocean by Asian and Oceanian scientists collaboration.

TP121 The presence, distribution, and concentration of microplastics in the lower basin of the Chesapeake Bay, USA near wastewater treatment plants
T. Duong, University of Mary Washington / Earth & Environmental Sciences; B. Odhiambo, M. Hoffman, T.E. Frankel, University of Mary Washington / Earth and Environmental Sciences

The Chesapeake Bay is a large estuary located along the east coast of the United States, with numerous wastewater treatment plants (WWTP) located throughout its basin. This area supports a vast diversity of aquatic biota throughout the eastern United States. While effluent from WWTPs has been identified as a major contributor to microplastic pollution, little research has been conducted to examine microplastic contamination in the Chesapeake Bay watershed areas surrounding these effluent streams. Microplastics are unique in that their size (<5mm) enables them to be easily ingested by aquatic organisms, causing adverse health effects such as energy depletion and digestive tract obstructions. MPs may also biomagnify throughout trophic levels, ultimately posing a threat to human health due to consumption. In this study, the presence of microplastics in major rivers in the lower basin of the Chesapeake Bay, USA was examined. Water samples and sediment samples were collected in the Potomac and Rappahannock river upstream, midstream, and downstream of WWTP outfall sites via dip sampling and grab/core sampling, respectively. Sediment samples were treated with a wet peroxide oxidation using Fenton’s reagent to digest natural organic matter and sodium chloride to separate MPs from the treated sample material, and surface water samples were filtered by vacuum filtration to separate suspended particles from water. The presence, type, and quantity of MPs was then assessed using light microscopy. While this project is currently ongoing, we expect to find that MPs are more abundant in samples collected at WWTP outfall locations rather than locations upstream or downstream from those sites. Additionally, we expect to find MPs accumulated in sediment below the alluvial bed, indicating that the sedimentation of plastics has been an ongoing occurrence in the past. The results of this study will provide novel information regarding the current and historical distribution of MPs in the Chesapeake Bay.
TP122 Chronic Toxicity of Micro- and Nanoplastic Particles on Daphnia magna

Q. Pikuda, S. Matthews, E. Xu, D. Berk, N. Tufenkji, McGill University / Department of Chemical Engineering

The presence of plastic debris in the aquatic environment is a potential threat to aquatic organisms. The continual degradation of larger debris under natural environmental conditions, as well as wastes from commercial production are sources of micro-sized and probably nano-sized plastic particles in natural waters. Studies have investigated the acute toxicity of micro- and nanoplastic particles on Daphnia magna. However, to date, information regarding their potential sublethal effects on aquatic organisms is limited. This study assessed the chronic toxicity of 20 nm and 200 nm polystyrene nanoparticles (PS-NPs) on Daphnia magna. The effect on survival, growth, swimming behavior, reproduction and feeding rate was investigated over 21 days using a static renewal method. During the chronic exposure, tested animals were reared in moderately hard rear water, fed with green algae (Chlamydomonas reinhardtii) and YCT following the recommended feeding standard by Environment and Climate Change Canada (ECCC) for chronic toxicity studies with Daphnia magna. PS-NP suspensions were added to the rearing media. The rearing media was changed three times a week, and the PS-NPs were renewed. Survival and reproduction were monitored by a daily count for mortality, immobility, number of neonates, number of broods and first day to brood. Other effects such as differences in hopping frequency, heartbeat rate, postabdominal curling, thoracic movement and swimming behaviour were also measured throughout the duration of the experiment. There was no significant difference in survival for animals exposed to both sizes of the PS-NPs relative to the controls. However, exposed daphnids exhibited reduced feeding and growth rates. Also, the first day to brood was delayed and the number of broods was reduced for both particle sizes relative to the controls. The reduced growth rate may be attributed to the reduced feeding rates of the animals in the presence of the PS-NPs. These results suggest that nanoplastics may have major impacts on the ecological system through delayed reproduction and reduced growth rate which may eventually lead to disruption in population size.

TP123 Occurrences, Distribution and Chemical Characterization of Microplastics in Lagos Lagoon

Q. Abiodun, Nigerian Institute for Oceanography and Marine Research / Department of Biological Oceanography; F.I. Osuala, University of Lagos, Nigeria / Department of Zoology; C.M. Fotsing, University of Johannesburg / Department of Applied Chemistry; A.A. Otitoloju, University of Lagos / Department of Zoology; D. Ndinteh, University of Johannesburg / Department of Applied Chemistry

Microplastics (MPs) particles are one of the most serious problems affecting the aquatic species and environment. However, there is still a lack of precise knowledge about the occurrences, distribution and chemical characterization of microplastics particles in Lagos Lagoon. Twenty-four sampling points were investigated within eight stations based on solid waste floating pathway. The results obtained demonstrate occurrences of MPs in all sampling points. Fragments particles were dominants across the stations consisting of (63.3%) while fiber (5.2%) were observed in lesser quantities. There were significant differences in MPs concentration between sampling stations (P < 0.05). The presence of different types of polymer in the MPs was confirmed by FTIR-ATR spectroscopy, with predominant abundance of polyethylene. Microplastics abundance in Lagos Lagoon varied markedly in sampling points, and positively correlated with the microplastics polymer morphological categories (P< 0.001 and P< 0.05), which confirmed the important role of anthropogenic factors in microplastics distribution.

TP124 Anthropogenic Fibres in the Embryonic Offspring of the Viviparous Surperch, Cymatogaster aggregata

G. Coventon, W. Fleming, University of Victoria / Biology; J.F. Dower, University of Victoria / School of Earth and Ocean Sciences

Anthropogenic fibres (AFs), including synthetic fibres (termed microplastics when < 5 mm in length), semi-synthetic fibres, and natural fibres are ubiquitious in aquatic environments. There is some evidence that AFs, especially microplastics, can be toxic to animals following ingestion, due to both physical and chemical interactions involving the polymer itself and other added or absorbed contaminants. Although AFs have been identified in a large number of marine species, it is unknown whether these fibres can be encountered by the developing embryos of viviparous fish. We investigated the presence of AFs in the gastrointestinal tracts (GIs) of pregnant female shiner surfperch (Cymatogaster aggregata) and in their unborn, embryonic offspring. Following chemical digestion, fibres were morphologically characterized using both light and scanning electron microscopy. A mixture of synthetic, semi-synthetic, and natural AFs was found in both the adult GIs and in the bodies of the embryos, at levels higher than levels of laboratory contamination. Preliminary evidence suggests that the AFs may occur in higher numbers in the embryo GIs compared with the rest of their bodies, indicating that these fibres may be entering the embryos from the uterus via either ingestion or incorporation during development, rather than direct maternal transfer via vasculization. This work provides further evidence of the widespread abundance of AFs, including microplastics, raising questions about the potential harm that these particles may cause to developing embryos, and highlighting scanning electron microscopy as a useful tool for characterizing AFs that have been isolated from biota.

TP125 Microplastic distribution in stormwater from different pavements and removal in bioretention cells

K. Smith, J. Drake, University of Toronto / Department of Civil and Mineral Engineering; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology; E. Passeport, University of Toronto / Department of Civil and Mineral Engineering and Department of Chemical Engineering

Despite the fast-growing research on microplastic distribution and quantification in aquatic environments, little research has focused on urban stormwater runoff. In urban environments, low impact development green infrastructures such as bioretention cells are often implemented to collect, infiltrate, and treat urban runoff. Bioretention cells consist of a depression in the ground filled with engineered media and are covered with mulch and vegetation. While they are typically designed to reduce flooding, they are also able to reduce the concentration of some contaminants such as total suspended solids. Given that microplastics are a type of particle, we hypothesized that bioretention cells would be efficient at removing microplastics from urban runoff. Our study site was located at the Toronto and Region Conservation Authority (TRCA) Kortright Centre in Vaughan, Ontario, Canada. Stormwater samples were collected from 4 different locations receiving runoff from 4 different pavement types: asphalt road, asphalt parking lot, concrete parking lot, and recycled-tire pavement. Water samples were also collected from the inlet and outlet of a bioretention cell receiving runoff from the recycled-tire pavement parking lot. The samples were sieved to 106 um and counted visually before characterization by FTIR spectroscopy. The concentration of microplastics increased as the size range decreased from > 1mm, 500 um - 1 mm, 300 um - 500 um, to 106 um - 300 um. The average concentration in the smaller size fraction was 3 to 10 times higher than in the larger size fraction analyzed. The results showed high percent decreases in microplastic concentrations between the inlet and outlet of the bioretention cell, e.g., a 62%-reduction from 147 particles/L to 56 particles/L and an 81%-reduction from 704 to 134 particles/L in a second pair of samples. Altogether, the results suggest that bioretention cells are efficient at filtering out plastic particles.
TP126 Can Microplastics Act as a Medium to Concentrate Waterborne Microcystin?

E. Hataley, Queen’s University / School of Environmental Studies; X. Ortiz Almirall, Ontario Ministry of the Environment, Conservation and Parks / Toxic Organic Section; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology; D.M. Orihel, Queen’s University / Department of Biology / School of Environmental Studies

The potent liver toxins microcystins (MCs) and microplastics (MPs) are both emerging environmental contaminants now recognized as being widely distributed across the globe. MCs are a diverse group of monocyclic heptapeptide hepatotoxins produced by several genera of freshwater cyanobacteria. MPs are defined as small particles of plastic less than 5 mm in diameter. MPs may impact ecosystems by adhering to and/or being ingested by organisms, which may cause harmful physical effects. Additionally, MPs may be a source of hazardous chemicals via their additive ingredients and/or sorption of environmental contaminants. The exchange of contaminants between MPs and ambient waters is influenced by the physicochemical properties of MPs, the nature of the contaminant, and environmental conditions. Studies have demonstrated the ability of MPs to act as a medium to concentrate hydrophobic (non-polar) contaminants in aquatic environments, driven by their characteristic surface hydrophobicity. This research has not been extended to MCs. MCs are relatively hydrophilic (polar) molecules, implying that their affinity for MPs is negligible; however, many MC congeners contain hydrophobic (non-polar) amino acid residues. Inherent in this lies the question: Can microplastics act as a medium to concentrate waterborne microcystin? To address this question, we developed a laboratory-based experiment to measure the rate and concentration at which a mixture of four MC congeners (MC-LA, -LR, -YR, and -RR) sorb to one of four types of plastic resin pellets (low-density polyethylene, polystyrene, polyethylene terephthalate, and polyvinyl chloride) with and without a biofilm. Our preliminary experiment indicates that MPs can act as a medium to concentrate waterborne MCs, dependent on type of plastic and MC congener. We found that (1) polystyrene exhibited greater sorption capacity across all MC congeners compared to low-density polyethylene, and (2) sorption concentration was directly related to MC congener polarity. This research seeks to understand if and how two dominant environmental issues—namely, microplastic pollution and cyanobacterial harmful algal blooms—interact in a freshwater environment.

TP127 Evaluation of the presence of microplastics in commercial fish and water from the Tecolutla estuary, Veracruz, Mexico

L.S. Hernández, Metropolitan Autonomous University / Department of Hydrobiology; P. Ramirez Romero, Metropolitan Autonomous University, Iztapalapa / Hydrobiology; H. Romero, Metropolitan Autonomous University / Ingeniería en Recursos Energéticos; V. Ramos-Sánchez, Autonomous University of Chihuahua / Química Aplicada y Educativa; R. Márquez-Montes, Centro de Investigación en Materiales Avanzados, S.C.

Microplastics are persistent pollutants with a maximum length of 5000 μm. They contain additives and are vectors of other toxic contaminants, such as POPs and metals. Their presence in sediment increase temperature and decrease permeability. On the other hand, plastic particles are transported efficiently through water bodies. Because of the scarcity of microplastics’ studies in Mexico, the objective of this work was to determine the length, number, color, and shape of microplastics present in commercial fish and water from the Tecolutla, Veracruz estuary. Samples were collected in five stations during three climate seasons (North winds, dry and rainy) in 2016 and 2017. In the laboratory, fish gastrointestinal tracks were dissected and digested using 30% H2O2 to disintegrate the organic matter. The residues were filtered through cellulose paper (Whatman No. 40). For water samples, the volume was measured and filtered through cellulose paper (Whatman No. 40). All filters were dried at 50 °C for 24 h. Finally, microplastics were characterized using a stereoscopic (Zeiss 475022) and a digital microscope (Celestron) with the help of ImageJ software. The validation of polymer particles was carried out by Fourier transform infrared spectroscopy (FTIR) on a Cary 600 FTIR spectrometer. In 155 fish analyzed, 882 microplastics were found, with lengths of 40 - 4180 μm. It is estimated that each organism consumed 4.72 pieces. In the 27 liters of water analyzed, the total number of particles found was 452, with lengths of 10 -1730 μm. There was a significant difference in the length of the microplastics found in water in the different seasons. The predominating color in both matrices was black, followed by blue and red. Regarding form, the most common in all cases was fiber. Based on FTIR analysis, the majority of detected microplastics were polyethylene (PE), polystyrene (PS) and polyethylene terephthalate (PET). The present work concludes there are microplastics in organisms and water in all climate seasons. This is the first evaluation of this pollutant in the Tecolutla estuary and therefore, it is essential to evaluate the ecological significance of plastic particles in aquatic environments.

TP128 Microplastics ingestion in an edible bivalve: Polymesoda caroliniana (Bosc, 1801) from Tecolutla, Veracruz, Mexico

Microplastics (MP) with a length < 5000 μm have become a concern in recent years because of their negative impact on aquatic environments. There is a lack of studies on this type of emerging contaminants in Mexico; this situation makes it difficult to estimate people’s exposure to these contaminants due to shellfish consumption. Therefore, the objective of this study was to calculate human MP ingestion through the analysis of the presence of MP in the edible clam Polymesoda caroliniana in Tecolutla in Veracruz, Mexico. Samples were collected in Larios estuary along three climate seasons (Rains, Dry, and North-winds). In the laboratory, the visceral mass of the clams was extracted to proceed with a 30% hydrogen peroxide (H2O2) digestion (10 mL / 1 g of tissue); the residues were filtered through cellulose paper (Whatman No. 40) and these were dried at 50 °C for 24 hours. The particles’ characterization was done with a stereoscopic microscope (Zeiss West Germany 47 50 22), a digital microscope (Celestron 10X - 150X) and ImageJ software. 88.3% of the clams presented MP, most of which were black fibers; the dominant MP size was < 638 μm. The estimated average concentration was 2.6±1.03 particles/g; therefore, in a 100 g clam cocktail, the consumer could ingest 296 MP. There were no statistically significant differences in the number and size of the analyzed particles among climate seasons. Exposure to MP through bivalve consumption is lower in Mexico (286 MP/year) than in Belgium (6,842 MP/year), France (2,024 MP/year) or China (13,650 to 68,250 MP/year). Fourier transform infrared spectroscopy (FTIR) analysis in a Cary 600 FTIR spectrum (Agilent), showed that the main polymers found in microplastics were: LDPE, Epoxy resin (ER), PET and Cellophane (CP). These results reveal the availability of these contaminants in the Tecolutla River, and therefore that people who consume this type of food are ingesting microplastics on a regular basis. This is the first investigation to perform an MP assessment on bivalve mollusks for human consumption in Mexico. As a result, it is recommended to establish a monitoring program to evaluate the presence of microplastics in edible organisms.

TP129 Ingestion and impacts of tyre particles and synthetic fibers on freshwater invertebrates

T.C. Schell, S. Martinez, A. Martin Quezada, R. Dafouz, IMDEA Water Institute / Ecotoxicology; A. Rico, IMDEA Water Institute; M. Vighi, IMDEA Water Institute / Earth and Environmental Sciences

Tyre wear particles and synthetic fibres are considered to be amongst the most common types of microplastics reaching aquatic ecosystems. Their effects on freshwater biota are, however, mostly unknown. Fibres are assumed to impact organisms mainly by ingestion and physical effects, while tyre particles may additionally release potentially toxic compounds.
This study aimed to determine the acute and chronic effects of tyre particles and fibres on freshwater invertebrate species with different habitat preferences and feeding strategies (i.e., Daphnia magna, Asellus aquaticus, Hyalella azteca and Lumbriculus variegatus). Tyre particles were milled from end-of-life passenger car tyres (Grenaa, Denmark) and sieved to obtain a particle size between 25 and 75 um. Fibres were produced by washing polyester fleece blankets and were between 101 and 2194 um (IQR: 493-992 um) in length and 29 um in width. Acute and chronic toxicity studies were carried out based on standard protocols (OECD 202/211/225 and ASTM E1706-05). Depending on their different habitats, the test organisms were exposed to five increasing concentrations in the water phase (D. magna, H. azteca, A. aquaticus; 0, 0.00015, 0.0015, 0.015, 0.15 g/L) or mixed into the sediment (A. aquaticus, H. azteca and L. variegatus; 0, 0.002, 0.02, 0.2, 2 g/kg). Ingestion and immobility or mortality were assessed for acute and chronic exposure. Additionally, reproduction was assessed during chronic exposure for D. magna and L. variegatus. Single fibres were ingested by all invertebrate species except for D. magna, but caused no adverse effects at the tested concentrations. Tyre particles were ingested by all test organisms in a dose-dependent relationship. Also for tyre debris, no adverse effects were observed at the tested concentrations, except for D. magna reproduction, which was significantly reduced (51%, p < 0.05) at the highest test concentration. The science is finally being published with several strong reports and critical reviews providing sound assessments of microplastic (MP) exposure concentrations vs. adverse ecological effects. Only in parts of Asia are MP concentrations at levels capable of causing adverse organism responses. These other stressors, such as macro-plastics, pesticides, other synthetic organic chemicals, metals, nutrients, altered hydrology and degraded habitat, are strongly linked to adverse ecosystem effects. Given the shortage of research and remediation funding, and the limited resources of environmental managers and their institutions, it is important to focus on those problems causing the greatest damage to our ecosystems.

TP130 Case studies on the use of metal-doped plastics to assess nano- and microplastic fibers in urban and natural environments
D.M. Mitrano, Eawag - Swiss Federal Institute of Aquatic Science and Technology / Process Engineering; J. Jimenez Martinez, Eawag Swiss Federal Institute of Aquatic Science and Technology; A. Pradas del Real, IMIDRA; G. Sarret, ISTerre Institut des SCIences de la Terre/Université Joseph Fourier; H. Castillo-Michel, ESRF-The European Synchrotron / ID; A. Tili, Eawag / Department of Environmental Toxicology

The time and resource intensive nature of particulate plastic (nano- and microplastic particles and fibers) analysis often hinders researchers from preforming mechanistic studies to understand the fate, transport and biological interactions these materials have in both urban and natural environments. While progress is still ongoing to develop analytical methods to measure particulate plastic in field studies, researchers who study these processes in bench top or pilot scale studies can take advantage of an entirely different approach. In the last years, we have synthesized a variety of particulate plastics with an embedded inorganic fingerprint which can be used as a proxy to detect plastic by common analytical techniques for metals analysis, such as ICP-MS, EDX, and XRF. This allows us to more quickly and quantitatively assess plastic in complex matrices than is currently possible with other methods that measure plastics directly. In practice, this allows us to investigate the basic processes and pathways which control particulate plastic fate and provide statistically robust datasets and replicates to form stronger conclusions about the associated risks particulate plastics pose. To highlight the utility of this approach, we used these materials in a number of different test systems investigating the movement and effects of particulate plastic. In this poster, I will provide a brief overview of these applications including 1) the use of sewage sludge as a fertilizer and subsequent nanoplastic mobility through porous media, 2) the interaction and uptake of nanoplastics with wheat plants and 3) the trophic transfer and effects of nanoplastic and microplastic fibers from biofilms to snails. Beyond the case studies specifically highlighted here, these metal-laden particulate plastics are suitable to study a wide variety of fate, transport, eco-toxicity and interactions with organisms. Therefore, this approach can also be used as a platform for others in their own field of study and this poster will provide a launch pad on which to discuss these topics with SETAC attendees.

TP131 Does increasing complexity of exposure scenarios change the toxicity of microplastic and chemical co-exposures to Daphnia magna?
K. Reilly, The University of Birmingham; D. Drage, The University of Birmingham / School of Geography Earth and Environmental Sciences; S.J. Harrad, The University of Birmingham; L.A. Ellis, J. Sadler, I. Lynch, University of Birmingham / Geography Earth Environmental Science

Although microplastics (MP) are increasingly recognised as a contaminant of concern in the environment, several recent studies have shown that the toxicity of pristine MPs is negligible. However, the potential of MPs to act as vectors for chemicals (co-pollutants) commonly found in the environment, often termed the Trojan horse effect, is currently being explored. This study aims to quantify the potential transfer of chemicals of concern and assess the toxicity of MPs to Daphnia magna. In addition to polyethylene microbeads (1-5 um), four chemicals were selected for the study; diclofenac (anti-inflammatory), triclosan (antimicrobial), DEET (insecticide) and Sodium Lauryl Sulphate (SLS) (surfactant) due to their range of uses and widespread presence in environmental water samples. Standard toxicity assays using the OECD 202 test (Acute 48 hour exposure) were conducted initially with the MP and the individual chemicals in varying media to explore a range of water conditions, including daphnia conditioned medium (with proteins). This allowed the calculation of the Lethal Concentration for 50% of the population (LC50 values) for each pollutant to establish the baseline for future comparisons of their mixtures, and to confirm that the MP are taken up dose-dependently. Particle stability in the media and surface charge were determined as this can affect subsequent surface binding. A chemical mass balance was undertaken to establish if the concentration of chemicals on the MP surface changes under competitive binding conditions, by comparing chemical concentration using GC/LC-MS and protein concentrations using a standard extraction. This exposure was performed at chemical concentrations equivalent to individual LC50 values as a starting point. Following this, further analysis was undertaken to represent more environmentally realistic scenarios (i.e. waste water outflows) in terms of the concentrations of chemicals used within the study, to ascertain any potential change in toxicity based on the environmental exposure conditions and chemical concentrations. This is an important step towards understanding the environmental toxicity of MPs in real world conditions and the interaction of MPs with other environmental pollutants.

TP132 We All Hate Plastic Garbage, But Microplastics Are Not the Villains
G.A. Burton, University of Michigan / School for Environment and Sustainability

The science is finally being published with several strong reports and critical reviews providing sound assessments of microplastic (MP) exposure concentrations vs. adverse ecological effects. Only in parts of Asia are MP concentrations at levels capable of causing adverse organism responses. These same areas, however, have elevated levels of chemicals, solids, BOD, and solids due to a lack of wastewater treatment. This raises an obvious question of which of these stressors cause the greatest ecosystem impairment? MPs are a minor vector for chemical biouptake compared to food and at concentrations below toxicity thresholds established in laboratory studies. Where they exist in high numbers, there are other stressors of greater importance from an ecosystem management perspective. These other stressors, such as macro-plastics, pesticides, other synthetic organic chemicals, metals, nutrients, altered hydrology and degraded habitat, are strongly linked to adverse ecosystem effects. Given the shortage of research and remediation funding, and the limited resources of environmental managers and their institutions, it is important to focus on those problems causing the greatest damage to our ecosystems.
TP133 Concentration of Microplastics in Wetlands and Stormwater Retention Ponds
T. Groenewold, T. Bujaczek, MacEwan University / Department of Physical Sciences; D. Locky, MacEwan University / Department of Biological Sciences; M. Ross, MacEwan University / Physical Sciences

Microplastics are small plastic particles, < 5 mm in size, and are an ill understood pollutant in Earth's environment. Urban rivers may be contaminated with microplastics and are a vector for microplastic transport to marine environments. Stormwater runoff, which is rainwater and snowmelt that collects airborne and ground level contaminants but does not penetrate into the soil, could be a potential route for microplastics from terrestrial environments into urban rivers. This project aimed to assess the magnitude of microplastic pollution in constructed and natural wetlands, including stormwater retention ponds, which accumulate contaminants present in stormwater runoff. It was hypothesized that the environment surrounding the ponds would have an impact on the magnitude of microplastic pollution, with high-population/high-use sites having a greater magnitude of microplastic pollution than low-population/low-use sites. Large-volume water samples were collected from stormwater retention ponds and natural wetlands from Edmonton, Alberta, Canada, corresponding to different use profiles: residential, industrial, agriculture, natural, highway-adjacent, parks. Samples underwent an extraction process with filtration to separate microplastics from other debris, peroxide digestion of organics, and size fractionation. The microplastics collected were counted via visual microscopy and confirmed by testing with a hot probe. The microplastic concentrations found were similar to other local freshwater bodies, though there was no variation according to land use. Fibres and films made up the majority of microplastics identified, with the concentration of microplastics increasing with decreasing size class. Further analysis with Raman spectroscopy is ongoing to determine the chemical identity of plastics that are present. Further research is required to understand how pond design and the stagnancy of stormwater retention ponds affects microplastic concentration in the water column compared to flowing river systems.

TP134 Microplastic contamination across several trophic levels within a deep-sea food web
B. Hamilton, University of Toronto / Ecology and Evolutionary Biology; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology; T.J. Hoellein, Loyola University Chicago; B.H. Robison, Monterey Bay Aquarium Research Institute; K.S. Van Houwen, Monterey Bay Aquarium; C. Choy, Scripps Institution of Oceanography

Microplastics (particles < 5mm) are ubiquitous in aquatic and terrestrial ecosystems. Ingestion of microplastics is a concern for wildlife due to toxicological and physical impacts. Trophic transfer of microplastics (i.e. the movement of material among trophic levels) has been observed in nature, but has not been documented in well-understood food webs. Understanding microplastics fate in food webs is crucial to quantify the ecological effects of microplastics worldwide, and will benefit from research conducted well-defined food webs. The Monterey Bay deep submarine canyon food web is well studied with multiple decades of ecological and environmental data, and is thus a model system to examine the trophic fate of microplastics. We sampled 17 different species across approximately five trophic positions, and captured a wide variety of feeding behaviors. Gut contents of each individual were digested in a potassium hydroxide solution, sieved using a 100um mesh, and visually quantified for microplastics greater than 100um in size. A representative subsample of particles was analyzed via Raman Spectroscopy to determine the polymer type and confirm that particles were anthropogenic. Microplastics were found in all species and across all trophic levels. Of the particles found, the majority were blue fibers, which aligns with other studies. There was no difference in microplastic concentration between animals from different trophic levels; however, there does seem to be a trend whereby larger animals have more microplastics in their gut. To better understand the fate of microplastics in food webs, other measurements should be assessed, such as tissue samples, respiratory pathways and other internal organs to test for routes of exposure and potential bioaccumulation and biomagnification. This work will contribute to our collective understanding regarding the fate of microplastics in food webs, and inform global models of microplastics distribution and movement.

TP136 Contamination of anthropogenic microparticles in resident and transplanted Mytilus californianus mussels in San Francisco Bay
E.L. Miller, San Francisco Estuary Institute / Molecular and Environmental Toxicology Center; M.D. Sedlak, R. Sutton, San Francisco Estuary Institute; N. Klasios, University of Toronto / Ecology and Evolutionary Biology; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology

High abundances of anthropogenic microparticles, including microplastics, have been found in San Francisco Bay waters and prey fish, indicating a need to evaluate more broadly the accumulation of microplastics and associated chemical contaminants in the Bay food web. Filter feeders such as bivalves are widely used for biomonitoring, as they can act as integrators of contaminants from the water column. Mussels are an important lower trophic level organism in the Bay, and may therefore represent a significant route of microplastic entry into the food web. The objective of this study was to quantify and compare the abundance and types of anthropogenic microparticles in 90-day transplant and resident Mytilus californianus mussels in San Francisco Bay. We collected resident M. californianus from three Bay sites and one less urban reference site outside the Bay, and 90-day transplants from seven sites within the Bay. We used KOH digestion on composite samples of seven whole organisms to recover anthropogenic microparticles. For a subset of extracted particles, we used Raman spectroscopy to identify chemical composition. For each transplant site, polycyclic aromatic hydrocarbon (PAH) tissue concentrations were also evaluated in composite samples of bivalves deployed and collected alongside those analyzed for microparticles. We detected anthropogenic microparticles in all sample types and at all sites, and fibers were consistently the most dominant category. Transplanted mussels had higher numbers of anthropogenic microparticles per mussel compared to mussels from the resident and reference sites, indicating relatively rapid uptake. We compared anthropogenic microparticle and PAH concentrations in mussels with concentrations in other Bay compartments and with similar bivalve studies reported in the literature. Implications for the magnitude of potential impact will be discussed.

TP137 Microparticles and Microplastics in San Francisco Bay Area Stormwater
A. Gilbreath, San Francisco Estuary Institute / Watershed Program; R. Sutton, M.D. Sedlak, A. Wong, San Francisco Estuary Institute; D. Lin, San Francisco Estuary Institute / Department of Civil and Environmental Engineering; C. Box, 5 Gyres; K. Munno, University of Toronto / Ecology & Evolutionary Biology; L. Werbowksi, University of Toronto / Department of Ecology and Evolutionary Biology; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology

Plastics in the ocean, and more specifically microplastics (< 5 mm), have been gaining global attention as a pervasive and preventable threat to the health of marine ecosystems. Stormwater runoff is believed to be one of the primary pathways for plastic pollution to enter San Francisco Bay. Primary microplastics from industry and other activities (e.g., plastic nurdles, plastic trimming operations), as well as secondary sources of larger plastics fragmented by photooxidative degradation or physical abrasion (e.g., tire abrasion due to roadway wear), can be entrained in stormwater runoff from the landscape and enter drainage systems. This study measured microplastics and other microparticles in stormwater from 12 small tributaries to San Francisco Bay. These tributaries varied in urban and non-urban land uses and were distributed across the region. We employed a new method, collecting depth-integrated samples during storm events to estimate microparticle loads in stormwater. Microparticles captured on sequential 355 micron and 125 micron sieves were manually
counted using visual techniques; approximately 7% of the microparticles were then analyzed using spectroscopy to determine whether they were microplastic. Microparticles were identified in stormwater from all 12 small tributaries, discharging between 1.3 and 30 microparticles per liter. The microparticle concentrations observed were consistent with some studies and higher than others previously reported in the literature. Black rubber fragments made up 47% of all particles sampled, potentially originating from tire wear. A load to the Bay of 10.9 trillion microparticles per year from small tributaries was estimated using a land-use/runoff model. Approximately two-thirds of those particles were estimated to be microplastic. This microparticle load estimate is 230 times greater than the estimated annual load from wastewater treatment plants discharging to the Bay. The results of the load modeling effort suggest that industrial areas may be linked to higher microparticle concentrations in stormwater. We recommend additional investigation into sources of microplastics in the landscape, including a greater number of relevant landscape attributes (e.g., imperviousness, proximity to roadways) to more fully explore factors that contribute to higher levels of microparticles in stormwater.

**TP138 PCB-spiked microplastics act as a vector for PCB bioaccumulation in to two marine polychaetes**

N. Hayman, G. Rosen, NIWC Pacific / Energy and Environmental Sustainability; H. Kranz, San Diego State University Research Foundation / Biology; K. Kowal, San Diego State University Research Foundation; M. Colvin, Naval Information Warfare Center Pacific / Energy and Environmental Sustainability; R. Adams, Loyola Marymount University / Civil Engineering & Environmental Science; A. Cook, USEPA Region 9 / Office of Research & Development; H. Allen, USEPA Region 9 / Superfund Emergency Response

Microplastic (< 5mm) pollution is a pervasive problem in marine waters and sediments. Macro- and micro-plastics have been found in marine mammal, bird, and turtle digestive systems at sites where these species are of ecological importance, and have been linked to mortality associated with starvation. In addition, lower trophic level tissue concentrations for legacy hydrophobic organic contaminants such as polychlorinated biphenyls (PCBs) might make microplastics an exposure risk to higher trophic levels. Hydrophobic pollutants, such as PCBs, sorb to plastics, and it is possible that microplastics act as a vector of these contaminants into the biological community. Current research on the relevance of this phenomenon, compared to traditional mechanisms of contaminant transfer to biological systems, is inconclusive. Towards understanding the role of microplastics as vectors of PCBs in marine sediments, we designed a bioaccumulation study using two Pacific Ocean relevant benthi polychaetes commonly used in EPA laboratory-based bioaccumulation studies: the free-burrowing deposit-feeding Neptys caecoides and the mucus tube-forming, surface, deposit-feeding Neanthes arenacodentata. Using high density polyethylene microplastic beads (63-75 um dia) spiked with PCBs typically used as performance reference compounds in passive sampling studies (i.e. not found in the environment), mixtures of plastic and sediment were created (0.1%-3.0% plastic w/w). Sediment varied in total organic carbon (TOC) content (approx. 0.1%-1%), PCB concentration (approx. 0-1 mg/kg), and physical characteristics (coarse coral sand to fine, silty sediment). Polychaetes (worms) were subsequently exposed for 28 d to assess bioaccumulation of PCBs. Because plastics were spiked with PCBs not commonly found in the environment, differentiation between spiked and natural sediment-associated PCBs accumulated in worm tissue could be determined. Polychaete survival was not adversely affected by plastic concentrations at the highest dose (3% w/w) in any sediment tested. PCB bioaccumulation results are in review and will be presented. This study addresses gaps in the literature regarding the effects of microplastics on the transfer of PCBs into biota in the presence of sediments, with a focus on those with relatively low TOC content. The coral sand sediment selected for this study represents a scenario of particular interest, where low TOC content and potentially high sediment plastic concentrations (due to collection from the North Pacific Gyre), may make microplastics a relevant source of biological uptake of PCBs in these systems.

**TP139 Microplastic behaviour in mesocosm wetlands**

S. Warrack, IISD-Experimental Lakes Area / Department of Environment and Geography; M.D. Rennie, Lakehead University / Biology; M.L. Hanson, University of Manitoba / Environment and Geography

Different factors may affect the settling rate of a microplastic particle e.g., nutrients, biofilm growth, shape of particle, particle type, emergent macrophyte growth, etc. Microplastics can be colonized by biofilms, which may change the plastics’ buoyancy, causing it to move deeper in the water column, or even settle in the sediments. Nutrients, such as phosphorous, can enhance biofilm formation. The shape and the type of polymer of the microplastic will affect its buoyancy and ultimately where it will end up within the water column. Microplastics within systems containing lots of emergent macrophytes, may also alter settling rates as microplastics may adhere to the plant. We conducted two studies, a long-term study to characterize microplastic settling rates, and a short-term study to assess whether nutrient addition and emergent macrophyte growth affected the settling rate of films and fibres in controlled outdoor mesocosm experiments. In the long-term study (July 2017 to April 2019), replicate wetland mesocosms were treated with microplastic fibres, films, foams, microbeads, and fragments. Densities of microplastics within the surface water and sediments were assessed over the span of the experiment. In the short-term study (July 2018-April 2019), all replicate wetland mesocosms were treated with both fibres, and films. There were three treatments: (1) control, (2) no cattails with nutrient addition, and (3) cattails with nutrient addition. Our long-term study indicated that foams, fragments, and microbeads (cosmetic) do not appear to settle within our system, and float on the surface of the water column. Fibres and films settle, and have higher densities within the sediment layer over time. Fibres followed a seasonal pattern when settling, peaking in late fall (2017: 4.3%, 2018: 6.14% fibres settled), and plummeting in spring (2018: 1.06%, 2019: 0.25% fibres settled). Our short-term study indicated that fibres settled within our systems, films did not. The no cattails with nutrient addition treatments had the highest amount of fibres settling. All treatments had highest amounts of settled fibres during the first 2 weeks of sampling (control: 2.42%, no cattails with nutrient addition: 4.62% and cattails with nutrient addition: 6.89% fibres settled). Biofilm development was higher within the nutrient addition tanks, which also followed the trend of increased densities of microplastics within the sediments. Our research on factors affecting microplastic settling rates in freshwater systems will help improve our understanding of microplastic behavior in freshwater systems. This research will also help improve existing management policies and practices in place that relate to microplastics.

**TP140 Microplastic exposure pathways in marine teleost fishes in the Charleston Harbor estuary, SC USA**

B. Parker, College of Charleston / Environmental Studies; B. Beckham, College of Charleston / Environmental Geosciences; G. Sancho, College of Charleston / Biology; B. Ingram, College of Charleston / Marine Biology; J. Ballenger, South Carolina Department of Natural Resources / Inshore Fisheries

Coastal estuaries represent a critical habitat for many species including plankton, fish, marine mammals and birds. These organisms use estuaries like Charleston Harbor, SC USA as vital breeding areas, nursery sites, and feeding grounds. As outlets of watersheds, and in this case in proximity to an urban center, estuaries may also carry increased levels of microplastic debris (defined as < 5mm). Increased trophodynamics in these organic-rich environments presents the potential for multiple pathways of exposure in estuarine ecosystems, such as trophic transfer via ingestion of prey, or consumption and filtration of water and sediment. Teleost fishes (Spot, Leiostomus xanthurus; Red Drum, Sciaenops ocellatus; Striped Mullet, Mugil cephalus; Bay Anchovy, Anchoa mitchilli; Atlantic Menhaden, Brevoortia tyrannus; and Spotted Seatrout, Cynoscion nebulosus) were sampled from Charleston Harbor estuarine waters and digestive tracts dissected. Gut contents of fish were digested in 1M KOH and sieved (63um-1mm). Microplastics from gut contents were counted and classified by color and type (fragment, fiber, tire wear, film,
Previous work using a dietary exposure model that applies results from a local study finding 1% of zooplankton contain microplastics shows that microplastic in zooplankton translates to significant exposure potential to filter-feeding fish. However, this dietary exposure model only accounts for the fraction of microplastics that are able to be ingested by zooplankton. Preliminary results in Atlantic Menhaden showed levels of (larger) microplastic generally higher than predicted for modeled dietary exposure via zooplankton (~1-15 particles for smaller individuals < 5 g, N=4). Observed microplastics in fish analyzed thus far (N=5) ranged from 89 to 177 particles, indicating a potential for other pathways besides solely trophic transfer. Large particles (100µm - 5 mm) were common, and detection in field collected samples of smaller particles (< 63 µm), which are biologically relevant to zooplankton, needs further method refinement to fully assess trophic pathways. Ongoing work will quantify presence of microplastic in fish from different feeding guilds to further relate to dietary exposure risk and fate of microplastics. Fishes that have discriminatory feeding behavior, such as predators like Red Drum and Spotted Seaturtue, are hypothesized to be less likely to encounter microplastics than filter-feeding fish, like Menhaden and Bay Anchovies.

**TP141 Investigating bacterial biofilms that form on bio-based microplastics: Evidence of distinct communities**

K. Uhlig, R.C. Hale, College of William & Mary / Aquatic Health Sciences; B. Song, Virginia Institute of Marine Science / Biological Sciences

Plastic debris provides a novel habitat for microbial fouling communities. Marine-borne microplastics may be more persistent than natural polymeric debris (e.g. cellulose, lignin and chitin) common in coastal and open-ocean systems, potentially allowing for greater transport and distribution of associated colonizing microbes (commonly referred to as a biofilm). Biofilm formation on microplastics affects the fate of plastic debris by way of altering the density of floating plastics, initiating biodegradation, and facilitating ingestion by organisms. Furthermore, pathogenic and invasive species have been found to colonize plastic debris collected from the open ocean. This study compared the estuarine biofilms of five polymer types using next-generation sequencing. The polymers examined include two conventional plastics (high-density polyethylene (HDPE) and polyvinyl chloride (PVC)), and two bio-based plastics, (poly-3-hydroxybutyrate (PHB) and polylactic acid (PLA)).

Two grams of production polymer beads (< 5mm) were deployed for up to four weeks in individual fiberglass mesh bags the lower York River, a major tributary of the Chesapeake Bay. Triplicate samples for each plastic were retrieved during low tide after 7 days, 14 days, and 28 days of immersion. The biofilms investigated in this study include three different stages of development: early colonization, exponential growth, and the pseudo-stable stage, with the goal of capturing early differences in microbial communities that may be blunted in field-collected samples. DNA was extracted from the biofilm microplastics and the 16S rRNA genes amplified using PCR. Purified amplicons were sequenced on the Illumina MiSeq platform and the resulting Amplicon Sequence Variants (ASVs) were taxonomically classified using the SILVA v.132 database at 80% similarity. Here we present findings that suggest that the microbial biofilm communities that form on bio-based microplastics are distinct from those on conventional plastics. We also investigate the presence of potentially pathogenic and hydrocarbonoclastic bacteria amid previous reports of increased Vibrio spp. presence on marine debris collected from the open ocean.

**TP142 Bioaccumulations of microplastics on medaka fish**

Y. Oshima, Faculty of Agriculture, Kyushu University / Fisheries; H. Ogawa, Y. Liu, Y. Shimasaki, Kyushu University / Faculty of Agriculture

This study was performed to elucidate the uptake and bioaccumulation of MP in Japanese medaka (Oryzias latipes) and assessed uptake and depuration kinetics. We exposed medaka to fluorescent MP (2 µmPS, 20 µmPS, 20 µmPE at 10^6 beads/L, 200 µmPS at 10^4 beads/L) for 2 weeks and depurated for 1 week. Water was changed once for 3 days. Fish were sampled at 1, 3, 5, 7, 10, 12, 14, 15, 17, 19, 21, 24 d and fixed with formalin, and then make optimally clean. MPs in the body were directly identified and counted by All-in-One fluorescence microscope (BZ-X810, Keyence, Japan). MP in water was counted after filtration. The calculated bioaccumulation factors in medaka were estimated to 206, 23, 22, 85 and its biological half-life until 17d were estimated to 0.6, 0.6, 0.63, 0.57 at 2 µmPS, 20 µmPS, 20 µmPE, respectively. Further, intake pathway of MP from drinking or filtration will be discussed.

**TP143 Investigation of Microplastics in the Waishkey Bay, Bay Mills Indian Community, Brimley Michigan**

D. Napoletano, A. McGlinch, D. Cryderman, Bay Mills Community College

The Waishkey Bay is located in Eastern Upper Peninsula of Michigan, along the land of the Bay Mills Indian Community, Brimley, MI. It’s location at the outflow of Lake Superior into the St. Marys River creates a unique aquatic ecosystem within the Laurentian Great Lakes. The Bay Mills Indian Community follows a traditional lifeway, which relies heavily on fishing and tourism industries within the bay. The Waishkey Bay watershed receives discharges from three National Pollutant Discharge Elimination System permitted facilities, one active landfill, and other non-point sources of contamination. These sources of contamination may be linked to a rising count of microplastics found in the Waishkey Bay. Microplastic is bio-accumulative and is a threat to the fish species, environment, and possibly human health. In a community-based participatory investigation, analysis of microplastics within Waishkey Bay began in fall 2017. Sediment was collected at ten locations throughout the bay and its tributaries. Approximately 300g was collected using either Ponar sampler in the open bay or stainless-steel spade in washable tributaries. Samples were separated by fraction using a stainless-steel strainer separating fractions at 1.00mm, 300um, and less than 300um. Samples were then digested in aqueous 0.05M Fe(II) and 30% hydrogen peroxide. Plastic particles and fibers were then picked from samples under microscope. Plastics were identified in samples collected from all locations throughout seasonal efforts. The average number of microplastics found within 1.00mm sediment fractions was 11, with an average plastics mass of 1.275mg per sample. An average of 35 microplastics were found in sediment fractions sized 300um, with an average mass of 2.6mg per sample. Sediment samples < 300um contained an average of 8 microplastic fibers, and the average mass of plastic per sample was 0.3mg. This data will be combined with biota and open water analysis during the current sampling season. In all, we are building a baseline of monitoring information upon which the Bay Mills Indian Community can focus future efforts.

**TP144 Modeling aquatic and terrestrial transport pathways for microplastics entering WWTP systems**

C.M. Holmes, Applied Analysis Solutions, LLC; J. Amos, Waterborne Environmental, Inc. / Geospatial Data Technologies; S. Dyer, LeTourneau University / Biology and Kinesiology

Microplastics may enter the environment from a number of sources and in many forms. Plastic particles may be present as influent into municipal wastewater treatment plants (WWTPs). A large portion of these are removed from the water phase during the treatment process, and generally end up in the solids (i.e., sludge). Sludge disposal varies by country, region and locality, including landfill, incinerator, compost, or as land-applied biosolids. There is potential for particles in biosolid applications to reach aquatic systems depending on application location and subsequent environmental conditions. We present a broad-scale model designed to estimate emissions and model the fate of plastic particles exiting WWTPs into the terrestrial and aquatic environments, using spatially-explicit information on WWTPs, river hydrology and terrestrial transport potential. This regional/continental scale model is based on publicly available datasets and contained in a modular and transparent framework which is scalable and portable to multiple geographies. This presentation will demonstrate the utility of the model as applied to different regions, and how the resulting information about ultimate mass disposition within the environment (e.g., soil, freshwater, sediment, marine) and surface water
Organisms in marine waters are exposed to a wide range of contaminants from a variety of sources including wastewater treatment plant effluent, surface runoff from roads, combined sewer overflows, and others. These exposures are often related to biological responses which can affect the health and behavior of individuals, alter reproduction, and impact species survival. Traditional analytical approaches have provided occurrence information on a selected set of traditional and emerging contaminants. In order to provide a more holistic assessment of exposures in the marine environment we are combing monitoring based on high resolution mass spectrometry (HRMS) approaches with hydrodynamic modelling. The HRMS methods provide a broad assessment of exposures by capturing a range of organic contaminants, including metabolites and transformation products, particularly compared to traditional targeted methods. For example, recent sampling in the Salish Sea incorporating HRMS analytical methods identified more than 80 compounds including herbicides, pharmaceuticals, vehicle-related compounds, plasticizers and flame retardants. Unexpected contaminants such as methamphetamine and toxic fungicide metabolite 4-hydroxy-chlorothalonil were detected, as well as transformation products of herbicides and plasticizers that have not been reported elsewhere. In addition to contaminant identification, HRMS methods are being utilized to develop source signatures based on the unique and consistent occurrence of a suite of organic contaminants for a given source category. This allows the evaluation of the magnitude of exposure from different sources at different time points. The Salish Sea Model is being used to incorporate transport considerations in the exposure assessment. The Salish Sea Model is a three-dimensional hydrodynamic and biogeochemical model capable of resolving inter-basin exchange and biogeochemical response. The hydrodynamic component of the model uses the finite-volume community ocean model, with loads from 99 wastewater outfalls and runoff from 161 watersheds, including 22 major rivers to the inner waters of the Salish Sea. The combination of watershed and point-source inputs allows assessment of cumulative exposures from multiple point and non-point sources. The model also facilitates separate prediction of the temporal and spatial exposure patterns of these unique source profiles. The HRMS data can provide a means to validate model outputs, and inform on actual exposure patterns based on model predictions. In this way the combination of HRMS analytical methods and advanced hydrodynamic modeling can provide exposure assessments from different sources and be used to inform management responses.

TP145 Exposure Assessment in Marine Waters Combining High Resolution Mass Spectrometry and Hydrodynamic Modeling

A. James, Z. Tian, University of Washington, Tacoma / Center for Urban Waters; T. Khangaonkar, Pacific Northwest National Laboratory

Organisms in marine waters are exposed to a wide range of contaminants from a variety of sources including wastewater treatment plant effluent, surface runoff from roads, combined sewer overflows, and others. These exposures are often related to biological responses which can affect the health and behavior of individuals, alter reproduction, and impact species survival. Traditional analytical approaches have provided occurrence information on a selected set of traditional and emerging contaminants. In order to provide a more holistic assessment of exposures in the marine environment we are combing monitoring based on high resolution mass spectrometry (HRMS) approaches with hydrodynamic modelling. The HRMS methods provide a broad assessment of exposures by capturing a range of organic contaminants, including metabolites and transformation products, particularly compared to traditional targeted methods. TP146 Non-targeted analyses of soybean grown hydroponically in municipal wastewater effluent and surface waters

S.A. Brecht, D. Anderson, M.L. Hedgespeth, North Carolina State University / Department of Forestry and Environmental Resources; D. Shea, Statera Environmental, Inc. / Biological Sciences; E. Nichols, North Carolina State University / Forestry and Environmental Resources

Water scarcity has led to water reuse for crop irrigation from different water sources that can contain organic chemicals of concern, including regulated and non-regulated chemicals. Previous studies have used targeted analytical approaches to quantify chemical concentrations in food crops, but, to date, no studies have used non-targeted or suspect-screening analyses via high resolution mass spectrometry (HRMS) to evaluate organic chemical features in food crops irrigated with different water sources. Soybeans (Glycine max) were hydroponically grown with secondary-treated municipal wastewater effluent, surface water, and tap water to compare the number of chemical features and types of tentatively identified chemicals in soybean shoots from each water source. After 14 days of hydroponic growth, soybean shoots were weighed for biomass and then extracted for HRMS analysis. Chemical features were compared against the USEPA's Distributed Structure-Searchable Toxicity database (DSTTox). Those with a >=90% match score were tentatively identified using the USEPA's CompiTox Chemicals Dashboard and categorized by chemical class, LogP, and molecular mass. Soybean biomass was significantly greater when grown in wastewater effluent compared to surface water or tap water. Municipal wastewater effluent contained about 400 chemical features of which 90 chemicals were tentatively identified at the >=90% confidence level. Soybean shoots grown in wastewater effluent had 1000 chemical features of which 300 chemicals were tentatively identified and classified as either hormones/pharmaceuticals and personal care products (n=60), industrial chemicals (plasticizers, flame retardants, dyes n=40), or biogenic compounds (plant and fungi compounds n=75). The numbers of chemical features in surface water and tap water, and their respective plant shoots, did not differ substantially from wastewater soybean shoots. Likewise, LogP histogram distributions for identifiable chemicals were similar among water samples and plant shoots as well as the number of chemicals in major chemical classes. These data suggest that chemical features for soybeans grown in wastewater were similar to soybean grown in nearby surface waters or tap water. These results indicate that wastewater effluent may be a viable source of water for growing edible crops. Ongoing work includes additional chemical analysis and a quantitative risk assessment of the chemicals present in soybeans grown in treated municipal wastewater.

TP147 The development of Non-Targeted Analysis workflows for the use of chemical prioritization in environmental water samples

The analysis of contaminants of emerging environmental concern has been an ongoing priority due to their potential for adverse effects on wildlife and human health. With many tens of thousands of chemicals in use today, prioritizing specific chemicals or mixtures of chemicals that should be targeted for analysis has become increasingly difficult. We are developing non-targeted chemical screening tools to look for a broad range of possible chemical contaminants present in environmental waters using liquid chromatography and quadrupole/time of flight mass spectrometry (Waters Xevo LC-QToF), as a first step in the process to assess which chemical contaminants pose a risk to human health and aquatic life and prioritize analytes for future targeted methods. A variety of analysis techniques are being used, including liquid chromatography with different stationary phases (C18, HILIC), and multiple sample collection and preparation methods, including both grab samples with solid phase extraction and polar organic chemical integrative samplers (POCIS) samples. Ideal method conditions needed for data analysis and assessment workflow, including blank subtraction, retention time monitoring, replicate injections, peak alignment, and sequence set up (with possible sample randomization) are also being investigated. One specific workflow is presented and applied to wastewater, surface water, and source and treated drinking water samples collected throughout a single watershed on multiple sampling seasons and flow conditions. The main goal of this work is to examine the occurrence, fate, and transport of chemical contaminants as they travel along a stream flow path from wastewater treatment plant discharge downstream to a drinking water intake and through finished drinking water. Such a sampling design will help determine where in the water cycle chemicals are introduced, which chemicals
resist attenuation via natural processes or during treatment, and whether any new, potentially toxic chemicals are released in the environment as a result of those treatments.

TP148 Examination of trends and variations in contaminants via non-targeted mass spectrometry: An Everglades case study
A. Henderson, Florida International University / Chemistry; B. Ng, Florida International University; S. Landeweer, Florida International University / Chemistry and Biochemistry; N. Quinete, Florida International University (FIU) / Southeast Environmental Research Center SERC; P.R. Gardinali, Florida International University / Chemistry & Biochemistry and SERC

The Contaminant Assessment and Risk Evaluation (CARE) project evaluated traditional contaminants in the Florida Everglades such as metals, nutrients, and organic contaminants. The CARE project was focused directly in the Everglades, and human inhabited areas such as Everglades City and Chokoloskee were excluded from the project. Making these prime areas for determining contaminant flux. The Barron River in Everglades City is fed from the wetlands to the North, which are fed by the agricultural areas near Immokalee. Surface water and sediment samples were obtained seasonally in 2018-2019 from the Barron River transect through Everglades City. Recently, citizen reports of symptoms of potential contamination has renewed interest in the area. These reports have spurred the development of a non-targeted screening method for surface and sediment matrices. Surface water samples (10 mL) were processed by online solid phase extraction followed by liquid chromatography-high resolution mass spectrometry using a Thermo Q Exactive. Samples were analyzed in positive and negative ionization modes in full scan from m/z 100-800 at a resolution of 140,000 and data dependent MS2 for confirmation with an NCE of 30. Data processing was performed using Thermo Compound Discoverer version 3.0. Sediment extractions were achieved through sequential analysis via a Dionex ASE 200 with water, methanol, and acetonitrile. This method proved to be the simplest extraction method, with no significant variation from separately extracting sediment samples. Features found in aqueous samples showed heavy seasonal and spatial variations. Spatial variation showed limited anthropogenic contamination in northern sites closest to the Everglades, while sites further south showed more features of human origins (i.e. pharmaceuticals (Oxyphenol), and industrial chemicals (Tetrahydrofurfuryl methacrylate)). Seasonal variations between the wet and dry seasons showed more anthropogenic contaminants during the dry season, as water flow from the wetlands is greatly reduced during the dry season. The sediment extraction method developed was successful in extracting a variety of compounds and elucidating the differences between sites. Sediment data showed a lower H:C ratio in the northern sites (mean 1.52, n=404) when compared to the southern sites (mean 1.65, n=452), likely from more heterotatox containing natural products, compared to higher amounts of anthropogenic compounds found at southern sites.

TP149 Assessing Reproducibility using Quality Controls for Non-Target Analysis of Environmental Samples
B. Ng, Florida International University / Chemistry and Biochemistry; N. Quinete, NC State University / Florida International University / SERC; P.R. Gardinali, Florida International University / Chemistry & Biochemistry and SERC

Majority of approaches for the screening of environmental contaminants target individual chemical compounds or classes of chemical compounds using highly specific analytical methods. Despite their ability for low level detection and quantification, novel contaminants or transformation products which may pose a risk to humans and wildlife are often overlooked by these methods. Recent advances in mass spectrometry as well as chemometrics have led to the evolution of non-targeted screening approaches to address the presence of unknown organic contaminants. Currently there are currently no established standard methodology or process in how non-target analysis (NTA) should be performed. The goal of quality assurance (QA) for analytical measurements is to reduce errors to acceptable limits and involves the use of quality control (QC). QA applies to the overall measures taken by a laboratory to ensure quality of operation, while QC relates to the measures associated with the quality of individual samples or batches of samples - control the errors. The purpose of a quality control in the analytical process is to acquire valid measurements. As of this moment, there are no established QA/QC guidelines for the validation of analytical performances for NTA. In this study, some quality control guidelines will be proposed to be followed in non-targeted screening methodologies. Workflow reproducibility was assessed using an in-house QC mixture containing selected compounds with a wide range of polarity that can be detected either by electrospray ionization (ESI) positive or ESI negative. The analysis was performed by liquid chromatography coupled to high resolution mass spectrometry (LC-HRMS).

Data processing was done using the software compound discoverer 3.0 using an environmental workflow, which searched a multitude of databases, including Chemspider, EPA Toxcast, MzCloud and others. In this study, we have specifically evaluated method precision, accuracy and reproducibility through an in-house QC mixture in terms of peak area and retention time variability, true positive detection rate and intraday (within days) and interday (consecutive days) variations. It was found that peak area varied a lot for both intraday and interday, but retention time did not, it had a relative standard deviation (RSD) of less than 5% for both intra and interday. The detection rate was greater than 75% for most of the detected compounds, with a few exceptions.

TP150 Pairing high throughput chemical and biological analysis in environmental assessment workflows
C. Zwiener, Environmental Analytical Chemistry, Center for Applied Geoscience, University of Tuebingen / Geosciences; S. Baumann, Agilent / Academic and Government Applied Marketing; T. Anumol, Agilent Technologies, Inc.; S. Vikstrom, Agilent Technologies

Exposure sample analysis for exposomics is increasingly using suspect screening analysis (SSA) in addition to routine targeted chemical analysis. Meanwhile, toxicology testing is increasingly using effects directed analysis (EDA) to supplement multiple/whole organism testing. High throughput methods like SSA and EDA require less time and money than traditional testing, a benefit to risk assessments and other assessments such as routine monitoring. Our goal is to introduce these new approaches and provide concrete examples of how EDA along with complementary SSA and non-targeted analysis help identify and prioritize anthropogenic compounds found in our environment and biological samples. Limited information exists about exposure and toxicity for tens of thousands of chemicals in commerce. High throughput techniques like non-targeted (NTA) and effects-directed analysis (EDA) enhance our understanding of the occurrence and biological activity of chemicals in exposure related samples and their impact on the environment. This course will describe the use of these high(her) throughput techniques and how they can be used to characterize toxicity and prioritize thousands of chemicals in samples related to exposure pathways (e.g., air, water, sediment, food) or biological samples (e.g., urine, saliva, blood). High resolution mass spectrometry (HRMS) is a prominent tool in suspect screening and NTA studies, as the technique can hypothetically detect all chemicals in a sample leaving the researcher to dissect the data to propose at their identities. EDA pairs biological activity testing (e.g., cellular, bioluminescence, and impedance assays) with HRMS to discover and identify compounds that produce effects. Software tools and multivariate statistics allows for high throughput evaluation of complex interactions between anthropogenic compounds, the environment, people, and health.
TP151 Understanding Pesticide Removal and Transformation in Woodchip Bioreactors

M. Hattaway, O. Wright, University of California, Davis / Civil and Environmental Engineering; A.S. Burant, California Department of Pesticide Regulation / Surface Water Protection Program; H. Bischel, T.M. Young, University of California, Davis / Civil and Environmental Engineering

Woodchip bioreactors are an inexpensive, low-tech solution to treat agricultural runoff and mitigate the amount of nitrogen, phosphorous, and possibly pesticides that is released into waterways. However, understanding how the many physicochemical and biological processes occurring in these systems affect the removal or transformation of pesticides in the bioreactor can be challenging. The current study will identify transformation products of a set of pesticides representing a broad range of classes, including neonicotinoids, pyrethroids, and fipronil, in bench-scale bioreactor effluent. Compounds will be analyzed using both liquid and gas chromatography time-of-flight mass spectrometry (LC-QTOF-MS and GC-QTOF-MS), and identified using suspect libraries generated from literature sources and pathway prediction models. Identification of breakdown products will aid in elucidating the specific processes and identifying parameters to be tweaked for optimal pesticide removal.

What’s in Your Neighborhood? Assessing and Understanding Metal(loid) Exposure and Risk in Urban Systems

TP152 Oxidative potential of fine aerosols from National Air Pollution Surveillance network in Canada - influence of source sectors and metal concentrations

P. Shahpoory, T. Harner, V. Celto, E. Dabek, Environment and Climate Change Canada / Air Quality Research Division

Air pollution is a major global health risk. It has been associated with respiratory and cardiovascular diseases as well as increased morbidity and mortality rates. Human exposure to fine particulate matter (PM), especially PM with aerodynamic diameter ≤2.5 μm (PM2.5), is one of the main causes of the adverse effects across the world. Oxidative potential (OP) is a measure of inhalation toxicity of airborne PM. The redox-active constituents of PM react with lung antioxidants in the epithelial lining fluid, resulting in oxidation of antioxidants. Excessive loss of antioxidants results in oxidative stress, inflammation of the epithelial tissue, and chronic diseases. The OP depends on various factors such as PM chemical composition, mass-size distribution, and ambient concentrations. PM chemical composition is influenced by the emission sources and transformation processes in the atmosphere. Among PM components, transition metals, water-soluble organic species and quinones are the major contributors to OP, however, metals are considered to have a greater impact due to their relatively high mass mixing ratios in PM. In this work, we investigated the OP of PM2.5 samples from the National Air Pollution Surveillance sites across Canada, covering urban, traffic, industrial, and background source sectors, as well as temporal profiles. We applied a novel OP method that we developed in-house – it considers the reaction of PM with major lung antioxidants in simulated lung lining fluid and determines the redox state of the samples. The results are evaluated through correlation analysis with PM2.5 components including total and soluble transition metals, and the measured electrochemical reduction potentials of the samples. The preliminary results indicated links between OP, the reduction potentials and changes in major PM2.5 components. This study introduces a new approach for evaluating the inhalation toxicity of PM. Moreover, it provides an insight into how the current trends in urbanization and anthropogenic activities, as well as various emission sources contribute to metal concentrations, human exposure and health risks associated with fine inhalable PM in Canada.

TP153 Long-term Monitoring and Inhalation Risk Assessment of Metals in PM10 in the Great Lakes Basin

W. Li, H. Dryfhout-Clark, Environment and Climate Change Canada / Air Quality Processes Research Section; K.A. Brice, Environment and Climate Change Canada / Air Quality Research Division; H. Hung, Environment and Climate Change Canada / Air Quality Processes Research Section

The Great Lakes is an important resource to wildlife and humans in North America. To protect this great freshwater lake system, Canada’s Great Lakes Basin (GLB) Monitoring and Surveillance Program has been monitoring contaminants in air and precipitation since the 1990s, aiming at assessing the atmospheric deposition of contaminants to the lakes. Long-term monitoring for metals in airborne particles was measured at three sites in the GLB: namely Burnt Island (1992-2013), Point Petre (1988-current) and Egbert (1988-2008) using PM10 high volume air samplers. Exposure to atmospheric metals may lead to a variety of toxicological symptoms in humans and wildlife. The temporal trends of metals in the GLB atmosphere may be changing in response to changes in their usage and emission patterns. To assess such changes, temporal trends were developed using the digital filtration method combined with the Seasonal Kendall test for trends. Sources of metals in the atmosphere were investigated by various techniques including enrichment factor analysis, positive matrix factorization analysis, and potential source contribution function analysis. Cancer and non-cancer risks were assessed for ten metals which have cancer or non-cancer toxicities and could pose a potential public health risk to people by inhalation exposure. It was found that the 19 target metals were detected in at least one sample, with concentrations ranging from not detectable to 850 ng/m3. Aluminum, iron and zinc were the dominant metals, while bismuth, cadmium, cobalt had the lowest concentrations. Trend analysis suggested that the concentrations of most metals decreased significantly with time, suggesting emission reduction during the sampling period. The United States (US) was the major source area for metals in airborne particles measured at the three sites. Generally, the estimated carcinogenic and non-carcinogenic risks were less than 10-6 and 1, respectively, which were within the acceptable levels according to the USEPA.

TP154 Metals in Road Dust and Implications for Urban Health in Toronto

C.L. Wiseman, University of Toronto / School of the Environment; J. Niu, C. Levesque, P.E. Rasmussen, Health Canada / Exposure and Biomonitoring Division

In a major urban system such as Toronto, characterized by a high population density and traffic activity, the volume of metal-enriched road dust originating from non-exhaust sources which may be resuspended to the air is a major public health concern. Road dust is enriched with toxic metals originating from, for instance, the wear and tear of brake system components, tires and asphalt surfaces. The goal of this study is to characterize the metal enrichment patterns in road dust particle size fractions that may be resuspended to the air and inhaled by exposed individuals in Toronto, Canada. As part of this, annual loadings and road-to-air resuspension fluxes of metals in inhalable fractions are estimated. Road dust samples were collected from 2015 - 2016 as a function of road class. Samples were fractionated into two particle sizes during collection: (1) bulk hopper (coarse debris), and (2) inhalable dust box (fine material, nominally 5 μm). Sixty four samples were digested in a mixture of HF, HClO4, HNO3 and HCl and elemental concentrations were measured in digests using ICP-MS. Annual elemental loadings to roads and resuspension fluxes (road-to-air) were estimated using measured metal concentrations combined with available data on the annual mass totals of road sweepings for Toronto. For this, the inhalable fraction was estimated to range between 5 and 10% of the mass total. Metals of health concern were found to be enriched in inhalable fractions of road dust. The greatest enrichments were observed for Cd and Zn. The respective geometric mean (GM) [95% CIs] concentrations of these elements in inhalable vs.
bulk samples were: Cd: 0.55 [0.47, 0.63] μg/g vs. 0.25 [0.22, 0.29] μg/g and Zn: 649 [575, 732] μg/g vs. 252 [218, 292] μg/g. Annual deposition rates for Toronto roads were relatively high for several elements, including Cu and Pb. For instance, a total weighted mean of 736 - 754 kg of Pb was estimated to be deposited on Toronto roads annually, of which 59–118 kg/yr Pb would have been available for resuspension in the inhalable fraction. The study results highlight a need to more closely examine the potential of road dust to serve as a primary source of atmospheric pollution and its role in contributing to a range of human health outcomes.

**TP155 Metalloid enriched topsoils in a multiple land-use area in Tuscany (Italy): Geogenic versus anthropogenic contributions and associated health risk**

F. Monaci, University of Siena / Life Sciences; E. Donegan, BOKU University of Natural Resources and Life Sciences; D. Baroni, University of Siena / Department of Environment Earth and Physical Sciences

The Piana di Scarlino is a partially refilled wetland in the SW of Tuscany (Central Italy) which has hosted chemical and power plants since the 1960s. Presently, in the area there are urban settlements (the main urban center, Follonica, has a population of approx. 25,000), farms, tourist facilities, and industrial districts, mainly based on H2SO4 and TiO2 production as well as waste incineration. In the last two decades the soil and groundwater of the Piana di Scarlino, have been found polluted with arsenic (As) and heavy metals. This prompted local authorities to implement remediation measures and environmental monitoring programs to protect the resident population and the local agricultural produce. In 2013, we initiated an environmental surveillance program in the area within an IPPC permitting procedure for monitoring As and heavy metals and assessing human health implications. The study initially aimed at establishing topsoil data to be used as baseline for long-term monitoring. Overall total As concentration of superficial soils (0-5 cm), collected from 44 sampling sites randomly selected within a circular area up to 1.5 km around the industrial district, was on average 33.8 ± 35.9 μg/g. This value, is approximately 3 times higher than the European baseline and highlights a general enrichment of topsoil As content. This is mainly attributable to widespread geochemical anomalies characterizing Southern Tuscany and to the historical mineral processing and smelting activities carried out in the Scarlino area until the mid-90s. The highest As concentrations were found in soils from sampling sites in the proximity of a pyrite ash dump, where concentrations over 200 μg/g were reached. Average concentrations (32.9 μg/g) from agricultural and grazing soils were also much higher than the baseline for Italian agricultural lands (7.56 μg/g). Although soils from urban sites generally showed the lowest As concentrations, average As concentrations for the urban area (21.8 μg/g) remained over the screening values (20 μg/g) for contaminated soils set by the Italian regulatory framework for residential areas. In this context, we used multi-element analysis supported by techniques for monitoring atmospheric depositions to improve estimation of exposure and related health risks arising from the nearby industrial activities as well as to assess the relative contribution of historical and present-day As sources in the Scarlino area.

**TP156 Effect of Soil Particle Size and Extraction Method on the Oral Bioaccessibility of Arsenic**

Y. Lowney, Alloy, LLC / Health Sciences; S. Roberts, University of Florida / Department of Environmental and Global Health; L. Stuchal, University of Florida / Center for Environmental and Human Toxicology; N.G. Odezulu, University of Florida / Physiological Sciences; M. Kozuch, University of Florida / Center of Environmental and Human Toxicology

Decades of research has clearly established that there are site- and soil-specific factors that control the bioavailability of arsenic from soil, and that these factors should appropriately be factored into human health risk assessment (HHRA) of contaminated sites. Guidance from the USEPA and several State agencies provide useful information regarding inexpensive “in vitro” methods to estimate the bioavailability of arsenic from soils, and the process for incorporating the in vitro bioaccessibility (IVBA) data into HHRA. The animal research that establishes the relative oral bioavailability of arsenic from soils, and which underlies the IVBA methods, was largely conducted using soils sieved to < 250 um. Recently, the USEPA updated their guidance on assessing exposures to chemicals in soil at contaminated sites, and now recommends that HHRA of contaminated soils focus on soil particles < 150 um. This research evaluates soils from several arsenic-contaminated sites to assess the effect of two different IVBA methods on soils from diverse regions and arsenic sources. For a matched set of soils, the research also evaluates the effect of particle size. The findings and implications for HHRA of arsenic in soil will be addressed.

**TP157 Characterizing Metals/Metalloids and Microplastics in Municipal Compost Produced from the Organic Fraction of Municipal Organic Waste**

M. Dodd, Royal Roads University / School of Environment & Sustainability; D. McCartney, University of Alberta / Civil & Environmental Engineering

Municipal leaf, yard and garden waste, and food scraps are currently banned from disposal in landfills in various municipalities including Victoria. Municipalities have therefore established composting facilities where these materials are converted into valuable soil amendments. Atmospheric input, road runoff, pesticides, paints on nearby structures, vehicular traffic, littering and other activities can potentially introduce metals and other contaminants such as microplastics into leaf and yard waste which may eventually end up in compost. It has been suggested that microplastics may adsorb metals thereby increasing their retention in different substrates including compost. This paper will present our findings of the metal and or metalloid concentrations present in compost, the metal and or metalloid concentrations present in compost, and the metal and or metalloid concentrations present in compost. The compost was sampled at 10 different facilities, each of which had primary leaf and yard waste as feedstock and the other five were facilities which had primarily residential food waste as feedstock, e.g., source separated organics. Three composite samples were collected at each facility. Each composite sample was prepared using ten 2-L increments (point samples) that were collected from random locations of the pile. Each gross sample was quartered in the field to provide about 3 L of sample. Samples were then split for analysis of general compost properties (TN, TP, TK, pH, OM, C:N, Na, Mg, Ca, Pb, Zn), metals/metalloids by ICP-MS and XRF, and in vitro bioaccessibility. After oxidation of organic matter in the compost samples using Fenton’s reagent, microplastics were separated by density separation with sodium iodide and characterized by microscopy and FT-IR. The results of these analyses will be presented including: differences between the two types of compost; relationship between metals and microplastics content; and potential human and environmental risk associated with using these municipal sourced composts incorporating metal bioaccessibility.

**TP158 Contaminant risks in stormwater leachate from crumb rubber and thermoplastic elastomer artificial turf infills used in Pacific Northwest playfields**

J.A. Colgan, King County Department of Natural Resources and Parks / Water and Land Resources Division

Many concerns exist surrounding the use of crumb rubber infill for turf fields. Some concerns are well-known and documented such as the release of metals to stormwater runoff at levels high enough to cause impacts to aquatic life. The large Pacific Northwest city of Seattle is located in King County, Washington. All County-owned artificial turf playfields contain crumb rubber infill. However, local regulations require crumb rubber fields to incorporate treatment technology to remove metals from stormwater effluent due to documented metals releases, particularly zinc. These
Benzobicyclon (BZB) is a recently registered rice pro-herbicide in the United States. Studies on the environmental fate of benzobicyclon have been conducted in regions including California and Japan. Benzobicyclon is pending registration in Louisiana, where rice and crayfish are cultivated in the same fields and harvested in production cycles. Pesticides applied to rice paddies have the potential to persist in the rice field and result in prolonged exposure to crayfish. Previous studies have shown that benzobicyclon has a strong affinity for sediment and a low toxicity to crayfish. Exposure of benzobicyclon to P. clarkii determined no acute effects, while chronic effects of benzobicyclon were reported in some invertebrates. Benzobicyclon undergoes hydrolysis in flooded rice paddies to form benzobicyclon hydrolysate (BH), the active ingredient. The purpose of this investigation was to determine how benzobicyclon degrades and persists in a Louisiana rice field. Fields treated with benzobicyclon were sampled for water and sediment through two growing seasons, 2018 and 2019. Benzobicyclon and benzobicyclon hydrolysate were extracted from water and sediment samples and analyzed by HPLC. Concentrations of BZB were found to be higher in sediment, suggesting that sediment acts as a sink for BZB, while BH concentrations were higher in water.

These data coincide with the partitioning trends of BZB and BH in other studies. Concentrations of both compounds were below the limit of detection after 43 days post-application. The hydroxyl radical rate constant of the hydrolysate was estimated in this study. Previous studies have shown that hydroxyl radical degradation is most significant in shallow waters, such as a flooded rice field. Characterizing the hydroxyl radical rate constant is important when determining the rate of degradation of benzobicyclon in Louisiana rice fields. The hydroxyl radical rate constant of BH was estimated using competition kinetics. An equimolar mixture of BH and a competitor, with a known rate constant, were exposed to hydroxyl radicals. The rate constant was estimated to be $9.8 \times 10^{12}$ (M$^{-1}$/h). Understanding the fate of benzobicyclon in Louisiana rice fields is pertinent to know how this pesticide will potentially impact crayfish production and health.

### Chemistry and Exposure Assessment

**TP160 Environmental Fate of Benzobicyclon in a Louisiana Rice Field**

*X. Pooles, Louisiana State University / Environmental Sciences School of the Coast and Environment; J. Landry, Louisiana State University / Department of Environmental Sciences; M. LaNasa, Louisiana State University / Environmental Sciences School of the Coast and Environment; E.N. Vebrosky, Louisiana State University / Department of Environmental Sciences; L.M. Basirico, Accounting Services / Environmental Sciences School of the Coast and Environment; K.L. Armburst, Louisiana State University / Environmental Sciences School of the Coast and Environment*

Benzobicyclon (BZB) is a recently registered rice pro-herbicide in the United States. Studies on the environmental fate of benzobicyclon have been conducted in regions including California and Japan. Benzobicyclon is pending registration in Louisiana, where rice and crayfish are cultivated in the same fields and harvested in production cycles. Pesticides applied to rice paddies have the potential to persist in the rice field and result in prolonged exposure to crayfish. Previous studies have shown that benzobicyclon has a strong affinity for sediment and a low toxicity to crayfish. Exposure of benzobicyclon to P. clarkii determined no acute effects, while chronic effects of benzobicyclon were reported in some invertebrates. Benzobicyclon undergoes hydrolysis in flooded rice paddies to form benzobicyclon hydrolysate (BH), the active ingredient. The purpose of this investigation was to determine how benzobicyclon degrades and persists in a Louisiana rice field. Fields treated with benzobicyclon were sampled for water and sediment through two growing seasons, 2018 and 2019. Benzobicyclon and benzobicyclon hydrolysate were extracted from water and sediment samples and analyzed by HPLC. Concentrations of BZB were found to be higher in sediment, suggesting that sediment acts as a sink for BZB, while BH concentrations were higher in water.

These data coincide with the partitioning trends of BZB and BH in other studies. Concentrations of both compounds were below the limit of detection after 43 days post-application. The hydroxyl radical rate constant of the hydrolysate was estimated in this study. Previous studies have shown that hydroxyl radical degradation is most significant in shallow waters, such as a flooded rice field. Characterizing the hydroxyl radical rate constant is important when determining the rate of degradation of benzobicyclon in Louisiana rice fields. The hydroxyl radical rate constant of BH was estimated using competition kinetics. An equimolar mixture of BH and a competitor, with a known rate constant, were exposed to hydroxyl radicals. The rate constant was estimated to be $9.8 \times 10^{12}$ (M$^{-1}$/h). Understanding the fate of benzobicyclon in Louisiana rice fields is pertinent to know how this pesticide will potentially impact crayfish production and health.

**TP161 A Critical Review on Snow Scavenging of Cyclic Volatile Methyloisoxanes**

*S. Xu, Dow Chemical Company / Toxicology and Environmental Research and Consulting*

Snow scavenging was speculated as a deposition mechanism in polar regions for airborne volatile methylsiloxanes (VMS), a group of emerging contaminants related to personal care products. In this presentation, the issue of snow scavenging of two representative VMS, octamethylenecyclotetrasiloxane (D4) and decamethylene-cyclododecasiloxane (D5), is critically reviewed. Modeling and experimental data are presented, as well as future research directions are proposed. Briefly, the snow scavenging of VMS was used to explain the unexpected detection of cVMS from the coastal area of Antarctica. However, model calculations suggest that sorption of VMS by atmospheric particulates and snow particles is minimal. In a recent laboratory study, the sorption coefficients on snowflakes (KiA) and the snow scavenging ratios were measured at different temperatures, varying from -2 to -20°C, using 14C-labeled D4 and D5 against a benchmark compound, cyclopentanone. The results - consistent with the modeling assessments - show that the sorption of VMS by snow is too small to increase their deposition potential. In these experiments almost 99% of all D4 and D5 in a snowpack was lost during the snow melting process through re-volatilization and degradation, and D4 and D5 became non-detectable in snowmelt water. Therefore, the existing data suggest that snow scavenging is not an effective deposition mechanism for these volatile hydrophobic compounds. In the view of these results, speculation of snow scavenging of methylsiloxanes in the coastal area of Antarctica seem to be questionable. It is planned to verify these findings by actual measurements in the future field research.

**TP162 Long-Term Monitoring and Trend Analysis of Cyclic Volatile Methyloisoxanes (cVMS) in Aquatic Environments Impacted by Wastewater Effluent**

*R. M. Sexton, Hyla Environmental Consulting, LLC / Toxicology, Environmental Research & Consulting; J. Kim, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting; C. Mund, T. Boehler, Evonik Nutrition & Care GmbH; N. Meguriya, Shin-ETSU*

Cyclic volatile methylsiloxanes (cVMS) are widely used in consumer applications. Because wastewater represents the major post-use disposal route for cVMS, the Silicone Industry Associations in North America, Europe, and Japan initiated a global monitoring program of predominant cVMS, including octamethylocyclotetrasiloxane (D4), decamethylene-cyclo-pentasiloxane (D5), and dodecamethylene-cyclohexasiloxane (D6) in surface
sediments and aquatic biota. Aquatic environments that are impacted by municipal wastewater effluents were selected as study areas for the monitoring program, and included Lake Pepin (USA), Lake Ontario (on the border between Canada and USA), Oslofjord (Norway), and Tokyo Bay (Japan). The target objective of the monitoring program was to determine if concentrations of cVMS were stable or changing, which is defined as a statistically significant (α=0.05) annual rate of change of ≥6% per year (net change of -2% to 34%) detected with 80% power (β=0.20). Target matrices for each study area include surface sediments, benthic invertebrates near the base of the food chain, low trophic level forage fish, and high trophic level piscivorous fish. The monitoring period was from 2011 to 2016. Generally, concentrations of cVMS in both surface sediment and biota showed decreasing trends over the monitoring period; however, the statistical power was relatively weak in many cases. Thus, considering the annual variability, concentrations of cVMS in biota and sediment have been stable or decreasing in most monitoring locations based on the aforementioned statistical criteria. This presentation will discuss more details of monitoring data and their trends over the project period by location and species.

TP163 Identification and Reduction of Analytical Bias for Analysis of Siloxanes

When analyzing for siloxanes, careful consideration of the potential for analytical bias is critical to success. It is therefore imperative that the proper quality control (QC) is performed to ensure the accuracy of results. This is especially true when the analytes are present in common personal care products, and/or the reagents and analytical instrumentation utilized in the method. Siloxanes possess physical/chemical properties that are distinctly different from carbon-based materials of similar size and also different reactivity with reagents, instrumentation and contaminants present in the environment or lab. These differences can lead to mis-identification, overestimation and even underestimation of the analyte of choice. In this presentation, various collection, processing, and analytical methods are critically reviewed to demonstrate sources of contamination and loss. Incorporation of a robust QC program allows for successful isolation and identification of sources of analytical bias. Some siloxanes undergo rearrangement in heated inlets, analytical chromatography columns or during sample processing under typical conditions of processing and analysis. Interactions and mass transfer of siloxane can also occur at the time of sample collection with typical collection media and sample processing environment or during storage over time. Therefore, a strong QC program utilizing matrix matched blanks, individual and combined spiked samples, and replications are critical when evaluating environmental and biological samples for concentrations of siloxanes. The types of QC samples necessary to identify locations of analytical bias are further discussed. Methods for reducing or eliminating analytical bias during sample collection, processing, and analysis are recommended. Some examples are 1) careful selection of sorbent material that does not catalyze rearrangement reactions of Si materials, 2) use of instrument septa and columns that do not contain Si materials, and 3) consideration of method conditions in order to a) avoid material exchange between samples and lab surroundings and b) minimize changes of pH and heat, thus reducing the potential for undesired reactions occurring during processing.

TP164 Quantification of ppb dimethylsilanediol in water by NMR

D. Eldred, The Dow Chemical Company / Analytical Sciences; S. Allmann, Wacker Chemie; D. McNett, The Dow Chemical Company / Toxicology Environmental Research and Consulting; H. Pracy, DuPont / Analytical Sciences; C. Roggenbuck, The Dow Chemical Company / Analytical Sciences; S. Xu, Dow Chemical Company / Toxicology and Environmental Research and Consulting

There is a growing interest to evaluate the environmental fate of volatile methyl siloxanes (VMS), particularly in aqueous environments. Dimethylsilanediol (DMSD) is the principle hydrolysis product of VMS and is relevant to detect at low concentration levels. 1H NMR is employed to achieve DMSD detection and characterization at single digit part per billion (ppb) concentrations through silylmethyl measurement. Relative to more selective 29Si NMR, 1H offers several advantages to facilitate detection at environmental concentrations. The number of equivalent protons per silicon, lack of 1H-1H coupling, high natural abundance, relatively short spin lattice relaxation, and strong gyromagnetic ratio are all features which lend themselves to facilitating DMSD detection by 1H NMR. To achieve low concentration silylmethyl detection in aqueous environments, water suppression through a composite of a multipass Shaped pulse PResaturation and WATER GrAdient Tailored Excitation with 5 pairs of symmetric pulses (SPR-W5-WATERGATE) is applied as an alternative to the more traditional presaturation approach. Measurement of DMSD can be significantly influenced by sample preparation. Siloxanes are frequently used as glass, metal and plastic lubricants; facilitate joint seals in chemical reactions; and are common in personal care products such as deodorants and shampoos. At the inlet for chromatography methods it is difficult to differentiate inadvertent siloxane exposure vs inadvertent condensation of DMSD. Measurement under standard NMR conditions avoids high inlet temperatures, and dramatic concentration shifts that may influence the sensitive hydrolysis and condensation balance for DMSD and silicone/siloxane materials in the sample. We demonstrate that the use of a reverse osmosis treated water supply with negligible DMSD content can be used to generate a suitable control standard, 4,4-dimethyl-4-silapentane-1-sulfonic acid. Introduction of a small amount of the weighed internal standard solution is demonstrated suitable for measuring DMSD with high fidelity.

TP165 Comprehensive Multiphase Nuclear Magnetic Resonance: A Powerful Tool in Optimizing Biofuel Production

P. Ning, D. Lane, University of Toronto; R. Soong, University of Toronto Scarborough / Department of Physical and Environmental Sciences; D. Schmidig, T. Frei, P. De Castro, I. Kovacevic, S. Graf, Bruker BioSpin AG; S. Wegner, F. Busse, Bruker BioSpin GmbH; J. Struppe, M. Fey, Bruker Corporation; H.J. Stronks, M. Monette, Bruker Ltd.; H. Heumann, Silantes GmbH; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences; A.J. Simpson, University of Toronto Scarborough / Department of Physical and Environmental Sciences

Algae are seen as one of the most important sources of biofuel. They can be grown rapidly and take carbon dioxide from the atmosphere during growth, reducing overall carbon emissions. Conventionally, subcritical water extraction (water under pressure and heat) is used to extract algae to produce biofuel. However, the composition of components, in the extract or left behind, is not well understood, and the chemical and physical mechanisms that prevent the materials from being extracted efficiently have yet to be elucidated. Nuclear magnetic resonance (NMR), a powerful tool to provide information at molecular level, traditionally has developed in to 3 separate fields dealing with solids, gels and solutions due to hardware requirements. Comprehensive Multiphase (CMP) NMR combines all electronics and hardware into a universal probe that permits a holistic overview of all phases (i.e., liquid, gel-like, semi-solid, and solid) in intact samples. Applying CMP-NMR to algae extraction provides a unique insight into what has been extracted (liquid phase), what has been swollen (potentially extractable with method optimization) and what is inaccessible to extraction solvent, subcritical water in this.
TP166 Distribution and Fate of Petroleum Hydrocarbons in Coastal Seawater, Sediment, and Bivalves after the Hebei Spirit Oil Spill Incident

M. Kim, J. Jung, J. An, S. Ha, U. Yim, Korea Institute of Ocean Science and Technology / Risk Assessment Research Center

An estimated 12,547 kilo liters (10,900 M/T) of crude oil was spilled in December 2007 after the collision between the oil tanker Hebei Spirit and a barge carrying a crane. More than 375 km of western coastline of Korea were impacted by the spill, threatening the health of natural marine ecosystem and various mariculture activities. Spatiotemporal variations of oil contamination were investigated until 2018 since the spill. Polycyclic aromatic hydrocarbons (PAHs) and/or total petroleum hydrocarbons (TPH) in seawater, sediment, and bivalves were analyzed. Immediately after the spill, the direct impact of the Hebei Spirit oil spill was clearly recognized at most sites surveyed. TPH concentration in seawater was 154 times higher than the Korean marine water quality standard of 10 ppb on average. PAH concentrations in sediments measured immediately after the spill ranged from 3.2 ng/g to 71,200 ng/g, with an average of 3,800 ng/g. Parent and alkylated PAHs in bivalves increased up to 1,200 and 106,000 ng/g, respectively, which were 60 and 1000 times higher than the pre-spill concentration level. The oil component concentrations in seawater and bivalves were several orders of magnitude higher than those detected at reference sites. The distribution of oil contamination showed considerable variability depending on the proximity to the spill location. Thereafter the oil contamination in the media have decreased gradually to background levels with varying degrees of half-lives depending on the matrices. Recovery from the impact was the fastest in seawater, followed by bivalves and sediment. The clear impact of the oil spill, however, was still observed at several sites even ten years after the spill. This results demonstrate persistence of the impact of oil pollution at sites of specific conditions. Continuous long-term monitoring of oil contamination is needed especially at the sites of lingering oil to understand and estimate the continuing impact of the Hebei Spirit oil spill.

TP167 Toxicological effects of Escravos light crude oil and three dispersants on Clarias gariepinus (the African sharptooth catfish)

E.G. Nwabudike, J.K. Salihu, University of Lagos / Department of Zoology

The control of crude oil spills in aquatic ecosystems involves the use of dispersants which act by breaking up the oil to facilitate degradation. However, dispersants may synergise or moderate the toxicity of crude oil. This study investigated the single- and joint-action toxicity of Escravos Light Crude Oil (ELCO) and three dispersants (Rig Wash/Degreaser (RW/D), Oil Slick (OS) and Gold Crew (GC)) against Clarias gariepinus, the African Sharptooth catfish. The biochemical, genotoxic, haematological and histological effects of sublethal concentrations (1% and 10% of 96 hLC50) of ELCO:dispersants mixtures were also investigated over a period of 28 days. The derived 96 hLC50 values revealed that the dispersants, RW/D (0.15 mL/L) was the most toxic, followed by OS (0.17 mL/L), GC (0.28 mL/L) and ELCO (7.53 mL/L) was the least toxic when acting singly. Joint action toxicity evaluations of ELCO:RW/D, ELCO:OS and ELCO:GC at ratio 9:1 was synergistic with synergistic ratio values of 2.12, 2.07 and 3.34 respectively. The biochemical studies revealed that the activities of reduced glutathione, superoxide dismutase and catalase in the kidney of C. gariepinus treated with 10% 96 hLC50 of ELCO:RW/D and ELCO:OS while glutathione-s-transferase levels in ELCO:RW/D and ELCO:GC were significantly (p < 0.05) reduced. Gill malondialdehyde levels in C. gariepinus exposed to sublethal concentrations of ELCO:RW/D and ELCO:OS were significantly (p < 0.05) higher than the control. Genotoxic indices such as micronuclei, blebbled nuclei, irregular erythrocytes, DNA tail length and tail DNA percentage were significantly increased (p < 0.05) dose-dependently in treated C. gariepinus. Haematologic indices such as erythrocytes, haemoglobin, packed cell volume and mean corpuscular volume were significantly decreased (p < 0.05) whereas mean corpuscular haemoglobin and mean corpuscular haemoglobin concentration increased significantly (p < 0.05) in treated C. gariepinus. Gill histological anomalies such as blunt and curved secondary lamella, necrosis, eroded epithelium, hyperplasia, and epithelial lifting were induced in C. gariepinus exposed to sublethal concentrations of the ELCO: dispersant mixtures. The results demonstrate the need for holistic evaluations of chemical mixtures for oil spill control and the consideration of fisheries in the receiving aquatic ecosystem in setting ecologically sensitive crude oil:dispersant ratios.

TP168 A more cost-efficient extraction method for polycyclic aromatic hydrocarbons (PAH) in sediments and soils using accelerated solvent extraction (ASE)

Z. Xia, N. Klaassen, I.G. Idowu, J. Stetefeld, G.T. Tomy, The University of Manitoba / Department of Chemistry

Accelerated solvent extraction (ASE) is a novel extraction method that is accepted by the U.S. Environmental Protection Agency (USEPA) for extracting solid matrices. ASE is commonly used to extract polycyclic aromatic compounds (PACs) from solid materials. PAHs, the most common PACs, have been identified as priority compounds by the USEPA. The development of ASE extraction methods for PAHs can be traced back to the 1990s. Recently, a one-step ASE method that negated the need for adsorption chromatography was reported by Kim et al. to extract PAHs from marine sediments. Inspired by the previous work, the Centre for Oil and Gas Research and Development (COGRAD), which is committed to advancing the analytical measurements of oil and gas related compounds in an ISO-17025 accredited laboratory, decided to further investigate the one-step ASE method for PAHs on two standard reference materials (SRMs). The overarching goal was to verify the suitability of the one-step method and its applicability to improve laboratory efficiency.

TP169 High Performance Liquid Chromatography Methods for Analysis of Polycyclic Aromatic Compounds in Ambient Air Samples from the Great Lakes Basin

N. Alexandrou, R. Park, Environment and Climate Change Canada / Air Quality Processes Research Section; K.A. Brice, Environment and Climate Change Canada / Air Quality Research Division; H. Hung, A. Pajda, M. Baroi, Environment and Climate Change Canada / Air Quality Processes Research Section

The determination of polycyclic aromatic compounds (PACs) in air samples is of concern due to the toxic, mutagenic and/or carcinogenic properties of these compounds. Since 1990, ambient air sampling has been conducted in the Great Lakes Basin (GLB), with the collection of particulate phase and vapour phase semi-volatile organic pollutants on glass fiber filters (GFFs) and polyurethane foams (PUFs), respectively, from approximately 350 m³ of air. Up until 1999, the GFFs were Soxhlet extracted with dichloromethane and since then with Accelerated Solvent Extraction (ASE) using a hexane:acetone mixture (7:3, v/v), while the PUFs were Soxhlet extracted with hexane. The extracts were subjected to clean-up using silica columns and dichloromethane elution prior to
Analysis by high performance liquid chromatography (HPLC) with fluorescence (FLD) and ultra violet (UV) detection methods that have been developed for the analysis of parent polycyclic aromatic hydrocarbons (PAHs) and alkylated PAHs. An acetonitrile/water gradient at 1.5 mL/min flow rate and a Vydac C18 high carbon content column (150 mm x 4.6 mm), 5 μm particle size was used in separating twenty-three parent PAHs. An Agilent C18 narrow bore column (150 mm x 2.1 mm), 5 μm particle size and an acetonitrile/water gradient at 0.6 mL/min was used in separating the twenty-two alkylated PAHs. For improved fluorescence sensitivity, the optimum excitation and emission wavelengths were used for all the PAHs, while the gradient solvents were degassed continuously to eliminate quenching of the response. The column temperature was maintained within ± 0.5°C for stable retention times. On-column detection limits in the range of 0.03 - 0.5 pg were obtained for the parent PAHs and 0.1 - 3.0 pg for the alkylated PAHs. The developed methods have been used successfully to determine the parent PAH levels in air samples collected since 1990 and alkylated PAHs since 2016.

TP170 Trends and Human Exposure to Polycyclic Aromatic Hydrocarbons (PAHs) in the Atmosphere of the Canadian Great Lakes Basin (GLB)
W. Li, R. Park, N. Alexandrou, Environment and Climate Change Canada / Air Quality Processes Research Section; K.A. Brice, Environment and Climate Change Canada / Air Quality Research Division; H. Dryjout-Clark, H. Hung, A. Pajda, M. Baroii, Environment and Climate Change Canada / Air Quality Processes Research Section

Polycyclic aromatic hydrocarbons (PAHs) are widespread contaminants that have been targeted for monitoring in the environmental due to their related health effects of lung, gastrointestinal, skin, and bladder cancers. Studying the long-term trends of PAHs in the atmosphere of the Great Lakes Basin (GLB) is important to determine whether the concentrations of PAHs are changing in response to domestic and international control strategies. To address the challenge, we investigate the spatial and temporal trends of atmospheric PAHs under the GLB Monitoring and Surveillance Program, which has been operating since 1990. High volume air samplers were used to collect air samples for the analysis of PAHs at three locations in the GLB, namely Point Petre, Burnt Island and Egbert, between 1995 and 2015. The atmospheric temporal trends of PAHs were determined by the digital filtration technique, and human exposure to atmospheric PAHs was estimated using the USEPA method for lifetime lung cancer risks. Our results suggest that the concentrations of total PAHs (ΣPAHs) ranged from 51-20,000 pg/m³ at the three sites. The highest concentrations of ΣPAHs were found in samples collected between December and February, while the lowest concentrations were detected in samples taken from June to August. Trend analysis suggested that most of the PAHs were decreasing at the Point Petre site located on the shore of Lake Ontario, while only a few PAHs were showing increasing trends at all three sites. Our exposure assessment suggested that the lifetime lung cancer risks associated with inhalation of PAHs were within the acceptable range (less than one in a million according to USEPA) at the three Canadian Great Lakes sites.

TP171 Analysis of Floating Oil Exposed to Ultraviolet Light Under Different Environmental Conditions
E.C. Pisarski, CSS, Inc. / National Centers for Coastal Ocean Science; E.F. Wirth, NOAA / National Centers for Coastal Ocean Science; D. Thrift-Viveros, C.R. Childs, NOAA / Office of Response and Restoration

Oil spills in the environment are subject to many weathering processes that alter the chemical and physical properties of oil. The process of photo-oxidation is now known to be a much larger contributor to weathering than previously thought. Products formed during the photolysis of oil have been shown to be more polar, and potentially more soluble in water. Understanding how oil weather under solar irradiation can improve modeling of the fate and transport of oil during spills. The aim of this study is to examine the chemical and physical changes that occur in floating oil that is exposed to ultraviolet light (UV-A) under different environmental conditions. Laboratory exposures of floating oil (Louisiana Sweet Crude) were prepared in beakers of seawater on an orbital shaker platform, with treatments consisting of either UV-A or fluorescent light (12h light/12h dark) and manipulations of various environmental factors (temperature, wave energy and/or strength of irradiation). Samples for chemical analysis were collected at different time points (6h, 24h, 48h, and 7d) and the oil was photographed to examine physical changes. Changes in chemical composition of the oil were analyzed by gas chromatography mass spectrometry and liquid chromatography tandem mass spectrometry. Preliminary results indicate that there are physical changes occurring in oil exposed to UV light as opposed to fluorescent light. Oil exposed to UV light became more viscous and formed “tar-ball” like substances whereas oil exposed to fluorescent light remained less viscous and more sheet-like. Additional chemical analyses will explore the relationship between the observed physical changes and chemical composition of the oil and examine if and how environmental factors relate to changes in chemical composition/weathering results. Results from this study will be used to improve models that forecast the fate of floating oil in the environment.

TP172 Influence of Photolysis on Rice Herbicides in Irradiated Water-Sediment Systems
M.A. LaNasa, E.N. Vebrosky, Louisiana State University / Department of Environmental Sciences; K. Armbrust, Louisiana State University / Environmental Sciences

Quizalofop (PROVISIA(R), ASSURE(R)) is a pro-herbicide that was recently approved for application on rice crops in Louisiana. Louisiana rice fields are a unique system in terms of environmental factors that could influence herbicidal behavior different than observed in other regions of the United States. Farmers often rotate rice and crawfish harvest on an annual or bi-annual rotation. Increased agricultural runoff and Louisiana's proximity to the Gulf of Mexico allows for the possibility of these herbicides to be transported through aquatic systems such as marshes and bayous into the Gulf of Mexico. Due to these additional influences, its chemical behavior and environmental fate need to be determined in order to better identify any negative environmental impacts. The purpose of this investigation is to determine the role photolysis has on the degradation and water-sediment partitioning of the herbicide. Irradiated water-sediment experiments will be conducted using an Atlas SUNTEST XTL + environmental chamber to produce a lab-simulated system that mimics sunlight in South Louisiana and includes rice field sediment. Both freshwater and seawater are to be used in the analysis due to saltwater intrusion and the close proximity to estuarine systems for rice fields. Samples will be placed under dark and light conditions, with water and sediment samples extracted and analyzed at 0, 2, 4, 8, 24, and 48 hours by HPLC. Preliminary results show that Quizalofop has the capability to undergo photo-degradation due to its UV-light absorption spectrum, and it has a photolysis/ hydrolysis half-life of 31.8 hours in deionized water. Quizalofop P-ethyl, an herbicide derivative of Quizalofop, degrades rapidly in deionized water, with a photolysis/hydrolysis half-life of 2.9 hours. Understanding the environmental fate of Quizalofop and its capacity to undergo photo-degradation is important in determining the persistence and efficacy of this herbicide in South Louisiana rice fields.

TP173 Lab and field-based determination of microbial and photo-degradation rates of 2,4-dichlorophenoxyacetic acid
A. White, C. Remucal, University of Wisconsin, Madison / Civil and Environmental Engineering; T. McMahon, University of Wisconsin, Madison / Department of Bacteriology / Civil and Environmental Engineering

The herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) is used in Wisconsin as a treatment for invasive Eurasian watermilfoil. However, the degradation rate and resulting lifespan of 2,4-D can vary widely, with complete degradation observed to range from 70 to 150 day, potentially increasing risk for off-target effects to fish and aquatic plants due to unintended long exposure times. We investigated the microbial and photochemical degradation of 2,4-D in aquatic environments using lab-based
microcosms and irradiation studies in combination with large field campaigns to monitor 2,4-D loss following whole-lake herbicide treatments to determine the controls on 2,4-D degradation in aquatic systems. Initial microcosm results suggest sediment is important to driving 2,4-D degradation, with complete removal of 2,4-D observed in microcosms with sediment but not 2,4-D loss in water-only microcosms. Loss rates in microcosms with sediment varied based on previous treatment history. Lakes with previous 2,4-D exposure had a half-life of 20 days vs. 70-100 days for non-previous exposed lakes, suggesting increased microbial degradation in response to repeat exposures of 2,4-D. While microbial degradation appears to be faster than photochemical degradation, both direct and indirect photochemical degradation occurred, suggesting lakes that experience extended periods of 2,4-D (such as lakes that have not been exposed to 2,4-D previously) may be more susceptible to photo-degradation than lakes that have been previously treated with 2,4-D. We expect field data collected Summer 2019 will relate water clarity, littoral zone area, abundance of genes associated with 2,4-D degradation, and extent of stratification in 8 different lakes to 2,4-D degradation rates. These results will be used to determine 2,4-D degradation rates to optimize the application of 2,4-D to Wisconsin lakes and support decision making that promotes healthy native plant and fish populations while attempting to protect and eradicate invasive pests.

**TP174 Methods for pesticide extraction from leaves: Comparing Accelerated Solvent Extraction (ASE) and Energized Dispersive Guided Extraction (EDGE)**

_A.D. Kinross, K.J. Hageman, Utah State University / Chemistry & Biochemistry; W.J. Doucette, Utah State University / Utah Water Research Laboratory_

As part of a project designed to generate leaf-air partition coefficients for pesticide fate modeling, we compared two automated instruments for extracting pesticides from plant leaves (alalfa and citrus leaves). Pressurized liquid extraction (PLE) has been widely used for extracting pesticides and other organic contaminants from a variety of environmental matrices. While considered one of the most effective and solvent efficient extraction methods available, PLE extraction vessels are often expensive and leak prone. Recently, CEM Corporation introduced the Energized Dispersive Guided Extraction (EDGE) automated extraction system that claims to combine PLE and dispersive solid phase extraction. The EDGE system is a potentially faster, more robust alternative to traditional PLE instruments. This project compared extraction efficiency of the Thermo Scientific Dionex Accelerated Solvent Extractor (ASE) and EDGE for 20 target pesticides from plant leaves. For comparability, the same critical operating parameters (e.g. extraction temperature, solvents, and in-cell cleanup sorbent amounts) were used for both systems. In-cell cleanup sorbents (Florisil and graphitized carbon black (GCB)) were used to reduce the levels of interferences due to lips and chlorophyll in the sample extracts. The percent recovery for the 20 spiked pesticides had a range of roughly 30-110% from both the ASE and the EDGE. The percent recoveries between individual compounds showed that only six had significantly different percent recoveries when comparing the ASE and EDGE extraction methods. For these six compounds, the ASE had higher percent recovery than the EDGE. When comparing citrus vs. alfaalfa, there were no significant differences in ASE extractions for individual compounds and there was only one compound that had a significant difference in the percent recovery when extracted on the EDGE and the percent recovery was higher from citrus leaves. Overall, the extraction methods are comparable. The main advantage for the ASE is that the percent recoveries are statistically higher (9.8-16.5%), but only for 6 of the 20 pesticide. Sample preparation and extraction times are shorter for the EDGE and fewer system errors occurred during extractions. Both systems used roughly the same amount of solvent. Currently, we are comparing recoveries from actual field samples using both extraction systems.

**TP175 Application and quantitative accuracy evaluation of GC/MS target screening analytical method for agricultural chemicals in raw and ground water**

_N. Kobayashi, NIH; Y. Tsuchiya, National Institute of Health Sciences; S. Takagi, Osaka Institute of Public Health; Y. Ikarashi, National Institute of Health Sciences_

Many agricultural chemicals in raw water and tap water are monitored by many of water suppliers in Japan, however, Japanese official analytical methods for the agricultural chemicals in drinking water are generally complicated. Therefore, we need more simple and efficient analytical method for agricultural chemicals, in order to ensure the safety of drinking water. In the present study, we have developed a target screening analytical method for agricultural chemicals by gas chromatography/mass spectrometry (GC/MS). Then we applied the analytical method to measure concentrations of agricultural chemicals in raw water and tap water in Japan. The target compounds of the present study are 176 agricultural chemicals, which are the “Complimentary Items” in tap water in the Japanese Waterworks Act. We have prepared and measured the standards solutions of all the agricultural chemicals by GC/MS, then, information of retention time, mass spectrum, and calibration curve of each agricultural chemicals was restored to our database. We used anthracene-d10, 9-Bromoanthracene, and chrysene-d12 as internal standards for GC/MS measurement. The sample preparation method is the same as the Japanese official analytical method released by the Ministry of Health, Labour and Welfare. 500 mL of water samples were concentrated to 1 mL by a solid phase extraction method. We have collected 108 raw water samples and 5 ground water samples in the 21 prefectures in Japan during May to September 2018, and then we apply the GC/MS target screening analytical method using the developed database. As a result, 52 agricultural chemicals were detected from the raw water samples. No agricultural chemicals were detected from ground water samples. Regarding to the most of detected agricultural chemicals, analytical results by GC/MS target screening analytical method were within the range of half to twice compared to those by official analytical methods. Therefore, we judged that the GC/MS screening analytical method we have developed in the present study was applicable to the analysis of agricultural chemicals in drinking water. In order to expand this GC/MS target screening analytical method as a standard analytical method of drinking water in Japan, we will conduct the validity test of the analytical method among other examination organizations.

**TP176 Development of an LC-MS-based Method to Study the Fate of Nanoencapsulated Pesticides in Strawberry Plants**

_P. Wang, McGill University / Food Science and Agricultural Chemistry; J. Galhardi, University of Montreal; V. Gravel, McGill University; K. Wilkinson, University of Montreal / Chemistry; S. Bayen, L. Liu, McGill University / Food Science and Agricultural Chemistry_

Nanoencapsulation has opened up promising fields of innovation for pesticides and plant protection products. Pesticide monitoring traditionally relies on the analytical methods developed and validated for “conventional” formulations. Because of their interaction with the nanoparticle, the environmental fate and the analytical approach could differ from conventional pesticides. In the present study, an analytical method was developed with the objective to detect/quantify two pesticides, oxazystrobin and bifenthrin, in strawberry plants treated with either a nanoencapsulated or a “conventional” formulation. For this purpose, a modified QuEChERS extraction method is applied for the extraction of active ingredients from different homogenized plant tissue samples (fruits, leaves and roots). Stable isotope-labeled standards were spiked prior to extraction. The sample extracts were analyzed by liquid chromatography coupled to mass spectrometry with time-of-flight analyzer (LC-QToF-MS). The method was applied to both spiked and incurred samples. Method detection limits, linearity, recoveries, precision and matrix effects were assessed for both the nanoencapsulated and
“conventional” pesticides. Some preliminary results for a controlled exposure experiment are presented to illustrate the fate, uptake and distribution of nanoencapsulated pesticides in treated strawberry plants.

**TP177 Evaluation of Pesticide Exposure of Agricultural Workers to Chlorothalonil in Green Pepper Field Trials**

*J. An*, Gyeongnam Department of Environmental Toxicology and Chemistry / Environmental Toxicology Research Group; *J. Kim, J. Song, Y. Kim, J. Jung, S. Jeong, Y. Cho, J. Seo*, Gyeongnam Department of Environmental Toxicology and Chemistry

The purpose of the study was to evaluate the dermal and inhalation exposure of agricultural workers through mixing, loading and application of the pesticide on fields of green pepper (10 field trials). Two types of formulations such as wettable powder and suspension concentrate for chlorothalonil were used to estimate exposure rate, and which were diluted about 600 times and 1000 times, respectively. They were uniformly sprayed to the crops using a power sprayer. The whole body dosimetry (WBD) method was applied as an exposure method and following application, outer and inner clothing were cut into various parts such as forearm, upper arm, chest/stomach, back, hip, thigh and shin, then analyzed by GC-MS/MS. The analytical method was validated in triplicate for all samples prior to analysis of each field sample, resulting in a recovery range of 85.6 to 110.4% with RSD.

**TP178 Exposure of rural farmers in Benue State Nigeria to pesticides results in several health issues**

*P.C. Ezeobi*, Benue State Hospitals Management Board / Environmental Monitoring Unit

In Nigeria, organochlorine pesticides (OCP) are most times used in the control of pest (birds, insects, rodents) during agricultural activities. The mismanagement of these chemicals results in different environmental and health issues among the farmers. Therefore, this study was undertaken to evaluate the health problems associated with use of OCP among rural farmers in Benue State, Nigeria. The evaluation was done with interview, laboratory experiments and statistical models. About 150 farmers attending hospital for a particular were selected for the interview. Also about 75 more persons were selected from health workers in the state. The health issues include bad vision and several respiratory disorders. The outcome of the study indicated that the health risks depend on the sex, age and the cultural practice. The highest risked groups were the pregnant women with several reported cases of pesticide intoxication. The next target groups were the uneducated farmers. The outcome of this investigation suggests that the precaution should be taken when pesticides are used in farm operations.

**TP179 In vitro Evaluation of Potential Hepatotoxicity Induced By Detergent-Processed Cassava Product (fufu) on Wistar Rat (Rattus norvegicus)**

*I.O. Awoyinde, O.T. Aladesanmi*, Obafemi Awolowo University / Institute of Ecology and Environmental Studies; *R.O. Akomolafe, Obafemi Awolowo University, Ile-Ife / Department of Physiological Sciences; *O.S. Olukiran, P.O. Akano, Obafemi Awolowo University / Department of Physiological Sciences

Potential toxic effects of cassava-based products on humans have been established. The recent use of detergent in processing cassava into food products such as fufu (a local delicacy Nigeria), may exacerbate its toxic effect. This study determined the hepatotoxicological effect of detergent-processed fufu on Wistar rat. The liver is a heterogeneous organ which is involved in detoxification of xenobiotics and is highly susceptible to injury from these substances. With the increase in chronic diseases among the Nigeria growing population, there is need to look beyond pathogenic and infectious diseases and focus on public health nutrition. Rat models were used in assessing the degree of damage caused on the haematological and hepatological parameters. Graded concentrations (7.5mg/L, 15mg/L and 22.5mg/L) of detergent was used in fermenting cassava for making the fufu which was used in the study. Wistar rats were given 7 feeding treatments (TRT): TRT I - positive control (commercial rat feeds only); TRT II - positive control (fufu only); TRT III - negative control (detergent only), TRT IV - designated control (Fufu bought from the open market), TRT V - VII (fufu plus graded concentrations of detergent). Liver marker enzymes were assayed in the plasma and liver homogenate, blood parameters were also analysed after four weeks of treatment. The 96 hr-LD50 value obtained was 21.00 mg/L. The water intake of the exposed rats reduced significantly. This could suggest that detergent stimulated the pathway that exerts an inhibitory drive on water intake, or alternative, that the detergent blocked thirst inducing pathways. Levels of marker enzymes such as Alanine Aminotransferase (ALT), Aspartate Aminotransferase (AST), and Alkaline phosphatase (ALP) were increased significantly across all the detergent treatment groups and TRT II and IV, while plasma ALP only increased in TRT III. No significant difference was observed in the liver homogenate except in AST which showed increase across all treatment groups except group VIII. There was no significant difference in the blood parameters across all groups. The consumption of detergent-processed fufu poses a high risk to the liver as evident in the photomicrographs with various degree of hepatocellular injury to the liver.

**TP180 Use of a zebrafish model to identify anti-convulsive properties of phyto-cannabinoid extracts**

*C.E. Murr*, Louisiana State University / AgCenter; *C.C. Green*, Louisiana State University / Renewable Natural Resources

Epilepsy is a neurological disorder that effects approximately 65 million people worldwide. While no drug can prevent the development of epilepsy, several compounds that the limit the severity of epileptic seizures have been identified. The clinical use of phytocannabinoids for the treatment of neurological disorders has increased in recent years, as they have been shown to have strong neuroprotective and anticonvulsive properties. The goal of this research is to use zebrafish (*Danio rerio*) as a model organism to identify the anticonvulsive properties of phytocannabinoids to provide insight for their potential use as anti-epileptic drug. Epileptic-like seizures were induced by exposing seven-day-post-fertilization zebrafish larvae to a 10mM pentylenetetrazol (PTZ) solution for 10 minutes. Larvae were then exposed to either cannabidiol (CBD), cannabinol (CBN), tetrahydrocannabinol (THC), or tetrahydrocannabivarin (THV) at concentrations of 0.125, 0.25, 0.5, or 1mg/L for 90 minutes. After the 90-minute cannabinoid incubation, larvae were individually placed into wells of a 48-well plate, and movements were recorded for 10 minutes using a DanioVision recording chamber. The total distance each larva moved during the 10-minute recording period was measured using Ethovision XT software. Larvae exposed to CBD exhibited significantly reduced seizure behavior across all concentrations, displaying movements similar to those seen under control conditions. These findings suggest that CBD is effective in reducing PTZ-induced seizure behavior. Investigations of potential anti-seizure properties of CBN, THC, and THV are ongoing in addition to determining their acute toxicity in larval zebrafish. It is anticipated this research will potentially support a larger body of work as production and use of phytocannabinoids increases.

**TP181 Arsenic-inhibited caudal fin wound healing is mitigated by treatment with estradiol in larval zebrafish**

*S. Dresler*, Northern Arizona University / Biological Sciences

Arsenic is a toxic natural metalloid found in ground and surface waters globally. Although drinking water standards are in place by the Environmental Protection Agency (EPA), many regions of the Southwest United States have reported water sources above these standards. Arsenic has numerous potential detrimental effects on health outcomes including increased risks for cancers and diabetes. Furthermore, arsenic interferes with estrogen signaling processes. In vitro models of wound healing demonstrate that arsenic also inhibits wound healing and that estradiol ameliorates the effect of arsenic. In order to determine whether these effects translate into an in vivo system, larval zebrafish were used to investigate the effects of arsenic and estradiol on wound healing. Zebrafish
are an ideal model for studying tissue regeneration because they can fully regenerate an amputated caudal fin in just a few days (2-3 days). At 24 hours post-fertilization, larvae were exposed to either control solution (0.3x Danieau’s), or arsenic at 0.1 μM, 1.0 μM, or 10 μM. The caudal fins were amputated 48 hours post-fertilization, 1 nM estradiol was added to treatments, and they were imaged every 24 hours for 3 days post-amputation. We conducted traditional morphometrics on images using ImageJ. Our measurements included body length, tail width, and tail area. We hypothesize that arsenic exposure at environmentally relevant concentrations will decrease caudal fin healing and 1 nM 17-β estradiol will promote healing in vivo. Tail regeneration was significantly diminished in the 10 μM arsenic treatment compared to controls, which were nearly healed. The addition of estradiol post-amputation restored tail regeneration to the control levels. Our next steps are to determine the underlying molecular pathways associated with arsenic-induced inhibition of wound healing and whether these are the same pathways through which arsenic acts to ameliorate this effect. In conclusion, environmentally relevant levels of arsenic inhibit wound healing and estradiol ameliorates the effects of arsenic in an in vivo model.

**TP182 Arsenic-inhibited wound healing is mitigated by estradiol**

B.L. Pinto, Northern Arizona University / Center for Bioengineering Innovation; O.R. Lujan, T.A. Bardsley, Northern Arizona University / Biology; C.R. Proper, R.S. Keller, Northern Arizona University / Biological Sciences

Cutaneous wound healing is a complex process that involves several physiological and molecular changes surrounding the damaged skin tissue. Environmental contaminants that impede wound healing place injured individuals at risk for infection and co-morbidities, while compounds that enhance healing limit these risks. Inorganic arsenic inhibits wound healing, and steroid hormones, such as estrogen, increase the rate and capacity for wounds to heal. Therefore, contaminants such as arsenic that interfere with estrogen signaling may impede healing, and estradiol treatment may ameliorate these effects. The broad goal of this research was to understand the risks of contaminant exposure and the potential for amelioration through local, non-systemic estradiol treatment. The current studies utilized a scratch (wound) assay and PrestoBlue(R)-CyQUANT Direct(R) combination fluorescent assay to elucidate the impact of arsenic on cellular migration, metabolism and viability in primary human dermal fibroblast cells (hDF). Additionally, gene expression from both wounded (scratched) and unwounded hDF cells +/- arsenic and estrogen was analyzed via RNAseq. Results demonstrate that cellular migration is delayed when fibroblasts are exposed to arsenic at time of wounding. However, arsenic pretreatment for 24 hours prior to wounding led to a 20-fold decrease in the effective dose that delays wound healing. These findings suggest that individuals chronically exposed to arsenic-contaminated water sources may experience delayed wound healing at lower arsenic doses compared to exposure at the time of wounding. Arsenic exposure decreased cellular metabolism and DNA content of viable cells in a dose-dependent fashion with increasing arsenic concentrations. RNAseq analysis data corroborated cell viability assays, suggesting that arsenic decreases the expression of many genes involved in the cell cycle potentially leading to impaired wound healing. Lastly, treatment with estrogen in the wound assay resulted in a mitigation of the negative effects of arsenic, indicating that estrogen may be interacting with arsenic while promoting cellular migration. Our findings are among the first to describe the deleterious effects of arsenic on wound healing, and the potential to mitigate these effects through the use of the estrogen hormone. This research may lead to translational treatments for arsenic-contaminated wounds in populations who do not have access to uncontaminated water resources.

**TP183 Evaluating Alternatives for Monitoring Mercury in Fish Tissue: Fish Biopsy Punch Versus Homogenized Whole Fillet Samples**

L. Stahl, US Environmental Protection Agency / Office of Water / Office of Science and Technology; B.D. Snyder, Tetra Tech; H.B. McCarty, General Dynamics Information Technology; T. Cohen, Tetra Tech / Center for Ecological Sciences; J. Healey, US Environmental Protection Agency / EPA/OOWST/ Standards & Health Protection Division

Investigating the bioaccumulation of contaminants in fish continues to be an important area of research necessary for human health protection and risk communication associated with fish consumption. Recently, biopsy punch (or fish plug) sampling is being applied in some fish monitoring programs as a more cost-effective alternative to obtain contaminant data (mercury data in particular) than the routine approach of removing, homogenizing, and analyzing entire fillets. EPA's Office of Science and Technology within the Office of Water is conducting a Fish Plug Evaluation Study to address the fundamental question of comparability between fish fillet plug sample versus homogenized whole fillet tissue results for mercury, i.e., to determine if fish plugs are a reliable surrogate for traditional whole fillet sampling and analysis. Secondarily, the study addresses the applicability of fish fillet plug sampling and analysis for conducting assessment monitoring associated with EPA's 300 ng/g (wet weight) fish tissue-based mercury water quality criterion. Initiated in June 2017, the Fish Plug Evaluation Study involved collecting six target species of fish commonly consumed by humans from three Great Lakes (i.e., lake trout, Chinook salmon, and walleye) and three mid-Atlantic rivers (i.e., smallmouth bass, largemouth bass, and blue catfish). A total of 10 specimens of each of the six species were used to prepare fish tissue samples including 5 replicate field plug samples, 5 replicate laboratory plug samples, and 5 replicate samples of homogenized fillet tissue (prepared in the laboratory) to produce a total of 900 samples for mercury analysis. The 15 replicate fillet samples from each of the 60 fish were analyzed individually. EPA used Analysis of Variance (ANOVA) to test the comparability of mercury results from field-extracted fish plugs, lab-extracted fillet plugs, and homogenized whole fillets. Study results are being used to determine if fish plug sampling and analysis can be applied as a technically comparable alternative to homogenizing and analyzing whole fillets for mercury, as well as to highlight any differences among the three tissue sample types across fish species.

**TP184 The Influence of Metal Exposure on Plumage Coloration in Several Songbird Species**

S. Chiparus, Eastern Michigan University / Biology

Heavy metals are found naturally in the environment but can be elevated beyond normal levels due to anthropogenic activities. Heavy metals continue to pollute many ecosystems in spite of emission control measures, potentially due to historical exposure or the continued expansion of human development. Organisms exposed to metal pollutants may be negatively impacted if fitness is reduced. Carotenoid-based bright plumage in many songbird species is thought to be a visual cue to potential mates - signaling high fitness levels. This is because bright plumage may reflect efficient foraging for diet-dependent carotenoids and/or the ability to allocate carotenoids to plumage coloration as opposed to anti-oxidant protection. Studies have shown a decline in carotenoid-based coloration along metal pollution gradients, and an increase in melanin patch size with increased metal exposure. We will relate plumage coloration characteristics of several songbird species, both from urban and rural locations in Southeast Michigan, to feather mercury levels. Identifying negative impacts of pollutants on wild animals is important for understanding the consequences of anthropogenic activities on wildlife.
TP185 Investigation Of The Relationship Between Potentially Toxic Metals (PTMs) Concentration In Soil And Plants Along Major Highways In Lagos, Nigeria

A.B. Sodiq, University of Lagos / Pure and Applied Chemistry

The possibility of bioaccumulation of potentially toxic metals (PTMs) by edible plants especially those grown along highly trafficked highways poses a threat to humans. This study investigated the levels of PTMs in soil and plants along six major highways in Lagos, Nigeria. The PTM concentrations in the soil and plant were determined by atomic absorption spectrophotometry (AAS) after digestion with aqua regia. Also the physicochemical parameters of the soil were determined by the appropriate standard methods. The results of the analysis showed that lead (Pb) had concentration which ranged from of 14 - 58 mg/kg with a mean of 25.02 mg/kg ± 14.29 for soil the samples and a range of 9 - 42 mg/kg (23.94 mg/kg ± 14.04) for plant samples. Nickel (Ni) and Copper (Cu) had concentrations ranging from 0.03 - 2 (0.61 mg/kg ± 0.43) and 0.3 - 2 mg/kg (0.28 mg/kg ± 0.46) respectively for the soil samples. The levels of Ni and Cu were below detectable limit in the plant samples. The study showed that consumption of edible plants sourced from farms along highway could be a threat to human health due to the possible levels of PTMs that they could contain.

TP186 Spatial and Temporal Variability of Selenium in an Urban Watershed in Colorado

S. Parvey, GEI Consultants, Inc. / Ecological Division; S. Skigen-Caird, GEI Consultants, Inc. / Ecology; S.P. Canton, GEI Consultants, Inc. / Ecological Division

Colorado has extensive areas with underlying geology that contributes to elevated selenium concentrations in ground and surface waters. Selenium in these regions can be mobilized through erosional processes and groundwater leaching. Selenium data were collected by several stakeholders to determine potential sources of selenium in the South Platte River in an urban area south of Denver, Colorado given the unexplained presence of selenium at concentrations exceeding the state water quality standards in this segment. To evaluate sources of selenium, samples were collected from four mainstem South Platte River sites, 13 tributary sites, and 3 discharges. The tributary sites were largely free from any point source discharges. In addition to dissolved selenium, sulfate was also measured, as increased concentrations of this parameter are postulated to decrease bioavailability, bioconcentration, and toxicity of selenate. Additionally, selenium and sulfate are often found together at elevated concentrations when originating from natural geologic sources. Seasonal patterns related to precipitation and possible dilution were observed at many locations, particularly at sites with elevated selenium concentrations. Five of the seven tributary sites that exceeded the chronic selenium standard were located in the portion of the watershed with drainages originating in the highlands southeast of the South Platte River, suggesting that this region may be a source of selenium. Several lines of evidence indicate that the elevated selenium concentrations are likely the result of natural or human-induced uncorrectable conditions resulting from selenium bearing strata - specifically marine shales. The highly variable selenium concentrations observed in the tributaries that were located in adjacent gulches provided insight to the elevated selenium concentrations in the South Platte River. These data were used to develop site-specific ambient-based water quality standards for selenium in tributaries to the South Platte that were ultimately adopted by the Colorado Water Quality Control Commission and approved by the Environmental Protection Agency. Spatial and temporal studies as such will assist with site-specific selenium criteria development in other regions with naturally occurring selenium and may help inform study design for additional investigation such as evaluation of fish tissue concentrations in these regions.

TP187 Determination of Oxybenzone, Sulfamethoxazole, and Clofibrate in Water, Sediment, and Fish from Galveston Bay and Clear Creek Areas

S.O. Atoibaye, Texas Southern University / Environmental and Interdisciplinary Sciences; J. Turner, Texas Southern University; P.K. Relangi, Texas Southern University / Department of Environmental and Interdisciplinary Sciences; M.A. Yakubu, Texas Southern University / Department of Environmental & Interdisciplinary Science

Environmental chemical contaminants have been of major concern as they can cause adverse health effects in single or multiple forms — even at trace levels. They are derived from different activities; and they include pesticides, personal care products, pharmaceuticals, and byproducts of various industrial processes. The contaminants often referred to as contaminants of emerging concern (CECs) are of growing awareness and concern because of their possibilities of interacting with biological systems to cause serious health issues. CECs are used daily and are continuously released into the environment via various waste streams. Galveston Bay and Clear Creek receive waters from several sources including runoffs which may contain a significant number/concentration of contaminants with a high possibility of human exposure. The potential adverse effects of the contaminants on humans, human environment, and the ecosystem can range from acute to chronic and are of significant importance. This study analyzed the presence of selected CECs: oxybenzone, sulfamethoxazole, and clofibrate in the water, sediment, and fish samples from the Galveston Bay and Clear Creek areas. Samples were collected from the identified locations, extracted using standard protocols, and analyzed using high-performance liquid chromatography coupled with an ultraviolet/visible detector. Results quantified, and bioaccumulation calculated. The results showed the presence of the contaminants in the samples analyzed. The concentration of oxybenzone in water and sediment samples were 1.85 ± 0.82 and 1.30 ± 1.55 ppm respectively. Oxybenzone in fish tissues/organisms was 38.49 ± 14.64 ppm, this is 2,081% and 2,961% its concentration in water and sediment samples. Clofibrate was detected at a concentration of 0.45 ± 0.31 and 2.28 ± 3.76 ppm in water and sediment samples. Its concentration of 7.76 ± 2.46 ppm found in the fish tissues/organisms is 17 and 3 times more than the levels in water and sediment. Sulfamethoxazole was below detection limits. Thus, the results revealed that oxybenzone and clofibrate are present in the locations analyzed and they bioaccumulate in fish tissues/organisms with a high probability of biomagnification in higher animals. Oxybenzone has a higher bioaccumulative capacity and may produce more toxic interactions. The data from this research is an impetus for the continuous monitoring of the levels of CEC in the Galveston/Clear Creek areas bodies of water and the aquatic environment.

TP188 Phthalates and other industrial compounds in San Francisco Bay water

I. Shimabuku, San Francisco Estuary Institute

San Francisco Bay is the largest estuary on the west coast of North America, drains approximately 40% of the state of California, and is surrounded by a dense urban population. These features make the region an excellent laboratory to study anthropogenic contaminants. The Regional Monitoring Program for Water Quality in San Francisco Bay (RMP) supports strategic studies of contaminants of emerging concern (CECs). A pilot study in 2017 analyzed 22 Bay water samples for ten phthalates and eight additional industrial compounds, including two benzotriazoles, two benzoazinones, two trimellitates, bis(2-ethylhexyl) adipate, and 3,5-di-tert-butyl-4-hydroxybenzaldehyde. These compounds have broad uses, including as ingredients in plastics, cleaning and personal care products, hydraulic fluids, lubricants, and corrosion inhibitors. Findings from this study will provide a more robust understanding of the industrial compounds present in water bodies near urban centers, as well as the risks they may pose to humans and aquatic life.
TP189 Analytical method validation aiming for glyphosate determination in surface water samples by ion chromatography

Q.P. Amarante, IFMA / DAQ; N.M. Brito, R.L. JESUS, Federal Institute of Maranhao / DAQ

Agrochemicals usage is directly proportional to the population increase and crops expansion. In this way, man has always sought alternatives to combat natural adversities. Herbs have been eliminated by herbicides application, but some compounds do not show enough efficiency due weed resistance. As a result, glyphosate has become the most widely used herbicide in the world for the control of a broad spectrum of plant organisms that grow as a "pest" in various crops. Its main degradation products are aminomethylphosphonic acid (AMPA) and the amino acid sarcosine. Due to its chemical properties, in evidence its zwitterionic character, glyphosate analysis and its degradation products in environmental matrices has been more easily performed by ion chromatography aimed at trace analysis. The present work optimized the analytical method described by Amarante Jr., et al., (2003) that apply ion chromatography for the determination of glyphosate and AMPA with ion exchange resin and conductivity detection. Chromatographic conditions were: Metrosep A Supp 7 ion exchange column, 250x4.0 mm; Flow 0.8 mL min-1; Oven temperature 45°C; Conductivity detector with self-regenerative suppression (MSM); Conductivity ~ 1μS cm-1; 200 μL injection volume with Metrohm's 858 Professional automatic sampler; Mobile phase: Eluent A (1.0 mmol L-1 of sodium carbonate and 15 mmol L-1 of sodium hydroxide) and Eluent B (15 mmol L-1 of sodium carbonate). Those conditions were determined during the method optimization. Validation parameters studied were: selectivity, precision, accuracy, limit of detection (LOD) and limit of quantification (LOQ), during recovery studies. Linearity of the work concentration range was investigated with analytical curves between 50 and 500 μg L-1. Recoveries were obtained between 95.6% and 99.6%. LOQ were 28 and 75 μg L-1, to Glyphosate and AMPA, respectively. LOD were 9 μg L-1, to the herbicide, and 25 μg L-1, to its degradation product. Evaluated parameters assure that the investigated method can be aplyed for this contamination monitoring, taking into account the current Brazilian legislation of these pesticides in natural waters.

TP190 Efficient extraction of estrogen receptor-active compounds from environmental surface water via a hydrophilic PEG-based molecularly imprinted polymer

T. Tanigawa, Chemco Scientific, Co., Ltd.; T. Kubo, Kyoto University / Graduate Schoo1 of Engineering; M. Yagishita, Prefectural University of Hiroshima; T. Naito, Kyoto University / Graduate School of Engineering; S.F. Nakayama, National Institute for Environmental Studies / Japan Environment and Childrens Study Programme Office; D. Nakajima, National Institute for Environmental Studies; K. Otsuka, Kyoto University / Graduate School of Engineering

We report an efficient screening procedure for selectively detecting compounds that are actively bound to estrogen receptor (ER) in environmental water samples using a receptor-mimic adsorbent prepared with a molecularly imprinted polymer (MIP). To mimic the recognition ability of ER, we improved the typical MIP preparation procedure by using a hydrophilic matrix with a polyethylene glycol (PEG)-based crosslinker and a hydrophobic monomer to imitate the hydrophobic pocket of ER. An optimized MIP prepared with methacrylic acid as an additional functional monomer and estriol (E3), an analogue of 17β-estradiol (E2), exhibited highly selective adsorption for ER-active compounds, such as E2 and E3, with significant suppression of non-specific hydrophobic adsorption. This indicates that the novel MIP-based adsorbent provided low hydrophobicity and highly selective adsorption towards ER-active compounds in comparison with typical hydrophobic adsorbents. The prepared MIP was then applied to the screening of ER-active compounds in sewage samples. The fraction concentrated by the MIP was evaluated by in vitro bioassay using the yeast two-hybrid (Y2H) method and liquid chromatography-quadrupole time-of-flight mass spectrometry (LC-Q-TOFMS). Compared to an authentic adsorbent or styrene-divinylbenzene (SDB)-based resin, the fraction concentrated by the MIP showed the 120% ER activity in the Y2H assay, and total peak volume was decreased to 25% in LC-Q-TOFMS. Furthermore, a few ER-active compounds were identified only from the fraction concentrated by the MIP, while no ER-active compounds could be determined from the fraction by the SDB-based resin due to the ion suppression under high levels of hydrophobic compounds. These results implied that the newly developed MIP effectively captured the ER-active compounds without capturing most of non-ER-active compounds.

TP192 Identification of groundwater pollution sources using artificial compounds as marker

S. Takemine, N. Ohtsuka, K. Nojiri, T. Kakimoto, Y. Horii, Center for Environmental Science in Saitama, Japan

Nitrate nitrogen pollution in groundwater have been confirmed all over the world. Its pollution results from infiltration of nitrogen-rich water. Examples of point sources include livestock waste and domestic wastewater, and non-point sources include use of nitrogen fertilizers in agricultural activity. It is necessary to identify pollution sources in order to take appropriate measures. In many researches, major ion composition and/or element stable isotope ratios of N and O in groundwater have been used as markers for identifying nitrate nitrogen pollution sources. In this study, artificial compounds consumed in daily life, livestock, and agriculture were attempted to use as markers to identify nitrogen pollution sources, as a novel approach. Artificial compounds which can characterize domestic wastewater, livestock waste, and agriculture are suitable for markers. Additionally, the artificial compounds possessing high water solubility and high consumption are preferable. In this study, ten artificial compounds were selected for marker candidates; two artificial sweeteners (acesulfame and sucralose) for domestic water markers, three veterinary drugs (sulfamethoxazole, sulfadimidine, and sulfadimethoxine) for livestock waste markers, and five neonicotinoids (dinotefuran, acetamiprid, clothianidin, thiacloprid, and imidacloprid) for agriculture markers. Groundwater samples were collected from 63 sites across Saitama prefecture, Japan. The marker candidates were extracted from the water samples by solid phase extraction, and then determined by LC/MS/MS. The detection ratios of marker candidates were as follows: acesulfame (61/63), sucralose (50/63), dinotefuran (38/63), clothianidin (21/63), imidacloprid (18/63), and sulfadimethoxine (2/63). Sulfadimidine, acetamiprid, and thiacloprid were below the detection limits (0.7 ng/L). Dinotefuran concentrations were found to be high in a farming area. It seems that dinotefuran was infiltrated from farming lands, and detected in groundwater samples. In the area, the use of nitrogen fertilizer has been also high, and nitrate nitrogen pollution of groundwater has been occurred. Therefore, it is possible that nitrogen infiltration from the farmland have caused the nitrate nitrogen pollution of groundwater. Dinotefuran possessing a high detection rate and infiltration from farmland might be used as an agriculture marker. Relationships between the other marker candidates and nitrate nitrogen pollution is under analysis.

TP193 Occurrence and Fate of Synthetic Phenolic Antioxidants in Various Canadian Wastewater Treatment Processes

Z. Lu, University of Quebec; Rimouski / Aquatic Contaminants Research Division Canada Centre for Inland Waters; S. Smyth, Environment and Climate Change Canada; A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate

Synthetic phenolic antioxidants (SPAs) are of emerging concern due to their potential environmental risks. However, the environmental occurrence and fate of SPAs are poorly understood. In this study, 13 SPAs were analyzed in 70 liquid and 21 solid samples collected from 12 wastewater treatment plants (WWTPs) to investigate the distribution and composition profiles of these contaminants in different wastewater treatment processes in Canada. The concentrations of total SPAs were in the ranges of 71 - 3193 ng/L in influent, less than method quantification limits (MQLs) - 520 ng/L in effluent, and 479 - 4794 ng/g in biosolids (dry weight (dw)). SPAs were effectively removed (e.g., median for total SPAs >75%) from the liquid stream in most WWTPs except for one aerated lagoon and two
primary treatment sites with low removal efficiency (median 26%-43%) for 4-tert-octylphenol (4-OP). These results indicated that wastewater effluent is a vector for some SPAs, including the endocrine disruptor 4-OP to aquatic environments in Canada. The mass balance approximation suggested the major removal mechanisms of these contaminants from the liquid stream in WWTPs are sludge sorption/separation and degradation. Future research should evaluate the environmental risks of SPAs associated with land application of biosolids and investigate the occurrence and fate of the degradation products of SPAs.

TP194 Water quality of raw and treated water in rural areas of the Colombian Caribbean grouped through Cluster analysis
J. Martínez-García, University of Cartagena / Science Doctoral Program; B.E. Jaramillo-Colorado, Agrochemical Research Group, Faculty of Exact and Natural Sciences, University of Cartagena / Chemistry Program

The water quality of the water used was evaluated using the Water Quality Index proposed by the CETESB - Brazil (IAP) composed of the toxicological index (ISTO) and a water quality index (ICA). This index was applied to drinking water samples or sources of raw water supply in the Colombian Caribbean region in the towns of Mahates, San Joaquin, Malagana and San Basilio de Palenque and Mandinga. The physical and chemical parameters, heavy metals, microbiological parameters (total coliforms and Escherichia Coli) and pesticides (organochlorine and organophosphorus compounds) used in the region for agriculture and livestock were determined. The samples were grouped taking into account the type of source and through a statistical analysis of Clusters. It was observed that the groundwater showed a high hardness and in the surface waters a high turbidity. In turn, microbiological contamination was found in water supplies and aqueducts, as well as Fe, Cr and Ni levels in water supplies, and Pb and Ni in drinking water samples higher than those allowed by both quality indexes. The statistical analysis also showed that these groups presented common characteristics that allow them to be grouped and analyzed in a different way, taking into account the type of source. The analyzed samples showed critical and in some cases higher IAP in the drinking water samples than in the raw waters. This research allowed us to study the contamination that affects water supplies and aqueducts in this region to provide environmental authorities with the necessary information to establish strategies and regulations to reduce the risks of water contamination.

TP195 Volatile Organic Compounds in Porewater from Protected Wetlands in Mexico - The Effect of Physicochemical Parameters
E. Norena-Barros, National Autonomous University of Mexico / Unidad de Química Sisal; A. Bussy, B. Lasáquez-Martínez, Metropolitan Autonomous University-Lerma; G. Rodríguez Fuentes, National Autonomous University of Mexico / Facultad de Química

The Ramsar Convention integrated a list of wetlands of international importance based on their biodiversity. Mexico ranks second in the world in terms of the number of sites included in the Ramsar list with 142 wetlands. The aim of this study was to obtain information on potential threats to the protected species present in two Ramsar wetlands located in different regions, associated with the presence of pollutants recognized as toxic to humans: volatile organic compounds (VOCs), which are generated by anthropogenic activities. Trihalomethanes (THMs) are produced by the association of organic matter with bleach residues, while BTEX (benzene, toluene, ethylbenzene and xylenes) are linked to fuel, paints and other solvents. Selected sites differed in their geological, climatic, demographic and socioeconomic characteristics, in order to investigate physicochemical influence on VOCs behavior: “Lerma wetland,” located in central highlands of Mexico at 2,600 m above the sea level, with a mean annual temperature of 12 °C, and “El Palmar,” a coastal wetland of the Yucatan Peninsula, with a mean annual temperature of 26 °C. Sampling devices allowed to collect both water column and sediment porewater samples to construct concentration profiles. At each site, samplers were placed in two points with different intensity of anthropogenic activities (high H and low L). BTEX and THMs were determined by headspace solid phase micro-extraction (SPME) and analyzed by GC-MS. Even if they were present in most samples, measured levels of VOCs were quite low, demonstrating that both wetlands are not polluted by these molecules. However, THMs presented concentrations relatively equivalent between sites, in the water column and in porewater, whereas BTEX levels were higher in porewater samples of Lerma wetland. The cleanest site was found to be L-site of El Palmar. Most of the profiles presented an increase of the concentration with the depth in the porewater, implying a possible accumulation process within the solid phase of the sediments. Chloroform and toluene were the pollutants found with the highest levels in both wetlands. Ethylbenzene and xylene profiles were highly correlated. Redox potential, conductivity/salinity and temperature profiles were quite different between the four sites; however, none of them presented a clear impact on VOC’s fate. In particular, porewater samples from El Palmar H-site were statistically equivalent to most of Lerma samples.

TP196 Identifying Naturally Sourced Benzene at a Tier 3 Risk Assessment Property in Trenton, Ontario
K. McSorley, S. Ward, C. Kelly, T. Phillips, Pinchin, Ltd. / Environmental Due Diligence and Remediation

In southern Ontario, oil and gas deposits are associated with limestones and shales. Oil compounds such as benzene, are formed from the decay of organic matter subjected to heat and pressure after burial of the sediments. Elevated concentrations of benzene (up to 140 µg/L) were identified in groundwater during a Phase Two Environmental Site Assessment (ESA) at a commercial property in downtown Trenton, Ontario. The property had historically been occupied by a retail fuel outlet, an automotive repair garage and a dry-cleaning facility, and was redeveloped in 2010 with a slab on-grade commercial building and associated parking lot. Preliminary field investigations identified the Site as a shallow soil property underlain by Verulam (Sherman Fall) Formation limestones and calcareous shales. The benzene that was measured in shallow groundwater at the site was preliminarily attributed to the presence of the former fuel tanks. Shallow, intermediate and deep bedrock monitoring wells were subsequently installed in an attempt to horizontally and vertically delineate the benzene impacts in groundwater, but to no avail, as concentrations increased by between one and greater than two orders of magnitude with depth. The results suggested that elevated benzene concentrations were unlikely to be the result of anthropogenic activities, but rather were due to the presence of fossiliferous limestones and calcareous shales underlying the Phase Two Property. Following consultation with the Ontario Ministry of the Environment, Conservation and Parks (MECP), a multiple lines of evidence approach, including a rock leaching procedure, characterization of local formation waters, and depth profiling of benzene with saline groundwater parameters was conducted, and a Tier 3 Risk Assessment is underway at the property. This phenomenon of naturally occurring benzene and related compounds in certain Ontario sedimentary rocks is well known amongst Ontario sedimentary geologists; however, literature on the topic is limited and the information has yet to be translated by the MECP into regulatory protocols for completing Tier 3 Risk Assessments for the purpose of obtaining Records of Site Condition. These conditions will surely be encountered with greater regularity as development in shallow bedrock environments east of the Greater Toronto Area continues; therefore, an improved understanding of the implications for Tier 3 Risk Assessments is essential.

TP197 AhR activity of brominated disinfection by-products of parabens in the river water
Y. Gouakon, Iwate University / Graduate School of Arts and Sciences; M. Terasawa, Iwate University / Department of Environmental Sciences

Parabens are used as preservatives in pharmaceuticals and personal care products (PPCPs). Parabens react with aqueous chlorine, which is used in disinfection processes, and readily leads to the formation of halo-genated parabens. The present study involved measuring brominated paraben concentrations in the Kitakami River, north Japan, which flows
through urban areas (sites K1 and K2) and mixed areas of residential and agricultural land (K3-K10) using the LC-MS. The major STPs were located at upstream from sites K2, K4, K5, and K10. Aryl hydrocarbon receptor (AhR) agonist activity was also assessed using a yeast (YCM3) reporter gene assay. Dibrominated methylparaben (Br2MP), ethylparaben (Br2EP), propylparaben (Br2PP), butylparaben (Br2BP), and benzylparaben (Br2BnP) and monobrominated benzylparaben (Br1BnP) were detected in 25-100% of river samples during the sampling period from 2017-2018 at median concentrations of 8.1-28 ng/L. Dibrominated paraben concentrations were comparable to those of dichlorinated parabens reported in our previous study in the central Pacific region of Japan. In the yeast assay, 12 of the 18 compounds exhibited AhR activity (activity relative to β-naphthoflavone, RA; 4.4x10-4-7.1x10-1). All monobrominated parabens exhibited greater activity than their parent parabens, however further bromination reduced or eliminated their activity. To assess the contribution of active compounds, median concentrations during 2017-2018 obtained from the chemical analysis were converted to BNF eq. by multiplying their corresponding RA values. The values of Σ BNF eq. of parabens were up to 150 pM; Br2MP and Br1BnP had the high BNF eq. among the active components. Contributions of parabens were also high at upstream sites (K1-K3) around urban areas, but low at the lower downstream sites, suggesting that the STPs are potentially a major source of brominated parabens into the Kitakami River. We have found novel aspects of brominated parabens originating from PPCPs.

**TP198 AhR-mediated effects of dioxins on liver in 3D co-culture system and Zebrafish embryo**

L. Yan, Nanjing University; C. Messner, University of Applied Sciences Northwestern Switzerland; A. Zenerk, University of Appl. Sc. Northwestern Switzerland; Institute of Ecopreneurship; L. Suter-Dick, University of Applied Sciences Northwestern Switzerland / School of Life Sciences; X. Zhang, Nanjing University / Environmental Science

Evidence on the association between the aryl hydrocarbon receptor (AhR) and liver fibrosis has been reported. Dioxin is thought to exert its biological and toxicological effects primarily by binding to AhR and recent studies suggest that chronic exposure to low doses of dioxin induced liver fibrosis development in mice. However, a high throughput method for predicting liver fibrosis of dioxins is sparse. Here we examine the feasibility of 3D liver micro tissue system and zebrafish embryos to identify the liver toxicities of dioxins. Three typical dioxins (TCDD, BaP, PCB126) and the hepatotoxic chemical –Thioacetamide (TAA) were chosen to test their liver toxicities in these two platforms. In this study, we decided to use specific gene markers indicating liver fibrosis (e.g., col1α1; αSMA), albumin ELISA assay and immunohistochemistry to examine if four compounds could induce liver fibrosis in 3D liver micro tissue system and zebrafish embryos. Four compounds induced cytotoxicity in monolayer cultures of HepaRG cells, i1ERT-HSC cells and THP-1 cells with 7-day treatment, but only TAA and BaP were observed in 3D micro tissues system with 14-day treatment. RT-qPCR analysis from micro tissues showed that liver fibrosis gene markers were up-regulated by TAA and BaP, with col1α1 down-regulated by PCB 126, while there was no significant change induced by TCDD. Immunostaining results also suggested that col1α1 and αSMA proteins expression of micro tissues treated with BaP increased. Further, albumin ELISA assay indicated that TAA and BaP caused liver damage with decreasing albumin compared with the controls. In zebrafish embryos experiments, these chemicals showed different apical endpoints. TAA disrupted zebrafish embryos’ hatch, with an IC50 of 1.803nM, while PCB 126 induced serious malformations with an EC50 (30.8nM), such as yolk sac oedema, pericardial oedema and bent spine. The half-lethal doses of BaP (39.8nM) could be calculated. In addition, it was observed that BaP at a low dose level could induce liver damage of zebrafish embryos by histology analysis. In summary, our data suggested that 2D monolayer cell culture was more sensitive than 3D micro tissues system in testing chemicals’ cytotoxicity, while liver fibrosis caused by TAA and BaP could be detected in 3D micro tissues system. When zebrafish embryos were treated with chemicals from 8hpf to 120hpf, development toxicity of chemicals could be observed, but it was not easy to identify liver fibrosis.

**TP199 Geographical distribution and temporal trends of organohalogen compounds in finless porpoises from Seto Inland Sea and Omura Bay, Japan**

R. Kawabe, Ehime University; A. Goto, Ehime University / Center for Marine Environmental Studies (CMES); M. Ochiai, Center for Marine Environmental Studies; A. Shiozaki, National Museum of Nature and Science / Department of Zoology; M. Amano, Nagasaki University / Graduate School of Fisheries and Environmental Sciences; Y. Tajima, T.K. Yamada, National Museum of Nature and Science / Department of Zoology; S. Tanabe, T. Kunisue, Ehime University / Center for Marine Environmental Studies (CMES)

Persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane and its metabolites (DDTs), polybrominated diphenyl ethers (PBDEs), and hexabromocyclododecanes (HBCDs) are known to be highly accumulated in cetaceans which are at the top of the marine food webs. Previous studies reported that concentrations of POPs in marine mammals have not significantly decreased, although those in environmental samples have been following a decreasing trend. In addition, cetaceans are known to accumulate natural organohalogen compounds such as methoxylated PBDEs (MeO-PBDEs) at the same level as POPs. These compounds have POPs-like chemical structures and are suspected to have similar environmental fate. This study aimed at elucidation of the recent levels, geographical distribution, and temporal trends of POPs and POPs-like compounds in finless porpoises (Neophocaena asiaeorientalis) from Seto Inland Sea and Omura Bay, Japan. Blubber samples (n = 89) of adult male finless porpoises stranded between 2000 and 2017 in Seto Inland Sea and Omura Bay were analyzed for PCBs, PBDEs, MeO-PBDEs using GC-MS, for DDTs, chlordane compounds (CHLs), hexachlorobenzene (HCB) and hexachlorocyclohexanes (HCHs) using GC-MS/MS and for HBCDs using LC-MS/MS. The target organohalogen compounds were detected in all the blubber samples, indicating the widespread contamination in Seto Inland Sea and Omura Bay. Interestingly, concentrations of PCBs, PBDEs, HBCDs, and HCB in the specimens from Seto Inland Sea were significantly higher than in the specimens from Omura Bay, while higher concentrations of natural organohalogen compounds were found in the Omura Bay specimens. A number of samples from Seto Inland Sea contained very high concentrations of HBCDs, suggesting specific pollution sources. In the Seto Inland Sea specimens, concentrations of DDTs, CHLs, and HCHs followed a significant decreasing trend from 2000 to 2016, but no significant changes were observed for PCBs, PBDEs, HBCDs, and HCB, indicating on-going exposure of finless porpoises to these compounds. In the Omura Bay specimens, no significant changes were observed from 2005 to 2017 for any compounds. Possible reasons could be unfavorable dispersal of contaminants from the highly enclosed bay and/or a short survey period. In both study areas, there were individuals with higher PCB concentrations than the level reported to cause immunotoxicity in harbor seals.

**TP200 Polychlorinated biphenyl congener analysis of regional wildfire-dominated air samples collected during summer 2017 in Spokane, Washington**

B. Era-Miller, S. Wong, WA State Department of Ecology

Summer of 2017 was an intense wildfire season for the Pacific Northwest. As part of an atmospheric deposition study for polychlorinated biphenyls (PCBs) in Spokane, Washington, several air samples were analyzed for PCB congeners and particulate matter size 2.5 microns. The air samples were collected as 24-hour composites with Polyurethane foam/XAD-2 during three different days between August 29th to September 6th, 2017. PCB congener patterns were nearly identical in all the samples suggesting that the PCBs released during wildfires smoke may be similar even with differing levels of PM2.5.
TP201 Atmospheric dust: how does transport influence reactivity?
A. Burnett, University of Alberta / Department of Chemistry; G. Lofti, University of Alberta; S.R. Schneider, University of Toronto / Department of Chemistry; S. Styler, University of Alberta / Department of Chemistry
Over one billion tons of dust are emitted into the atmosphere each year. This dust can then be transported across the globe, including to urban areas, where pollutants have the potential to partition to its surface. Because of its photocatalytic properties, dust can catalyze the photochemical oxidation of pollutants, thereby influencing their fate in the atmosphere. Since larger dust particles sediment more quickly, only smaller dust particles are transported over longer distances. Because the composition of dust is size-dependent, this implies that its photoreactivity may also change with transport. However, to date, no studies have explored this possibility. In this study, we investigated the effects of transport on dust chemistry by using the production of hydroxyl radical as an indicator of dust photoreactivity. In our system, the hydroxyl radical is too reactive to be measured directly; therefore, we instead used 1-propanol as a molecular probe to quantify its production. With our optimized method, we quantified hydroxyl radical production by size-fractionated dust samples from Niger, Alaska, Cape Verde, and Edmonton, where size fractionation was used to simulate the gravitational settling effects of dust transport. Our results provide new insights into how dust reactivity changes with atmospheric transport and have implications for the atmospheric lifetimes of dust-associated pollutants.

TP202 Potential of Conductive Soil Particles to Enhance Direct Interspecies Electron Transfer (DIET) for Methanogenic Organic Acid Degradation
T.P. Ezeezah, Department of Biochemistry; I.N. Onwurah, University of Nigeria / Department of Biochemistry; C.O. Onwosi, University of Nigeria,Nsukka / Department of Microbiology; E.J. Nweze, University of Nigeria / Biochemistry Department; M. Miah, University of Birmingham / Molecular Biotechnology
Anaerobic digestion (AD) is an attractive bioprocess for organic waste treatment as it proffers a clean source for energy generation and environmental remediation. However, the process over the years has suffered from limited applicability due to the prolonged lag phase, being easily influenced by environmental changes and substrate-induced inhibition. Several studies are ongoing for AD process optimization. Direct interspecies electron transfer (DIET) is a syntrophic association characterised by electron transfer between two microbial species in contact with each other. Enhancing DIET efficiency between acetogens and methanogens invariably enhances methane generation and the overall efficiency of AD. Several conductive particles such as graphite, activated charcoal and haematite have been used in the past with great success to “hardwire” microbes for DIET. However, there are no reports on the use of soil particles for DIET, as they are ubiquitous, cheap and silicon derivatives (semiconductor). To this end, this study was aimed at investigating the potential of soil particles for enhancing DIET. Conductive clayey particles (CCP) were chosen from 5 different soil types after a conductivity assay (77.33 ± 1.12 µS/m) and were assessed for DIET enhancing ability. Different setups with varying concentrations of activated charcoal were used as positive controls whereas a setup without any additives was the negative control. The setup with CCP (40 g/L) gave the highest methane yield (3496.60±105.10 mL/g) and production rate (223.11±7.00 mL/g/d), which corresponds to an enhancement of 44.7% and 38.5% respectively when compared to the negative control. Activated charcoal (1.5 g/l) resulted to 25.6% overall yield and production rate enhancement which was consistent with findings from literature. There was no significant difference between the production rate of CCP and the positive control. The linear regression equation for production rate plot of the clayey particle (40 g/L) was modelled to y = 0.0325x + 232.45, while the negative control was y = -3.3859x + 188.18. Comparing their gradients suggests a sustained stability and delayed decline in production rate of the clayey setup. Hence, CCP, a representative of soil particles, has the potential to enhance DIET for anaerobic digestion. There is a need for further studies to unravel the mechanism of DIET enhancement by CCP and to further explore this novel approach.

TP203 Characterization of Recycled Tire Crumb Rubber Used on Synthetic Turf Fields in the United States
K. Thomas, US Environmental Protection Agency / National Exposure Research Laboratory; E. Irvin-Barnwell, Centers for Disease Control and Prevention / Agency for Toxic Substances and Disease Registry / Division of Toxicology and Human Health Sciences; A. Guteippi-Elie, US Environmental Protection Agency / OCSP/RAD; A. Rugin-Wilson, Centers for Disease Control and Prevention / Agency for Toxic Substances and Disease Registry / Division of Toxicology and Human Health Sciences; J. Zambrana, US Environmental Protection Agency / Office of Research and Development
Crumb rubber from recycled tires is widely used as an infill material in synthetic turf fields which has raised issues concerning potential exposures. However, recycled tire crumb rubber is a complex material which presents challenges when evaluating potential exposures (i.e., what is in the material as well as how people are actually exposed). As part of U.S. Federal Research Action Plan on Recycled Tire Crumb Used on Playing Fields and Playgrounds, researchers collected recycled tire crumb rubber samples from across the U.S. (nine tire recycling plants; 25 outdoor and 15 indoor synthetic turf fields) and characterized the samples for chemicals (with a total of over 3000 analyses) as an initial step in characterizing exposure. Multiple analytical methods were applied to characterize particle size, metals, volatile (VOCs) and semi-volatile organic compounds (SVOCs). Particle size analysis used a sieve method to generate seven particle size fractions for each sample, ranging from ≤ 0.063 to > 4.75 mm. Twenty elements were measured by microwave acid digestion and ICP-MS analysis. Forty-nine PAHs, phthalates, thiizoles, amines, and other SVOCs were measured by solvent extraction with GC/MS/MS and LC/TOFMS analyses. Releases of SVOCs and thirty-one target VOCs (including BTEX chemicals, formaldehyde, styrene, and 1,3-butadiene) from tire crumb rubber were measured by dynamic emission chamber testing at 25°C and 60°C. Suspect screening and non-targeted analyses were applied to tentatively identify additional VOCs and SVOCs associated with the material. Bioaccessibility of metals was measured using simulated gastric fluid, sweat plus sebum, and saliva at 37°C. When compared to previous studies, the mean concentrations measured for most metal and SVOC chemicals were similar. While many chemicals are present in recycled tire crumb rubber, exposure may be limited based on what is released into air or biological fluids, but this needs confirmation. For the microbial analysis, all tire crumb rubber samples collected from the 40 synthetic turf fields tested positive for a universal bacterial gene (16s rRNA) at levels similar to those found on household products. Results from this research (and the follow up exposure characterization which is underway) improves our understanding of the potential for human exposure to chemicals associated with recycled tire crumb rubber material used on synthetic turf fields.

TP204 Analysis of Exhaust Gases of 3D printers and Odors from Modeled Objects
M. Muraoka, N. Takemoto, N. Higeta, Toray Research Center, Inc.
3D printers are widely used in various fields (e.g., prototype modeling, aerospace industry, medical technology) in recent years. Little information concerning with the health and safety effects of 3D printers and their product has been reported. To investigate the safety of 3D printing systems, we analyzed exhaust gases from several 3D printers and outgases from modeled objects. In this study, material extrusion type and material jetting type 3D printers using resin materials were applied. We analyzed the gases and outgases using GC/MS and HPLC. Uncured residual monomers and its reaction products including aldehydes were detected. Gas compositions were differed by the modeling method and using materials of 3D printers. It should be noted that residual monomers and aldehydes were specific odorous compounds for the evaluation of 3D printing.
systems. The each analyses data give us characteristic information, which we can use for development and optimization of the 3D-printer instruments, ink materials, the designs and the printing procedures.

**TP205 Using Mud to Clear the Waters: Use of a Sediment Geochemical Marker to Derive Nitrogen Standards for Coastal Waters**

*W.S. Boothman, US Environmental Protection Agency / National Health & Envir. Effects Research Laboratory; L. Coiro, USEPA / Office of Research and Development National Health and Environmental Effects Research Laboratory / Atlantic Ecology Division*

Despite significant study and improvements in modelling and measurement, direct quantitative relationships between increased inputs of nitrogen to coastal water bodies and environmental effects are difficult to obtain, making the task of setting standards for nitrogen loading to such water bodies problematic. Part of the problem in obtaining better relationships is the complex combination of factors that influence various effects of nitrogen at any one time / observation. Molybdenum (Mo) in sediments can be used as a geochemical marker of periods of hypoxia in bottom waters overlying those sediments. Reaction with sulfide in pore waters of sediments underlying hypoxic waters precipitates Mo present in seawater, a process that acts as a chronometer of the period the bottom waters are hypoxic. The longer time period encompassed by sampling sediments integrates the effects of nitrogen loading over long time periods (years) and may thereby reduce variability due to other shorter-term factors that affect the occurrence and severity of hypoxia (e.g., precipitation / river inflow, wind speed and direction). Mo was measured in surface sediments of coastal waters in Narragansett Bay (RI, USA). Multiple sampling sites were selected within and among the estuaries, so that the sites would be evenly distributed over the full range of expected normalized loading. The resulting estimates of frequency of hypoxic bottom waters correlated strongly with estimates of nitrogen inputs derived from a nitrogen land-use model, normalized for hydrodynamic characteristics of the water bodies. The strong relationship between normalized nitrogen loading and frequency / duration of hypoxia can then be used in a statistical / reference condition approach to set a standard for nitrogen loading to coastal water bodies to prevent / limit the occurrence of hypoxia.

**TP206 Identification of key lipids and proteins associated with cold tolerance in Arctic char Salvelinus alpinus**

*Y. Gong, C. Wang, J. Tang, S. Su, University of Saskatchewan / Toxicology Center; P.D. Jones, University of Saskatchewan; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences*

The Arctic char (Salvelinus alpinus) is a cold-water fish with a circumpolar distribution, and few other freshwater fishes are found at such high latitudes. Fish forced to live at temperatures higher than their natural range show reductions in growth, reproduction, and are susceptible to disease. Global climate change puts the Arctic region at the greatest risks and threatens the survival of Arctic char populations in nature as well as the Arctic char farming industry. In the present study, juvenile Arctic char were labeled individually, and survival, growth, and food consumption were recorded to evaluate fitness changes in response to different water temperatures. Advanced mass spectrometry-based multi-omics technologies, including lipidomics, metabolomics, and proteomics, were applied and integrated to identify essential lipids and proteins associated with cold tolerance in Arctic char. Network analysis of lipid and protein dynamics was also employed to get insights into how Arctic char adapt to temperature changes and how these crucial lipids and proteins interact with each other. This data could benefit both population-based conservation initiatives for native Arctic char populations as well as the Arctic char farming industry by facilitating the development of robust broodstocks.

**TP207 Lowering of the Concentration Range of the Ready Biodegradability Method OECD 301F**

*D. Koch, S.P. McLaughlin, Smithers Viscent, LLC / FATE; K. Malekani, Smithers Viscent, LLC / Environmental Fate and Metabolism*

The OECD 301F Guideline ‘Manometric Respirometry Test’ has been a standard method in determining if a test substance is ‘readily biodegradable’ for several decades. If a test substance exposed to a dilute inoculum generally comprised of activated sludge achieves 60% biodegradation equivalent to 60% of its organic carbon being converted to CO2 within a 10-day window (once reaching 10% CO2 evolution) during the 28-day test, the test substance can be labeled ‘readily biodegradable’. However, based on the method in its current form with starting concentrations at 100 mg/L, some compounds that could potentially be biodegradable may fail this test if they are inhibitory at this relatively high concentration which may be above many compounds’ Predicted Environmental Concentrations (PEC). A 301F study design was modified in this experiment by conducting the prescribed test with one of the standard reference substances, sodium benzoate, but at lower than guideline concentrations. This was conducted to determine the sensitivity of the test method at much lower and more environmentally relevant concentrations. The concentrations used in this experiment are 100, 10, 5, 2 and 1 mg/L. The results will demonstrate if the method is appropriate at concentrations of 1/1, 1/10th, 1/20th, 1/50th, 1/100th of the lowest test concentration of 100 mg/L currently stated in the OECD 301F Guideline.

**Creating Pathways to Restoration in the Great Lakes: Addressing Beneficial Use Impairments in Areas of Concern**

**TP208 Phytoremediation of an Anthropogenically Salinized Wetland in the Great Lakes Region**

*A. Litalien, Royal Military College of Canada / Chemistry and Chemical Engineering; B. Zeeb, Royal Military College / Chemistry Chemical Engineering Dept*

Soil and freshwater salinization are growing issues worldwide but of particular interest in the Great Lakes Region. Anthropogenic sources of salinity such as road salt and industrial wastes like cement kiln dust (CKD) can release salts into the environment at concentrations that are harmful to plant, benthic and aquatic life. Salt tolerant plants known as recrethohalophytes can remove salts from soil, excrete them on their leaf surfaces and dilute them within the air column. Native recrethohalophytes have been used to stabilize and extract salts from a marshland adjacent to a CKD landfill site at a cement manufacturing plant in Bath, ON, preventing entry of harmful ions into a stream that feeds into Lake Ontario. In soils with 4 mg Cl/g, S. pectinata can extract up to 26 g of Cl/m² and distribute a portion of the excreted salt over a region of land greater than 20 km² allowing deposition concentrations to fall well below background soil chloride concentrations. This effectively dilutes the chloride concentrations to those that are not only harmless, but potentially beneficial to plant and animal life. This study demonstrates that plant based strategies utilizing recrethohalophytes can sustainably remove salts accumulated in soil and prevent their leaching into freshwater bodies.

**TP209 Restoring sites in human-dominated systems: What is the reference point, which stressors dominate, and how to determine beneficial uses?**

*G.A. Burton, E.C. Cervi, University of Michigan / School for Environment and Sustainability; W.H. Clements, Colorado State University / Fish, Wildlife and Conservation Biology*

Most Superfund, Areas of Concern and contaminated sites are in heavily human-dominated watersheds. These often are near the mouths of rivers and/or harbors where industrial and municipal outfalls, stormwater runoff, and agricultural runoff constituents are deposited in quiescent zones. This plethora of chemicals is primarily attached to fine particles which then
form the dominant substrate habitat and are surrounded by shorelines comprised of armored walls with few vegetated zones, high boating activity, and high flow regimes. The multitude of contaminant sources in the watershed cannot be managed realistically, given the many business and public interests. Global change is resulting in increasing habitat degradation, agricultural and urban runoff and extreme flow events. What then are realistic reference conditions for comparing and setting remediation goals that apply at present and in the future? Is it okay to leave toxic sediments in-place after remediation? Is recolonization after remediation by a pollution tolerant benthic community acceptable? Should habitat enhancement be required to support improved benthic and fish communities? Can upstream and local stressor sources be significantly reduced? We provide a framework for ecologically sound remediation targets, utilizing realistic assessment methods to document goals are attained in human-dominated systems where stressor loadings will continue and likely increase.

Water Treatment Technologies for Removal of Emerging Contaminants and Biological Methods to Measure Effectiveness

TP210 Assessment on the Environmental Safety of Advanced Oxidation Water Treatment System (AOS)

Y. He, City University of Hong Kong / School of Energy and Environment; G. Goss, University of Alberta / Biological Sciences; L. Patterson-Fortin, R. Smith, BioLargo Water, Inc.

The Advanced Oxidation System (AOS) is a water treatment technology for bacterial disinfection and contamination remediation. The AOS can effectively remove bacterial and organic contaminants from water through the electrochemical manipulation of potassium iodide salt, electrolysis, and expanded graphite adsorption. Iodine acts as the primary disinfectant in the system. Evidence shows formation of additional iodinated and oxidative species, which may contribute to the disinfection and decontamination achieved by the AOS reactor. However, the formation of reactive oxygen species and potential secondary oxidative species may pose additional hazards to aquatic organisms living in the receiving water affected by the post-treatment effluent. The effect of exposure to AOS treated waters, especially the long-term effect on aquatic ecosystem receptors (fish, invertebrates) is a commonly raised subject of concern, and thus requires further investigation to demonstrate both efficacy and safety of this process. To examine the long-term effects of AOS treated water, a 21-day chronic daphnia exposure, a 96-hour acute zebrafish embryo exposure, and a 14-day chronic rainbow trout exposure, were conducted, with treated and untreated municipal wastewater effluent (MWE) spiked with model organic contaminants, benzo[a]pyrene and 17β-estradiol. The results indicated AOS treatment significantly reduced the adverse effects caused by exposure to MWE and model organic contaminants to baseline levels in daphnia (reduced fecundity), zebrafish embryo (elevated ERod activity), and rainbow trout (elevated plasma vitellogenin). Overall, this study demonstrated that AOS treatment is a promising and environmentally friendly technology for wastewater treatment.

TP211 Use of ozonation and sand filtration during drinking water treatment and implications for nanoplastic particle removal

Microplastics have been recently detected in bottled drinking water as well as in drinking water sources. Studies addressing the fate and removal of nanoparticles during drinking water treatment are currently lacking. Ozonation is a key treatment step in modern drinking water treatment plants due to its excellent disinfection and oxidation properties. Therefore, we evaluated the impact of ozone treatment on the physicochemical properties of three types of nanoplastics in terms of morphology, surface charge and particle aggregation state. The effect of rapid and slow sand filtration in terms of nanoplastic breakthrough taking into account the influence of the flow rate, grain size and particle roughness was also evaluated. Two plastic particles, a rough polyacrylonitrile/polyurethane co-polymer (PAN/PS) and a smooth polyacrylonitrile particles (PAN), were synthesized and showed a hydrodynamic diameter of 215 nm (PDI:0.077) and 150 nm (PDI:0.043), respectively, in agreement with the diameter derived from transmission electron microscopy (TEM) images. Commercially available 100 nm polystyrene spheres represented the third plastic particle (PS). In individual batch experiments, the plastic particles were reacted with ozone (0.5, 1 and 5 mg/L) in either buffered-DI H2O or in a lake water (used as a source of drinking water for the city of Zurich, Switzerland). After the ozone treatment in the experimental media, the hydrodynamic diameter of the particles suspended in buffered-DI H2O and lake water increased in the range from 253–409 nm, 550–620 nm and 116–150 nm for PAN/PS, PAN and PS, respectively. All the plastic particles kept a negative surface charge once suspended in the experimental media, but, after ozonation, the Z-Potential decreased from -20 to -30 mV for particles suspended in the buffered-DI water and from -14 to -17 mV for particles suspended in the lake water. Initial results from TEM investigations of particles which underwent ozone exposure revealed a very similar size and surface structure as observed for the pristine particles. Thus, ozonation does not appear to either fragment plastic particles nor dramatically change their surface charges. Whether more subtle changes on the surface properties are induced by the ozone treatment is currently under investigation. Results from sand-packed column experiments will be presented during the meeting.

TP212 A Simple Polydimethylsiloxane (PDMS) Sponge for the Removal of Environmental Organic Contaminants

B. Ng, Florida International University / Chemistry and Biochemistry; N. Quinete, NC State University / Florida International University / SERC; P. R. Gardinali, Florida International University / Chemistry & Biochemistry and SERC

Water quality affects all of us daily: through the water we drink from the tap, shower and swim in, and use to irrigate crops and plants with. Due to everyone sharing the same relative space, air and water, environmental impacts are concentrated in smaller areas, including waterways. Large amounts of pollution enter urban waters from a variety of sources, such as industrial discharge, residential/commercial wastewater, trash and polluted stormwater runoff from urban landscapes. As urban communities often share centralized water sources, this pollution creates both environmental and public health hazards such as lower drinking water quality and bodies of water that are not safe for recreational use. Water scarcity is a serious and growing issue worldwide, there is a need for clean and safe water supplies. Polydimethylsiloxane (PDMS) is a polymer based material with high absorptive properties that has been increasingly used as a passive environmental sampler for persistent organic compounds. PDMS sponges have been previously used for the selective absorption of oil from water. In this study, we have made a simple PDMS sponge to be tested for the removal of emerging environmental organic contaminants from aqueous matrices. The PDMS sponge was made using a simple, minimal preparation procedure using commercially available PDMS pre-polymer and curing agent applied to a sugar negative template. This resulted in an environmentally friendly technology for wastewater treatment.

G. Goss, University of Alberta / Biological Sciences; L. Patterson-Fortin, R. Smith, BioLargo Water, Inc.

The Advanced Oxidation System (AOS) is a water treatment technology for bacterial disinfection and contamination remediation. The AOS can effectively remove bacterial and organic contaminants from water through the electrochemical manipulation of potassium iodide salt, electrolysis, and expanded graphite adsorption. Iodine acts as the primary disinfectant in the system. Evidence shows formation of additional iodinated and oxidative species, which may contribute to the disinfection and decontamination achieved by the AOS reactor. However, the formation of reactive oxygen species and potential secondary oxidative species may pose additional hazards to aquatic organisms living in the receiving water affected by the post-treatment effluent. Overall, this study demonstrated that AOS treatment is a promising and environmentally friendly technology for wastewater treatment.
compounds in order to evaluate the applicability of PDMS sponges in the remediation of contaminated water bodies. The manufactured PDMS sponge has shown to be a reusable, scalable adsorbent material that can be shaped and introduced to multiple sampling and cleaning applications.

TP213 Endocrine Disruptor Chemical Removal using Modified Chitosan in Water Treatment

X. Solimando, A.F. Rich, M. Cunningham, Queen’s University; P. Champagne, Queens University / Civil Engineering

Endocrine disruptor chemicals (EDCs) are micro pollutants that interfere with endocrine systems, leading to developmental, reproductive, neurological and immune disruptions. EDCs arising from domestic, agricultural and industrial activities migrate through water into our ecosystem. However, no processes that target EDC removal in drinking water or wastewater treatment have been developed, exposing individuals to potentially harmful compounds. This work describes the development of a method involving modified biopolymer particles for the selective capture of EDCs. Bio-sourced selective beads to adsorb EDCs from water by simple contact were developed and tested, contributing to a long-term goal that ensures EDC-free drinking water is feasible. Chitosan (CTS) is a natural polysaccharide derived from industrial food-processing industry waste (crustacean exoskeleton, fungi, etc.). In this study, CTS is modified by grafting synthetic polymers, using free radical polymerization, to enhance its ability to bind to EDCs in water. In order to tune the properties of the CTS, a variety of synthetic monomers were investigated. Spherical particles (beads) were then prepared with grafted CTS via aqueous precipitation method. After a chemical crosslinking step (preventing the particles from being redissolved in water) the beads were dispersed in contaminated water for EDC capture. The study focused on the adsorption of Bisphenol A because it is the most produced (5000 ktons/year) and the most detected synthetic EDC in water at this time. It was noted that after grafting CTS with synthetic polymer, its binding ability with BPA was enhanced. As an example, it has been shown that the grafting of poly(4-vinylpyridine) on CTS increased its BPA sorption ability from 25 to up to 75%.

TP214 Effect of UV radiation types on photodegradation and toxic effects of Triton X-100

E. Jho, D. Yoo, Hankuk University of Foreign Studies / Department of Environmental Science

Various chemicals including pesticides, surfactants, and wetting agents are widely being used in agricultural practices. Uses of these chemicals can lead to environmental pollution, particularly water pollution. Previous studies focus more on the fate of active ingredients in pesticide formulation; however, there are other ingredients in pesticide formulation that may be as toxic as the active ingredients. Surfactants are included in pesticide formulation to enhance the performance of active ingredients. Therefore, the surfactants applied on agricultural land with other agrochemicals can eventually reach nearby water bodies and become pollutants. One way of naturally removing water pollutants is photodegradation. Thus, this study investigated how a surfactant in water are photodegraded and how the toxic effects are changed during the course of photodegradation. Different types of UV radiation (i.e., UV-A, UV-B, and UV-C) were used to degrade Triton X-100 dissolved in water, and the changes in the toxic effects before and after photodegradation were determined using bioluminescent bacteria. With UV-A, the Triton X-100 removal was 25% within 35 d, while with UV-B and UV-C Triton X-100 removals of 81% and 96%, respectively, were achieved within only 24 h. The toxic effects were also changed after photodegradation. The toxic effects were greater with the UV-C-radiated sample that the others. This may be explained by the generation of intermediate products. The possible generation of intermediate products is being analyzed using NMR spectroscopy. This study shows that toxic effects may increase with photodegradation of Triton X-100 in water, so the inert ingredients of pesticide formulation other than active ingredients may also need to be managed and regulated.

TP215 Estrogen composition varies in effluents discharged from various secondary municipal wastewater treatment plants in Ontario

N. Srikanthan, L. Bragg, H. Dhiyebi, University of Waterloo / Biology; S. Smyth, Environment Canada / Water Science Technology Directorate; M.R. Servos, University of Waterloo / Biology

Emerging contaminants in municipal wastewater have been a growing concern for several years. Recent changes to the Federal Wastewater Systems Effluent Regulations (WSER) in Canada require all wastewater treatment plants (WWTPs) to be operating with secondary treatment or equivalent by 2020. Infrastructure upgrades across the country will improve the quality of final effluent discharged into the receiving waters. These treatment upgrades are targeted at “deleterious substances,” which could include contaminants of emerging concern, such as pharmaceuticals and personal care products (PPCPs) and endocrine disrupting compounds (EDCs). These compounds have become more prevalent in effluent discharges and have been associated with adverse impacts on aquatic life downstream of WWTP outfalls. Natural and synthetic estrogens are potent EDCs that have been linked to intersex in fish. This study compares the concentration and composition of estrogens in influent and final effluents from nine WWTPs in southern Ontario with varying levels of secondary treatment. Samples were collected using cooled 24-h composite samplers and extracted using solid phase extraction. The samples were analyzed using both a biological assay (yeast estrogen screen) for total estrogenicity and chemical analysis (LC-MS/MS) for specific hormone concentrations. Results show that across the various treatment plants the relative composition of the raw influent is fairly consistent and predominantly composed of the natural estrogen, estrone. After treatment there is a significant reduction in estrogenicity and a change in the relative composition of the estrogenic chemicals, which differs across the treatment plants. WWTP processes are very site specific, therefore studying the fate and composition of estrogenic compounds at various plants can provide insight into processes influencing the removal and biotransformation of these compounds, and whether they need to be specifically targeted for additional removal.

TP216 Adsorption of HIV and AIDS related drugs from environmental wastewaters using a nanofibers

T. Kebede, UNISA / Chemistry

Emerging contaminants can be defined as synthetic or natural compounds which have now been discovered or suspected to be present in the various aquatic environment and causes known adverse ecological and human health effects. One of the most utilized emerging contaminants are pharmaceuticals and personal care products, such as antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs), antidepressants, sedatives or contraceptives and b-blockers and antiretroviral drugs. Among them, antiretroviral drugs are the most utilized in South Africa than any nation in the fight against HIV/AIDS, with an approximate figure of 2150 880 receiving ARVs. This condition contributes to the presence of the compounds in the environment at a greater extent. However, their release to the environment is not regulated and they are not routinely screened for their presence in water, sediment or tissue. As a result, in South Africa HIV and AIDS-related drugs have been detected in surface water, waste water, river water and dam water. This evidently proofs that our wastewater treatment plant is not designed to effectively remove such contaminants. They are mainly designed to remove solids, dissolved organic matter and nutrients from wastewater. Thus far, some conventional treatment methods have been used for the removal of HIV and AIDS-related drugs, including activated sludge, trickling filters and anaerobic pond; however, they are inefficient of removing these drugs. In this project, the nanofibers from Moringa seed extracts were used, since nanomaterials have advantages over the others due to significantly improved physicochemical properties. From the result, it was observed that the removal efficiency of the nanofibers was in the range of 65 - 85% for 14 drugs.
TP217 Removal of Micropollutants from Wastewater by Immobilized Laccase on Hollow Silica Embedded Plastic Packing Reactor

G. Yüksel, University of Sherbrooke / Civil Engineering; D. Okutman-Tas, Istanbul Technical University / Environmental Engineering; H. Cabana, University of Sherbrooke / Civil Engineering

Over the last years, laccase-based processes have gained interest in water and wastewater treatment, unfortunately, there are many economic and large-scale operating challenges associated with the use of free enzymes in full-scale systems. Consequently, the large-scale application of laccases in bioremediation necessitates immobilization/insolubilization of the biocatalysts to enhance their operational stability and reusability in the treatment of wastewater. This research aims at optimizing the immobilization condition of the laccases of Pleurotus dryinus on hollow silica embedded plastic packing, to characterize the resulting biocatalyst and used it in a packed bed reactor for the elimination of trace organic contaminants. The resulting biocatalyst will be used in a pilot scale packed bed bioreactor in order to remove pharmaceutical active compounds from municipal wastewaters. Through these solid catalysts, approximately 10 L volume packed bed reactor will be operated to treat a local wastewater treatment plant effluent. During reactor operation; laccase activity and selected pharmaceuticals removal efficiency will be monitored. The preliminary batch test results already showed that immobilized laccases silica packing helped to improve stability and reusability of the enzyme. According to laccase immobilization optimization, 6% glutaraldehyde concentrations was optimal to activate the packing for laccase immobilization. During optimization process, pH 5.5 conditions was applied for activation by glutaraldehyde and enzyme loading. The stability of the laccase-based biocatalysts is also examined under pH 3.5 and 5.5. The residual activity is also monitored with 10 cycles of uses over a 4-month period. Also, the preliminary tests performed with the free laccase from P. dryinus have highlighted the high potential of this enzyme for the elimination of trace organic contaminants such as acetaminophen. The proper design of a packed bed reactor has been ensured long term and continuous treatment of PhACs from wastewater treatment plant effluents.

TP218 Pharmaceutical exposures in a temperate region wastewater effluent-dominated stream: Muddy Creek, Iowa

H. Zhi, University of Iowa / Civil and Environmental Engineering; D.W. Kolpin, US Geological Survey / Central Midwest Water Science Center; L.R. Iwanowicz, US Geological Survey / Leetown Science Center; R. Klaper, University of Wisconsin, Milwaukee / School of Freshwater Sciences; E. Meade, University of Wisconsin, Milwaukee / School of Freshwater Sciences; S.M. Meppelink, US Geological Survey / Central Midwest Water Science Center; M. Powers, The University of Iowa / IHR-Hydrosciences & Engineering; J. Quin, G.H. LeFevre, University of Iowa / Civil and Environmental Engineering

The increasing use of pharmaceuticals has translated to a corresponding increase in concern over their potential impacts on ecosystem and human health worldwide. An important environmental pathway for such pharmaceutical exposure is via wastewater treatment plant (WWTP) discharge as incomplete removal of pharmaceuticals during wastewater treatment can potentially effect aquatic and terrestrial organisms. Small effluent-dominated streams represent an ideal scenario for evaluating and predicting aquatic responses to pharmaceuticals as such chemicals are continually discharged into these less diluted systems. To this end, Muddy Creek, a small (22.5 km²) effluent-dominated temperate region stream that flows through the town of North Liberty, Iowa, was selected as a field laboratory for this study. Although the population serving the North Liberty WWTP is small (18,500 people), it is the second fastest-growing city in Iowa. To determine spatial and temporal trends in pharmaceutical exposures, four sampling sites were selected for this study: (1) approximately 100 m above the WWTP outfall, (2) the WWTP outfall, (3) approximately 100 m below the WWTP outfall, and (4) approximately 5 km downstream of the WWTP outfall. From September 2017 to August 2018, water samples were collected on a biweekly basis and analyzed for 13 pharmaceuticals by the University of Iowa and collected monthly and analyzed for 110 pharmaceuticals by the U.S. Geological Survey. The top 13 pharmaceuticals in terms of concentration accounted for over 85% of the overall chemical mass measured in the collected environmental samples. The total concentration of the top 13 pharmaceuticals ranged from 2,550 to 37,800 ng/L in the WWTP outfall. The parent-to-product ratios for five pharmaceuticals were calculated spatially and temporally as a measure of differential attenuation. Bench experiments are being conducted in the laboratory to elucidate transformation kinetics including photolysis, sorption, and biodegradation of targeted pharmaceutical mixtures. Ongoing and future efforts will relate pharmaceutical results to fish exposure and bioluminescent yeast estrogen assays to better understand potential environmental impacts from pharmaceutical exposures.

TP219 The Removal of silver nanoparticles from aqueous samples using milled activated charcoal

L. Morrison, National University of Ireland, Galway / Earth and Ocean Sciences; E. J. McGillicuddy, Technological University Dublin / School of Chemical & Pharmaceutical Sciences; M. Cormican, National University of Ireland, Galway / Discipline of Bacteriology; D. Morris, National University of Ireland, Galway / Antimicrobial Resistance and Microbial Ecology Group / School of Medicine

The environmental impacts of silver nanoparticles (AgNPs) is now of interest due to their incorporation in numerous nano-functionalised consumer products. Products include; medical devices, food contact materials, paints and textiles. The incorporation of AgNPs into these products presents potential risks to the environment as AgNPs may be released throughout the products lifetime from manufacturing to end-of-life disposal. Activated charcoal, Norit(R) CA1 (Sigma-Aldrich), a commonly used filter material, was investigated as a potential material to capture AgNPs from water samples. Initial investigations used 100 ppb samples of 25 nm PVP coated AgNPs (nanoComposix) in water generated with Milli-Q water. These samples were exposed to the charcoal for 20 hours after which the change in silver concentration was measured using ICP-MS. The removal efficiency of the charcoal was improved by milling the charcoal. The processed charcoal was then exposed to samples containing AgNPs as in initial tests. Initially approximately 10% of the silver was removed from the water samples using the unaltered activated charcoal granules. The capture of the AgNPs was improved using the milled charcoal, with a capture efficiency of 94% at concentrations of 10 ppb. This study found that increasing the surface area of the charcoal increased the silver reduction in the samples. Further a procedure was developed allowing the silver captured by the charcoal to be quantified using a HCl leaching procedure.

TP220 Release of Silver Nanomaterials from Textiles: Generating weathered nanoparticles for toxicity testing

D. Patch, V. Gagnon, I. Koch, Royal Military College of Canada / Chemistry and Chemical Engineering; D. O’Carroll, University of New South Wales / Civil and Environmental Engineering; K.P. Weber, Royal Military College / Chemistry and Chemical Engineering

Engineered nanomaterials (ENMs) are artificially created objects that have at least one dimension between 1-100 nm and can exhibit physico-chemical properties different from their bulk material counterparts. Textiles often contain silver nanomaterials to take advantage of silver’s antibacterial properties, which prevent odour in textiles during use. Recent research has shown that silver nanomaterials (AgNMs) are released from textiles during their active life cycle which can pose a risk to microbial communities in environmental systems. The objective of this study is to develop representative methods for the artificial wearing of silver-containing textiles which will be compared to data from previously performed true wearing scenarios. The experimental set-up involved the physical stretching of silver-treated textiles with a 3D printed apparatus inspired by techniques used in the textile manufacturing industry. Following physical pre-treatment, textiles were washed in a detergent solution at parameters closely mimicking typical laundry conditions. Wash water samples were analyzed through a combined suite of
characterization techniques including: SP-ICP-MS, size fractionation via filtering, SEM/EDX, DLS and XRF. It was found that artificial wearing of the textile had a significant effect on the concentration (~60% increase) and the size morphology (higher percentage of smaller particles) of silver released during a first wash cycle, when compared to an unworn textile. It was also found that wash solutions made with deionized water resulted in a higher silver release (~85%) when compared to tap water wash solutions. This indicates silver release characteristics could vary geographically based on the water chemistry of the area. Future plans include the incorporation of artificial sweat, further exploration of the relationship between water chemistry and silver release, and investigations into silver-release mechanisms. Successful development of an artificial wearing method will lend itself to use in ecotoxicity studies, which currently use pristine materials that are not necessarily representative of realistic exposures.

TP221 The fate of pristine and weathered silver nanomaterials from commercial products in subsurface planted wetland mesocosms

A. Farooq, Royal Military College of Canada; V. Gagnon, D. Patch, Royal Military College of Canada / Chemistry and Chemical Engineering; D. O’Carroll, University of New South Wales / Civil and Environmental Engineering; K.P. Weber, Royal Military College / Chemistry and Chemical Engineering

Due to their antimicrobial properties silver nanomaterials (Ag NMs) are frequently employed in a variety of industrial and consumer products such as clothing and personal care products among others. Due to their abundance, Ag NMs are predicted to be released into the aquatic environment, via treated wastewater effluent, at concentrations, which may cause potentially toxic effects. However, current research focuses on the effects of pristine ENMs rather than those released from commercial products. The fate and effects of nanomaterials release from commercial products in the environment, such as wetlands, are largely unknown. Wetlands ecosystems have an innate ability to transform a wide range of pollutants into harmless by-products mainly through their microbial communities and could be impaired by the release of Ag NMs. This project aims to examine the fate and effect of both pristine and weathered Ag NMs in twenty-four batch-fed subsurface flow wetland mesocosms, planted with Phalaris arundinacea; twelve intensified with artificial aeration and twelve non-aerated. The experiment consisted of four design types including a positive control, a negative control, a pristine Ag NM and an artificially weathered Ag NM exposure, all conducted in triplicate. Two separate in situ exposures were conducted and monitored using a characterization suite consisting of five assessment categories (water quality, hydrological, microbial, plant health, and NM assessment) to profile the impacts on treatment performance and microbial function. Finally, the overall fate of silver within the mesocosms was determined through the destructive sampling of the constructed wetland biofilm, plant roots, and aboveground plant biomass. The analysis of microbial activity for the aerated and non-aerated CW systems illustrated no discernible difference between the silver treatments and their respective controls indicating that the CW systems are quite robust when exposed to Ag NMs at environmentally relevant concentrations. Silver removal kinetics were tracked in the CW systems for both exposures, which revealed that the aerated CW systems remove the Ag NMs more rapidly than the non-aerated systems. Total silver data from the deconstruction indicates that the highest concentrations of silver were located in the gravel-associated biofilm; in particular in the 30-60 cm layer. In the long term, this accumulation may reach a concentration that could be toxic to the microbial communities.

TP222 Investigation of the effectiveness of an electrochemical treatment train process for treatment of synthetic and real municipal stormwater

N. Bettman, K. McPhedran, University of Saskatchewan / Civil Engineering

The pollution caused by contaminants carried in anthropogenic-based wastewaters is of increasing concern as they impact ecosystem and human health. Contaminant sources include municipal and industrial wastewaters, agricultural runoffs, and stormwaters. For example, stormwater contaminants may include suspended and dissolved solids, polyaromatic hydrocarbons, heavy metals, fecal coliforms, among others. Many stormwaters systems, such as those in the Canadian prairies, have numerous untreated stormwater outfalls into receiving waters making the collection and treatment of these waters challenging logistically and economically for municipalities. BioLargo Water Inc., an Alberta based company has developed a wastewater treatment technology, the Advanced Oxidation System (AOS). In collaboration with BioLargo Water and through NSERC Engage Plus Funding, our research goal is to create a simple, effective treatment process that can be viable for use in multiple outfall locations such as those found in Saskatoon, Saskatchewan. The AOS is a type of electrochemical treatment that uses oxidative species that can be used to effectively treat contaminants in stormwaters with iodide and chloride showing potential to be valuable for creation of potent oxidative species. Thus, it is important to determine the concentrations and locations of these species in an AOS-type reactor to assess the reactor performance and to optimize the treatment conditions. Spectrophotometry was used to determine the concentration of chloride and iodide oxidative species within the AOS reactor. These species include chlorate, chlorite, and hypochlorite for chloride; and periodate and iodate for iodide. After success in initial experiments, the AOS reactor is currently being assessed in a treatment process train that includes a standard pre-treatment step for removals of solids prior to entering the AOS reactor. This treatment train will be tested and optimized for the treatment of synthetic and actual stormwater samples from Saskatoon outfalls during the spring and summer of 2019. The findings of this research will lead to the production of an effective stormwater treatment train process that can be useful for municipalities that currently release contaminated stormwater without treatment into receiving waters. This is treatment is going to be needed in the face of existing and potential stormwater effluent regulations as are currently being assessed in Canada and beyond.

TP223 Direct and indirect photodegradation of triclosan in wetland

S. Lam, University of Toronto / Department of Chemical Engineering & Applied Chemistry; S. Nélieu, P. Benoit, INRA-AgroParisTech; E. Passeport, University of Toronto / Department of Civil and Mineral Engineering and Department of Chemical Engineering

Triclosan is an antimicrobial agent incorporated into many household products, such as soaps, detergents, and toothpaste. Triclosan is ubiquitously found in the aquatic environment, potentially toxic, and readily bioaccumulated. Passive water treatment systems, such as wetlands, have shown potential to reduce triclosan pollution. This study investigated three factors that affect the aqueous phototransformation of triclosan in wetlands, i.e., pH, nitrate concentration and dissolved organic carbon (DOC) concentration, using a three-parameter three-level Box Behnken experimental design. The effect of pH on triclosan phototransformation was tested given its pKa of 8.2 is close to typical wetland pH. Further, nitrate and DOC concentrations were selected as common surface water photoinducers capable of promoting the formation of reactive species. Both the direct and indirect phototransformation of triclosan followed pseudo first-order kinetics. The results showed that the kinetic of direct phototransformation increased as the pH increased. The Box Behnken Model analysis revealed that pH and DOC significantly affected indirect phototransformation rates. At pH 6 (pH < pKa), an increase in DOC concentration did not significantly change the kinetic constant; whereas, at pH 8 and 10 (pH > pKa), the highest phototransformation rates were obtained with the lowest DOC concentrations. Both direct and indirect phototransformation experiments formed several phototransformation products, including 2,4-dichlorophenol, a known toxic compound. At pH 6, phototransformation products were continuously formed and accumulated; whereas at pH 8 and 10, the products were formed and depleted. The results showed that minimal changes in classical wetland design would be needed to sustain triclosan removal by phototransformation, even though larger pH values would result in faster triclosan phototransformation and lower by-product accumulation.
TP224 Removal of triclosan by the green alga Euglena gracilis
S. Lam, University of Toronto / Department of Chemical Engineering & Applied Chemistry; E. Passeport, University of Toronto / Department of Civil and Mineral Engineering and Department of Chemical Engineering

Triclosan is an antimicrobial agent that is incorporated into many household products, such as soaps, detergents, and toothpaste. A fraction of the triclosan contamination that reaches the sewage treatment plant remains uncaptured and is then released into the aquatic environment where it can be further transformed into toxic products. Constructed wetlands can be effective water treatment systems for emerging contaminants by promoting adsorption, plant uptake, phototransformation, and biotransformation of chemicals. Algae develop naturally in constructed wetlands and lagoons, and are even used in high-rate algal ponds to treat wastewater.

However, to date, little is known about the role of algae on trace organic contaminant removal. This study used the green alga Euglena gracilis to investigate the reaction mechanisms that control triclosan removal in wetland water, autoclaved wetland water, Euglena medium, and Milli-Q water. The study was done in 1-L Erlenmeyer flasks containing 600 mL of algae spiked with triclosan. Samples were taken on day 0, 3, 7, 14, and 21 to quantify the concentration of triclosan and its transformation products. The algae was also subjected to three different light conditions: white, red, and absence of light. The red light control was conducted to inhibit triclosan phototransformation while maintaining algae growth, thereby promoting conditions where biotransformation - if any - would dominate.

TP225 Mechanisms of Pharmaceutical and Personal Care Product Removal in Algae-Based Wastewater Treatment
E. Passeport, University of Toronto; C. Larsen, University of Toronto / Civil and Mineral Engineering; Z. Yu, R. Flick, University of Toronto / Chemical Engineering and Applied Chemistry

The widespread distribution of pharmaceuticals and personal care products (PPCPs), in particular in the built environment, has led to increased concern about their potential to affect human and ecosystem health. In this research, we investigated the role of algae species Scenedesmus obliquus and Chlorella vulgaris in governing PPCP transfer and transformation mechanisms in algae-containing environments. Lab-scale algal bioreactors were created under various conditions of light, water matrix, and sterilization method to isolate and elucidate reaction mechanisms affecting carbamazepine, ibuprofen, gemfibrozil, and triclosan. The parent compounds and their potential transformation products were analyzed in both the water and algae phases. The results showed that ibuprofen was primarily biotransformed thanks to synergistic relationships between the algae and the bacteria. Ibuprofen biotransformation products such as hydroxy-ibuprofen, carboxy-ibuprofen, and 4-isobutyratechol were detected in several samples. In all the reactors exposed to light, triclosan underwent both phototransformation and biotransformation. Triclosan biotransformation took place in Scenedesmus obliquus, as demonstrated by the presence of triclosan-O-sulfate in the algae extracts. No evidence of significant carbamazepine and gemfibrozil transfer or transformation was observed under the experimental conditions tested. These results suggest that microalgal-bacterial consortia can facilitate PPCP transformation in algae-based passive water treatment systems.

TP226 Evaluating the efficacy of native halophytes in the phytoextraction of road salt (sodium chloride) from contaminated soil
E. Mann, Queens University / School of Environmental Studies

Salt from the soil in a process known as phytoextraction. Salts taken up from the soil are stored in the above ground biomass, and by harvesting this plant material salts can be removed from the site before they accumulate to toxic levels or leach into groundwater. This study investigated the ability of three native halophytes: Atriplex canescens, Atriplex patula, and Atriplex hortensis to remove sodium chloride from contaminated soil. Both field and greenhouse studies were completed in order to determine survivability in roadside areas, and Na+ and Cl− extraction ability. The Atriplex spp. accumulated 41-64 mg Cl/g dry weight (DW), and 18-55 mg Na+/g DW when grown for a two- month period in soil spiked with NaCl to realistic levels. Salt content in separate shoot components (seeds, stem, leaves) was determined in order to provide further insight on phytoextraction processes. In all three Atriplex species, the leaves had the highest salt concentration, followed by the seeds (bracteoles included), with the lowest concentrations found in the stem. A column study was also completed to investigate the movement of road salt through soil during the spring melt. The results from this study will be presented and discussed. This research aims to inform remediation and management practices for salt-contaminated soil in order to reduce the environmental impact of road salting.

TP227 Nature-based solutions: The use of a floating wetland system as an alternative to effluent’s treatment

Conventional physicochemical methods for effluent treatment are expensive and the resulting discharge can still be harmful to the environment. Thus, alternative ecotechnologies that are low cost such as constructed wetlands (CW) are a solution traditionally used. A variant from CW is the Floating Wetland Treatment (FWT) that uses a floating structure that allows the formation of a root mat to bioremediate polluted waters. The aim of this study was to evaluate the efficiency of a FWT system in the removal of pollutants from a real effluent. The search for a low cost-effective technology is crucial especially in developing countries such as Brazil, considering that around half of its sewage effluent is released into water bodies without any treatment. So, this challenge could be minimized by the application of an ecotechnology through phytoremediation. The current study performed three experiments with triplicates, using effluent from the Federal University of Rio Grande do Sul. It was considered three tanks with macrophytes (M) and its respective controls (with no plants) (C). Water quality parameters analyzed were total nitrogen, total phosphorus, conductivity, pH, color, and turbidity. Inflow and outflow event were quantified to verify pollutant removal and also to compare the treatments (M vs. C). According to PERMANOVA, macrophyte tanks were more efficient than controls in the effluent polishing considering the parameters analyzed in all experiments (p=0.001). There was also a significant difference between inflow and outflow considering both treatments (p=0.001). The results also suggest that control tanks presented some efficiency, which may have occurred by interactions such as photo-oxidation processes and/or the presence of algae proliferation, that might also have acted as phytoremediation agents. Further analysis is being performed evoking ecotoxicological assays and metal quantification for these effluents. As an overall conclusion, FWT is a good alternative to effluent’s treatment, although its action alone is not enough to fit legislation’s requirements. The relevance of this study encompasses collecting more information regarding the efficiency of FWT along with bringing a new insight for the potential to be achieved for effluent treatment in developing countries.
TP228 Do Vegetated Treatment Systems “Treat” OPEs by Evapotranspiration?
T.F. Rodgers, University of Toronto / Chemical Engineering and Applied Chemistry; A. Perantoni, University of California, Berkeley / Department of Civil and Environmental Engineering; R. Robitaille, University of Toronto / Earth Sciences; A. Cecchetti, University of California, Berkeley / Department of Civil and Environmental Engineering; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; D.L. Sedlak, University of California Berkeley / Civil Environmental Engineering; M.L. Diamond, University of Toronto / Department of Earth Sciences
Organophosphate esters (OPEs), compounds used as flame retardants and plasticizers, are found at high levels in urban areas worldwide. Rodgers et al. (2018) previously found that wastewater treatment plants (WWTPs) were the largest pathway for OPE emissions from the city of Toronto to Lake Ontario, accounting for ~70% of total loadings for six of the most abundant compounds. Chlorinated OPEs (Cl-OPEs), which are examples of persistent and mobile organic compounds (PMOCs), have low removal through traditional WWTPs. The Oro Loma Horizontal Levee is a subsurface flow wetland located next to San Francisco Bay, California, designed as a pilot system to treat nitified secondary domestic wastewater effluent. The Oro Loma system has high evapotranspirative flows and a residence time of about two weeks, which may allow for better treatment of PMOCs like Cl-OPEs than conventional WWTP processes. Some Cl-OPEs have KOW values in the optimal zone for uptake by plant shoots through the transpiration stream and have been shown to accumulate in the shoots of wheat plants. We hypothesize that Cl-OPEs are removed from the WWTP effluent through transpiration, thus reducing loading in the final effluent. We are developing a continuous, dynamic multimedia model of the system to investigate the distribution and fate of OPEs in the Oro Loma system. Our “Subsurface Sinks” multimedia model is based on the activity concept so as to be broadly applicable to trace organic contaminants commonly found in WWTP effluent, including pharmaceuticals and other compounds that ionize in water. The model consists of 8 compartments, including a detailed 3-compartment model of plant roots used to predict plant uptake from water. We are evaluating the model against measured OPE water concentrations taken at multiple points along the Oro Loma system. Preliminary measured OPE concentrations from the Oro Loma Horizontal levee confirm the presence of OPEs in the Levee effluent at detectable concentrations. Preliminary model results indicated that the topsoil compartment tends to accumulate CI-OPEs through uptake to the plant compartment and subsequent litterfall and plant death, while non-Cl-OPEs are transferred to the soil compartments through sorption to soil particles and lipids in plant roots. Overall, our results indicate that the large evapotranspirative flows in the Oro Loma Horizontal Levee provide higher removal of Cl-OPEs from the WWTP effluent than would be predicted for sorption alone.

TP229 Multi-tracer Experiment in a Bioretention Cell to Study the Transport of Trace Organic Stormwater Contaminants
X. Gu, University of Toronto / Chemical Engineering and Applied Chemistry; S. Spraakman, University of Toronto / Department of Civil and Mineral Engineering; T.F. Rodgers, University of Toronto / Department of Chemical Engineering and Applied Chemistry; M.L. Diamond, University of Toronto / Department of Earth Sciences; J. Drake, University of Toronto / Department of Civil and Mineral Engineering; E. Passeport, University of Toronto / Department of Civil and Mineral Engineering and Department of Chemical Engineering
Bioretention cells are a widely applied urban low impact development (LID) strategy focusing on the infiltration and treatment of stormwater runoff. These cells have been shown to effectively remove contaminants such as suspended solids, dissolved nutrients and trace metals in field and laboratory studies, though with variable efficiencies. Limited research has probed the fate of emerging trace organic contaminants in bioretention cells, especially under field conditions. Although present in low concentrations in the environment, these contaminants have raised increasing concerns recently due to their toxicity and persistence. To fill this knowledge gap, we performed a tracer experiment at a bioretention cell site to obtain in situ field data at a high time-resolution with the goal of investigating the underlying transport, transfer and transformation mechanisms of various stormwater trace organic contaminants. A tracer mixture containing bromide, rhodamine WT, nitrate, phosphate, benzotriazole, and four organophosphate esters (OPEs) was injected as a pulse at the inlet of a bioretention cell located north of Toronto. Outflow samples were collected at different time points and analyzed to generate tracer breakthrough curves for these compounds. The results were modelled to obtain important parameters including recovery rate, mean residence time and variance for each compound, as well as hydraulic efficiency of the bioretention cell. The results showed that the bioretention cell had a short retention time of less than 2 hours. The calculated effective volume ratio was 0.39 suggesting the presence of dead volume and/or preferential flow paths. The recovery rate was 95% for the water tracer bromide, and 35 and 51% for nitrate and phosphate, respectively, indicating removal of these nutrient species. Recovery of benzotriazole was 71%, consistent with this compound sorbing poorly to soil. Given the short retention time that is typical of conventional bioretention cells, biotransformation and plant uptake of the contaminants were likely limited. This field tracer experiment produced valuable information on the performance of the bioretention cell in mitigating trace organic chemicals. These results demonstrated the need to use new design strategies to effectively sorb or transform these contaminants, such as increasing the retention time, incorporating soil amendments, and selecting specific plant species for better treatment performance.

TP230 Production of extracellular lipase expressed by Aspergillus flavus isolated from crude oil polluted soil for remediation of contaminated water
J.O. Osuoha, B.W. Abbey, University of Port Harcourt; E.C. Egwim, Federal University of Technology, Minna; E. Nwaichi, University of Port Harcourt
For enhanced production of lipase by a novel fungal strain: Aspergillus flavus, optimization of selected environmental conditions and fermentation medium were performed using response surface methodology and factorial design. The results from factorial design reveal that agitation, substrate concentration, temperature and pH were the crucial elements affecting the production of lipase. The optimum medium conditions obtained for lipase production using response surface methodology were agitation 150 rpm, substrate concentration of 2.75 v/v, temperature of 45 °C and pH 8.5. This model was authenticated by replicating the experiment under the established conditions, which led to maximum expression of lipase by the organism 5.05 U/mg (predicted response 4.91 U/mg), hence substantiating the reliability of the model. Unexplored Aspergillus flavus strain isolated from crude oil contaminated soils was used for this study. This study underscores the capability of Aspergillus flavus, for lipase production and highlights the practicability of response surface methodology for the optimization of environmental conditions and fermentation medium for enhanced production of lipase.

TP231 Investigation of the Phototransformation Processes of Benzotriazole in Surface Waters Using Compound-Specific Isotope Analysis Approach
L. Wu, University of Toronto / Departments of Civil & Mineral Engineering; E. Passeport, University of Toronto / Department of Civil and Mineral Engineering and Department of Chemical Engineering
Benzotriazole is widely used as an antifreeze, a corrosion inhibitor, and the production of fungicides and pharmaceuticals. As a result, it is frequently detected in urban runoff, wastewater, and receiving aquatic environments. Benzotriazole does not adsorb significantly onto surfaces and is typically resistant to biodegradation. In addition, hydrolysis is not expected due to the lack of hydrolysable functional groups. Aquatic direct and indirect phototransformation of benzotriazole can be the major transformation pathways in surface waters. However, to date, little research
Compound specific stable carbon isotope analysis of semi-volatile substituted chlorobenzenes coupled with solid phase microextraction

S. Suchang, University of Toronto / Civil & Mineral Engineering; E. Passeport, University of Toronto / Department of Civil and Mineral Engineering and Department of Chemical Engineering

Compound specific isotope analysis (CSIA) is an established technique to assess the origin and fate of volatile organic pollutants in the environment. The isotope ratio of contaminants mainly changes as a result of the formation and breaking of chemical bonds. This effect has been exploited to distinguish between destructive and non-destructive in situ processes. However, the application of CSIA for semi-volatile organic compounds, such as amino- (NH2-) and nitro- (NO2-) substituted chlorobenzenes are limited due to the difficulty to extract sufficient analyte mass from the liquid sample matrix. In this study, we developed a CSIA method coupled with the solid phase microextraction (SPME) technique using a divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) adsorbent fiber to determine the δ13C signature of the selected chlorinated anilines and chlorinated nitrobenzenes. The effect of different SPME factors on the isotope fractionation of the selected compounds was evaluated using the design of experiments (DoE) methodologies. Initially four SPME factors, i.e. extraction time (30-70 minutes), extraction temperature (50°-90° C), desorption temperature (200°-260° C), and agitation during extraction (200-500 rpm) were evaluated using a two-level fractional factorial DoE to screen the factors most affecting the isotopic fractionation of the compounds. The second step consisted of identifying the values of the most influential parameters found in the screening design using a composite surface response DoE. The concept of desirability function was used to minimize the isotope fractionation while maximizing the analyte signal amplitude in the isotope ratio mass spectrometer (IRMS). Next, the isotope fractionation due to the potential sorption competition for the SPME adsorption sites was evaluated within the linear range of the analyte mass in IRMS. The limits of detection (LOD) and the linearity for C isotope by the SPME technique were determined for each compound, and the trueness of the measured isotopic signature was evaluated by comparing the δ13C values determined by SPME-GC/IRMS and elemental analyzer IRMS (EA/IRMS). Finally, the applicability of the developed method was demonstrated using contaminated groundwater samples. The developed SPME technique has the potential to apply CSIA for the remediation of groundwater contaminated with the selected semi-volatile compounds.
Relationships Between the Bioaccumulation of Organic Chemicals in Aquatic and Air-Breathing Organisms

TP234 In vitro biotransformation in fish and mammals: Differences and similarities
A. Sangioni, University of Toronto / Department of Physical and Environmental Sciences; K. Foster, Karen Foster Environmental Research / Trent University / Applications of Modelling & Quantitative Methods (AMOD); J.M. Armitage, AES Armitage Environmental Sciences, Inc. / Physical and Environmental Sciences; M.R. Embry, Health and Environmental Sciences Institute (HESI); E. Papa, University of Windsor / Great Lakes Institute for Environmental Research; F. Gobas, Simon Fraser University / Resource & Environmental Management

Historically, the globally accepted model for determination of bioaccumulation has been fish and bioaccumulation assessment has been driven by the octanol-water partition coefficient ($K_{OW}$). The ECHA guidance document on PBT/vPvB assessment, released in 2017 (Chapter R.11), includes the octanol-air partition coefficient ($K_{OA}$) to extend the screening criteria to air breathing organisms. However, biotransformation can be a key factor and can strongly impact the extent to which hydrophobic chemicals accumulate in aquatic and terrestrial organisms. Accounting for biotransformation in bioaccumulation assessment is of importance for very hydrophobic and poorly volatile chemicals because for such chemicals even low rates of biotransformation can dominate the overall chemical elimination process. Hence, there is a need to develop methods for bioaccumulation assessment that include biotransformation. Standardized methods using fish liver hepatocytes and S9 sub-cellular fractions have been approved by the OECD to quantify the metabolic turnover of chemicals under in vitro test conditions in fish. Similar methods have been developed and applied to mammalian species for decades, e.g., pharmaceutical development. This work summarizes preliminary explorations of similarities and differences in biotransformation rates obtained from various in vitro systems in fish and mammal species. An extensive literature search was performed to review and compile existing data of intrinsic hepatic clearance measured in vitro in fish, rodents and humans reveal satisfying interspecies correlation $R^2 > 0.5$. The statistical distribution of experimental responses shows that data of intrinsic hepatic clearance measured in different species are comparable and cover the same range of values. Based on these preliminary and encouraging findings, future analyses and applications of the datasets are outlined.

TP235 Comparing trophic magnification of perfluoroalkyl substances in an avian terrestrial food-web to aquatic food-webs
K. Fremlin, Simon Fraser University / Biological Sciences; J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch Ecotoxicology and Wildlife Health Division; K.G. Drouillard, University of Windsor / Great Lakes Institute for Environmental Research; F. Gobas, Simon Fraser University / Resource & Environmental Management

Several types of legacy persistent organic pollutants (POPs), such as organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs), and emergent POPs like perfluoroalkyl substances (PFASs) are released from many sources into the environment and negatively impact exposed wildlife. Protocols to assess bioaccumulation of these persistent chemicals within terrestrial systems are far less developed compared to aquatic systems. Consequently, regulatory agencies in Canada, the USA, and the EU currently use only aquatic information to assess bioaccumulation potential of chemicals. However, studies have shown that some chemicals that are not bioaccumulative in aquatic food-webs do biomagnify in terrestrial ones. To better understand the bioaccumulation behaviour of chemicals in terrestrial systems, we assessed the biomagnification of POPs and PFASs in a terrestrial food-web that included an avian apex predator, the Cooper’s Hawk (Accipiter cooperii). Over 100 samples were collected from an urban food-web including hawk eggs, songbirds, invertebrates, and berries. We estimated the trophic position of each organism using stable isotope analysis of $δ^{13}C$ and $δ^{15}N$ signatures. We analyzed the samples for concentrations of PCBs, OCPs, and PFASs listed on the Government of Canada’s Chemicals Management Plan. Trophic magnification factors (TMFs) were determined for contaminants that were detected at appreciable levels in all of the biota samples (>50%). We compared our terrestrial TMFs to those observed in aquatic food-webs. TMFs of PFASs ranged from 13.02 – 86.19, indicating PFASs are readily biomagnifying. TMFs reported in aquatic food-webs for PFASs were 4 – 20 times lower than the terrestrial TMFs we estimated.

TP236 Bioaccumulation and Biotransformation Databases for Organic Compounds in Birds
D. Kuo, City University of Hong Kong / Architecture and Civil Engineering

Robust experimental data and field observations are indispensable in advancing bioaccumulation and biotransformation science in birds as they constitute the basis for establishing regulatory guidelines, conducting risk assessment, and developing mechanistic prediction models. This project reviewed and compiled bioaccumulation and biotransformation data of organic compounds from primary experimental sources, covering both legacy and emerging organic pollutants. Over 15,000 bioaccumulation and biotransformation data entries (~1,000,000 filled cells of information) were compiled following a critical review of over 300 studies and reports. These included some 400 organic on close to 300 wild avian species and domestic breeds. Data were reviewed for their quality and subsequently organized under four differently themed databases: main, metabolic pathway, field survey, and enzymatic activity. The main database carried key bioaccumulation metrics and toxicokinetic parameters, as well as reported pharmacokinetic parameters and biotransformation rate constants. The field survey database qualitatively documented the availability of tissue-specific measurements in various birds under field exposed conditions. The metabolic pathway database provided basic availability information on metabolic pathway and number of metabolites reported. The enzymatic activity database summarized the type of biotransformation-relevant enzymatic activities reported for different substrate compounds in the presence (or absence) of organic compounds. Data characterization and preliminary explorative data analyses were conducted on these 4 databases. Preliminary findings in this on-going review effort will be highlighted.

TP237 Refining bioaccumulation screening of neutral hydrophobic organic chemicals in air-breathing organisms from in vitro liver S9 biotransformation assays

The use of in vitro biotransformation assays followed by in vitro-in vivo extrapolation (IVIVE) is of increasing importance in bioaccumulation screening to reduce in vivo bioaccumulation testing. Recently, the Organisation for Economic Co-operation and Development (OECD) has developed test guidelines (No. 319B) to determine the in vitro intrinsic clearance of a test chemical using the substrate depletion approach in incubations with liver S9 of rainbow trout (RT-S9). Given the demands of bioaccumulation screening for air-breathing organisms, there is a need for mammalian bioaccumulation screening protocols involving in vitro approaches. This study reports on the development and testing of a screening approach for bioaccumulation assessment of neutral hydrophobic organic chemicals in air-breathing organisms using rat liver S9 biotransformation assays. It is based on the OECD RT-S9 protocols with modifications to provide all the information needed to conduct IVIVE for the purpose of bioaccumulation assessment. Modifications include the
determination of the unbound fraction (fu,inc) of the test chemical in the incubation, which is not included in current RT-S9 protocols. We illustrate that fu,inc can be estimated using a composition-based approach by including lipid and protein analysis of rat liver S9, or measured experimentally in the bioassay along with the depletion rate constant constant using a solvent-free passive-dosing approach. Results show good agreement between model estimated and experimental fu,inc values. Results further indicate that an in vitro depletion rate constant in a rat liver S9 greater than 0.3 d-1 is sufficient to negate biomagnification in rats.

**TP238 The Bioaccumulation Assessment Tool (BAT): Case studies for the assessment of bioaccumulation of chemicals in both air-breathing and aquatic organisms**

L. Toose, Liisa Toose Environmental Research; J.M. Armitage, AES Armitage Environmental Sciences, Inc. / Physical and Environmental Sciences; K. Foster, Karen Foster Environmental Research / Trent University / Applications of Modelling & Quantitative Methods (AMOD); M.R. Embry, Health and Environmental Sciences Institute (HESI); L. Hughes, ARC Arnot Research & Consulting; J.A. Arnot, ARC Arnot Research & Consulting

Persistence, Bioaccumulation and Toxicity (PBT) assessments are carried out by many regulatory programs such as REACh, TSCA, CEPA, and CSCL. These assessments aim to identify the hazards and risks posed by chemicals to the environment and human health. There is a wide variety of available data describing the bioaccumulation and biotransformation of neutral and ionic chemicals in both aquatic and terrestrial organisms. The freely-available Bioaccumulation Assessment Tool (BAT) was developed to aid the collection, evaluation and integration of various lines of evidence (LOE) with available toxicokinetic (TK) information and related B classification criteria in both aquatic and terrestrial biota. It is a platform designed to aid decision-making using a quantitative weight of evidence approach. Recent work has extended the capabilities of the BAT to robustly assess bioaccumulation in air-breathing organisms and invertebrates. The BAT is used to integrate physical-chemical properties and estimates of biotransformation in fish and mammals with measured and/or estimated bioaccumulation metrics (bioconcentration, bioaccumulation, biomagnification and trophic magnification factors, i.e., BCF, BAF, BMF and TMFs). Within the BAT framework is a generic environment with both aquatic and terrestrial food webs as well as simulated laboratory models used to estimate these B-metrics. Experimental, field and in silico LOE are evaluated for reliability, based on data quality assessment methods derived primarily from OECD testing guidelines. Output from the BAT includes a summary of the results, relevance and reliability scoring of input data; these are presented in concise tables, figures and in a generated PDF report. We provide an overview of the BAT and demonstrate its application with two case studies. The first example illustrates the aquatic-based bioaccumulation results for a typical B chemical. The second example is for a chemical which shows bioaccumulation potential in terrestrial ecosystems, but is not screened in as potentially B for aquatic systems because of its low octanol-water partition coefficient. This work demonstrates the value of considering bioaccumulation in non-aquatic organisms for regulatory purposes by employing a tool that allows the user to consider a breadth of available empirical and modelled information for assessing bioaccumulation.

**TP239 Application of Toxicokinetic Models to Simulate Organic Chemicals in Air-breathing Animals for B assessment**

J.M. Armitage, AES Armitage Environmental Sciences, Inc. / Physical and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting

Bioaccumulation assessment (B) for regulatory purposes has traditionally relied upon data for aquatic organisms (fish) and a partitioning property referenced to water (i.e., octanol-water partition coefficient, KOW). OECD guidance for laboratory testing with fish is available and widely accepted (OECD 305) and there is a relative abundance of empirical data characterizing bioaccumulation potential in fish (i.e., bioconcentration factors, BCF). The abundance of empirical data has supported the development, evaluation and application of several approaches to simulate BCFs in fish including Quantitative Structure Activity Relationships (QSARs) and mechanistic bioaccumulation (toxicokinetic) models. Food web bioaccumulation models have also been developed to simulate bioaccumulation potential in the field (e.g., bioaccumulation factors, BAFs and biomagnification factors, BMFs). These tools can be used to support regulatory activities such as PBT assessment and exposure/risk assessment. Regulatory guidance from the European Chemicals Agency (ECHA) now includes B screening threshold criteria for air-breathing organisms linked to KOW and the octanol-air partition coefficient (KOA) (e.g., Chapter R11: PBT/vPvB Assessment). Unlike the situation for fish, there is no standardized test for bioaccumulation assessment in air-breathing organisms (e.g., laboratory rats and mice). However, a wealth of toxicokinetic data has been generated using mammals for other regulatory purposes (e.g., pesticide registration). These tests are frequently single dose studies (intravenous, oral bolus) and their interpretation for B assessment is less obvious compared to fish BCF data. The objective of this study was to develop and apply one- and multi-compartment toxicokinetic models (1-CoTK and PBTK respectively) to simulate the behaviour of organic chemicals in laboratory animals for interpretation in the context of B assessment. As a case study, the models were applied to laboratory test data for several organic compounds of interest and their performance assessed. Different sources of data characterizing biotransformation (e.g., in vitro S9 data, QSARs) were considered to parameterize the models and demonstrate the key role of this process in mitigating bioaccumulation potential. The results are then interpreted with respect to bioaccumulation assessment in air-breathing organisms.

**UVCB Risk Assessment: Venturing Into Another Dimension**

TP240 A linear regression model for predicting sigma profiles

A. Celesie, Queen's University; J. Parnis, Trent University / Chemistry

Linear regression models can be very useful for predicting chemical properties with high environmental significance. Quantitative structure-activity relationships (QSARS) and linear free energy relationships (LFERs) are examples of linear regression type models often used in environmental science to predict properties such as partition ratios or biotransformation half-lives. Sigma profiles are chemical properties which estimate the distribution of charges over the molecule's surface area. An example is shown for ethanol in Figure 1a. Andreas Klamt has shown that sigma profiles can be used to characterize any chemical or mixture of chemicals and used this as the basis for developing the quantum mechanics-based COSMO-RS theory. COSMO-RS has been implemented into the software COSMOtherm for predicting chemical properties such as partition ratios, solubilities, vapour pressures, Henry's law constants (HLCs), and others. In this study, a multi-parameter linear regression (MRE) model has been developed using HLCs as descriptors in order to predict sigma profiles of chemicals. Predictions can be made for pure chemicals or for mixtures of unknown or variable composition (UVCBs). Sigma profiles are then indirectly input into COSMOtherm in order to predict chemical properties such as partition ratios. A sigma profile for ethanol predicted using this MRE model is shown in Figure 1b. Figure 1: A) left: Shows the sigma profile of ethanol. B) right: A predicted sigma profile of ethanol which was generated using the MRE in this study. Partition ratios were predicted for a group of 250 neutral organic compounds in an ethanol/water medium as well as for a 'predicted ethanol'/water medium and these partition ratios were graphed against each other, shown in Figure 2. Graph of partition ratios in a 'predicted ethanol'/water medium vs. in an ethanol/water medium and regression statistics. RMSE = 0.29. This process was repeated for all 49 test chemicals giving an average RMSE of 0.49 log units for predicted partition ratios. These results are promising for using experimentally determined HLCs (which can be converted from vapour pressure) to characterize relevant properties of environmental media, especially for UVCB substances.
TP241 An Approach to Estimating the Aquatic Risk of Complex Petroleum Substances Following Wastewater Treatment

J. Cermak, Environment and Climate Change Canada / Ecological Assessment Division, Science and Risk Assessment Directorate; A. Redman, ExxonMobil Petroleum and Chemical / Toxicology and Environment Science Division; J. Shen, D. Delage, Environment and Climate Change Canada / Ecological Assessment Division, Science and Risk Assessment Directorate

Petroleum substances are considered to be substances of Unknown or Variable composition, Complex reaction products or Biological materials (UVCBs), consisting of 10’s to 1000’s of individual components in variable proportions, the majority of which are hydrocarbons. These substances are used in many different industrial, commercial and consumer applications, and may be released to wastewater that eventually undergoes wastewater treatment (WWT). The physical and chemical properties of each individual component affect its removal in wastewater treatment processes, resulting in changes in the relative proportion of individual components of the substance post-treatment. This leads to two issues for an ecological risk assessment: 1) removal rates for WWT being dependent on the initial composition of the substance; and 2) a potentially different hazard profile of the UVCB substance post-treatment compared to pre-treatment. An approach was needed to estimate the removal of petroleum UVCBs and resulting changes in composition in order to appropriately develop predicted environmental concentrations (PECs) and estimate hazard of the substance released to the environment after WWT. The Ecological Assessment Division (EAD) of Environment and Climate Change Canada uses a model, PETROTOX, which can estimate the toxicity of a petroleum substance if some details of its composition are known. Therefore, EAD wanted an approach to estimate WWT removal of petroleum substances which could be used with PETROTOX. An approach was developed that combined the library of hydrocarbon representative structures and mapping scheme of structures to hydrocarbon blocks found within PETROTOX with wastewater removal models to estimate the removal of hydrocarbon components during WWT. This approach was then used to estimate the total removal rate of the substance, which was used to estimate the PEC, and the post-treatment composition, which was entered into PETROTOX to estimate hazard. The PEC and hazard were then compared to determine risk. Overall risk decreased due to the removal of petroleum constituents during WWT. However, the modeling analysis indicated that the composition of the UVCBs shifted, which affected the hazard differentially dependent on the specific petroleum substance. The approach is described, and the impact of assumptions (e.g., block size in PETROTOX) and compositional data resolution on the results are discussed.

TP242 Analyzing complex mixtures for bioaccumulation potential using the trout in vitro metabolism assay (OECD TG 319A & B): A case study, fir (pine) oil

K.M. Johanning, KJ Scientific; A. Lapczynski, Research Institute for Fragrance Materials (RIFM) / Dept of Environmental Science

Bioaccumulation potential determination using the bioconcentration factor (BCF) is used widely by regulatory agencies (e.g. REACH, ECHA) for the PBT (Persistency, Bioaccumulation and Toxicity) criteria in risk assessment of chemicals. Biotransformation of chemicals is a key component in order to determine if a chemical is enzymatically degraded by organisms in the environment and impacting environmental and human health. We are utilizing the recently approved OECD TG 319A and 319B trout in vitro metabolism methodology to assess the bioaccumulation potential of fir (pine) oil. The objectives of the present study are several-fold: a- determine the metabolism of pine oil by assessing biotransformation of 9 main components (alpha-pinene, beta-pinene, camphene, carene, limonene, terpinolene, borneol, bornyl acetate, and caryophyllene) in a Natural Complex Substance (NCS) b- compare these results with a recent in vivo benchmarked fish dietary study of the same fir oil mixture that has been undergoing in McLeod’s laboratory at the Stockholm University c- compare the in vitro biotransformation of the components in the NCS mixture and individually. In our animal alternative methodology in vitro study we are utilizing rainbow trout liver S9 and cryopreserved hepatocytes. The analytical method has been optimized in order to separate and resolved the main components of this mixture for accurate analysis. In addition, individual components have been used to match the identity of the components in the complex mixture of fir oil. These individual components will also be assessed in a subsequent phase of the study for in vitro metabolism using the same TG 319A and 319B and compare the results with the behavior of each component in the mixture. The in vitro metabolic assay is a powerful tool that can be used to determine BCF of test chemicals and also provides data to build the database information on fragrance materials for fish metabolism and modeling. In addition, this in vitro methodology offers the great advantage and flexibility of varying factors at the cellular level in order to obtain a more realistic scenario of the chemicals-enzyme interactions (e.g. inhibition, induction) which is not possible utilizing in vivo methodologies.

Estimating Environmental Hazard and Risks from Exposure to Perfluorinated and Polyfluorinated Alkyl Substances (PFAS): Outcome of a Focused Topic Meeting

TP243 An Evaluation of the Acute and Chronic effects of PFAS in avian species to derive threshold values

J.L. Newsted, Ramboll / Environmental and Health Sciences; D. Tazelaar, OBG, Part of Ramboll

Perfluoroalkyl substances (PFAS) are synthetic fluorinated organic compounds that can be released into the environment during manufacturing processes, from commercial products and applications, or indirectly via oxidation of precursor molecules containing fluoroalkyl chains. Currently over 3,000 PFAS have been identified in environmental biotic and abiotic media that can include perfluoralkyl carboxylates (PFCAs), perfluoralkyl sulfonates (PFSAs), perfluoralkyl phosphonic acids (PFPA) and fluorotelomer alcohols (FTOHs). Recently, PFAS have received increased attention in federal and state monitoring programs that have primarily focused on aspects related to human exposure and health. Ecologically, numerous studies have demonstrated the bioaccumulation of PFAS into aquatic organisms and avian and mammalian wildlife, however the significance of these data relative to the risk they pose to wildlife is difficult to ascertain due to the lack of ecotoxicity data. This issue is especially relevant for avian species where few laboratory studies have been conducted and of which most have focused on either perfluorooctane sulfonate (PFOS) and perfluorooctanoate (PFOA). To address this issue, we have conducted a review of avian laboratory studies and field studies with a focus on apical endpoints (survival, growth and reproduction) and other indices of health including immunological and neurological endpoints. Field studies with avian species that relate exposure to potential adverse health outcomes will be discussed taking into account both direct effects of PFAS on avian populations, and confounding factors (study design, endpoint selection and presence of additional chemical classes) that influence interpretation of results. Finally, these data will be evaluated relative to their potential utility in deriving scientifically useful and defensible toxicity reference values (TRVs) along with insights into what is still needed to provide a greater understanding of potential risks that PFAS pose to wildlife.

TP244 Ecological Assessment Challenges/Data Gaps for Short-Chain (C4-C7) Perfluoroalkyl Substances and Long-Chain (C9-C20) Perfluoroalkyl Sulfonic Acids

J. Kurias, Environment and Climate Change Canada / Department of Environment and Climate Change

Risk assessments conducted under the Canadian Environmental Protection Act, 1999 for perfluorooctane sulfonic acid (PFOS), perfluorooctanoic acid (PFOA) and long-chain (C9-C20) perfluoroalkyl
carboxylic acids (PFCAs) have concluded that these substances are harmful to the environment. Concerns raised internationally that short-chain (C4–C7) perfluoralkyl substances (PFAS) and long-chain (C9–C20) perfluoralkyl sulfonic acids suggest that these substances have similar ecological impacts as PFOA and PFOS. These substances are not manufactured in Canada but are found in Canadian biota/environment. There are significant ecological assessment challenges including data gaps for these substances. Environment and Climate Change Canada is presently developing a report outlining data gaps and their relevance to the evaluation of ecological risk to encourage data generation. Some key points include: Air-breathing marine/terrestrial mammals and birds are the species most bioaccumulative for PFAS and of most ecological interest; Short-chain PFAS toxicity values ranged from 110 to 20 250 mg/L in fish, daphnia and algae. Similar results were seen for PFOA, PFOS, and long-chain PFCAs; Obtaining ecotoxicity data for marine/terrestrial mammals is difficult given the large number of substances to test and large body sizes. New approach methodology can be helpful to evaluate toxicity if links from molecular/cellular level can be made to a mode of action or gross effect (i.e., reproduction, growth & development), and if modes of action are conserved across species (if so, which modes of action and for which species) to allow for read-across to marine/terrestrial mammals, birds or saltwater fish; PFAS bioaccumulation based on fish, daphnia and algae alone cannot be used to reliably predict food web bioaccumulation for marine/terrestrial mammals or birds; Species differences result in different rates of bioaccumulation making extrapolations between species and between PFAS chain length difficult; Short-chain PFAS and long-chain PFAS are QSAR-difficult. Estimates of log Kow or using log Kow of neutral species can result in unreliable bioaccumulation predictions. Some bioaccumulation models incorporate key characteristics of PFAS (i.e., ionizing and preferential protein partitioning). However, model results remain unreliable as training sets are based on freshwater fish, few empirical data or use either protein-partitioning or lipid-partitioning, but not both.

**TP245 Fluoropolymers are ‘benignly persistent’, analytically distinct PFAS that pose no hazard to human or environmental health**

In order to protect public health and the environment, efforts to restrict/regulate PFAS must focus limited resources on those that pose the greatest risk. Exposure pathways, physical, chemical and toxicological properties, and valid analytical methods are needed to identify and regulate appropriately. The recent legislative definition of “PFAS” is overly broad and includes fluoropolymers satisfying the OECD Polymer of Low Concern (PLC) criteria, as well as drugs, pesticides, veterinary drugs and those PFAS listed or recommended for listing as Persistent Organic Pollutants. This definition is not adequate for grouping for hazard assessment, risk management, regulation, monitoring or analyses. Presented here is a science-based approach for prioritizing efforts to better understand PFAS toxicity to inform regulatory decision-making. Tables comparing the properties of the polymeric and non-polymeric PFAS categories and the five PFAS classes response to each type of analytical method are presented. Also presented is a proposal to designate one or more specific PFAS subclass as “PFAS of concern” and exclude polymers that meet OECD PLC criteria. Toxicity data, physical/chemical/thermal properties and residuals demonstrate that fluoropolymers that are PLCs are not bioavailable, toxic, or bioaccumulative. They have little to no water solubility or volatility and pose a low risk of environmental mobility. They are stable/persistent and do not degrade in biota or the environment, nor do toxic substances leach from them, even under exaggerated extraction. This fluoropolymer data has been approved by global regulatory authorities for commercial permanently implanted cardiovascular medical devices. Fluoropolymers that are PLCs are “benignly persistent” PFAS that do not pose a hazard to human or environmental health. They are a distinctive PFAS class that can be analytically differentiated by readily available, reliable, and reproducible methods. Accordingly, “benignly persistent” PFAS should not be the focus of limited resources to protect public health.

**TP246 Modeling of Potential PFAS Leaching from Land Applied Biosolids to Groundwater**

M. Propato, Stone Environmental, Inc.; M.F. Winchell, Stone Environmental Engineering & Science, Inc. / Environmental Systems Modeling; N. Beecher, NEBRA

One source of potential concern for the entry of PFAS into the environment is the land application of biosolids. Biosolids, often from municipal wastewater treatment facilities, are most often applied to agricultural land to provide nutrients required for plant growth. Due to the ubiquitous nature of PFAS in our society, their presence in wastewater biosolids is often detected at variable concentration levels. Understanding the limits to the concentrations of PFAS in land applied biosolids that are required to be protective of groundwater sources for drinking water is of high importance. Screening level approaches for estimating PFAS concentration limits in agricultural soils have been largely derived from contaminated sites, which assume a very different conceptual model than a biosolids application to cropland. The use of inappropriate models in deriving regulatory concentration limits on PFAS in biosolids has the potential to result in mismanagement of biosolids as a beneficial resource. An approach to modeling the leaching of two common PFAS chemicals, PFOA and PFOS, was developed based on contaminant transport modeling used by USEPA in the regulation of agriculturally applied pesticides. The Pesticide Root Zone Model (PRZM) predicts surface runoff, erosion, and leaching of chemicals applied at the land surface, and accounts for sorption/desorption and multiple degradation processes when relevant. The PRZM model was applied to evaluate the potential for PFOA/PFOS leaching to groundwater in Maine, and to estimate biosolids concentration limits required to protect groundwater resources. A spatial analysis of cultivated cropland and pasture/hayland in Maine was conducted to identify four representative soils in these areas, ranging from sandy low water holding capacity soils to clay high water holding capacity soils. These four soils were used to parameterize the PRZM model using Maine specific weather and crop growth parameters. An ensemble of model simulations, evaluating a range of sorption characteristics (Kd), groundwater depths, and biosolids application rates, provided data that allowed for better informed determination of the relationships between PFAS concentrations in land applied biosolids and their presence in groundwater.

**TP247 Perfluorooctanesulfonate (PFOS) induces apoptosis of neuronal cells via NMDA receptor-mediated ERK pathway**

S. Park, Daegu Catholic University / Pharmacology/Toxicology; J. Yang, Catholic University of Daegu / Pharmacology

Perfluoroalkyl compounds (PFCs) may pose a potential risk of neurotoxicity. Perfluorooctanesulfonate (PFOS) is one of the major PFCs found in humans. PFOS is one of the major PFCs detected in serum samples taken from the general population as well as in umbilical cord and breast milk. Serum level of PFOS in children has been reported to be greater than adults. Many studies have demonstrated that the early exposure to environmental chemicals increases the risk of neurodegenerative diseases such as Parkinson’s disease in later life. This raised a concern over their health effects. While PFOS is known to induce neuronal cell death, its mechanism remains unclear. In this study, the effects of PFOS on neuronal cell death were examined using PC12 cells as a model of dopaminergic neuron to understand the underlying mechanisms. The treatment with PFOS reduced cell viability in a dose-dependent manner. PFOS increased cell apoptosis which was measured by caspase-3 activity and TUNEL staining. MK801, a NMDA receptor antagonist, reduced PFOS-induced apoptosis. PFOS increased the activations of ERK1/2, JNK and p38 MAPK with different temporal modes. The treatment with PD98059, an ERK inhibitor, significantly reduced apoptosis, whereas SB203580, a p38 MAPK inhibitor, had no effect. JNK inhibition by SP600125 significantly increased apoptosis. PFOS exposure also
increased ROS formation, which was completely blocked by antioxidants, Trolox or N-acetylcysteine (NAC). However, neither Trolox nor NAC reduced PFOS-increased apoptosis, suggesting that ROS may not be a critical mediator for PFOS-induced apoptosis of cells. These results have demonstrated that PFOS induces the apoptosis of dopaminergic neuronal cells via NMDA receptor-mediated ERK pathway. Our results may contribute to understanding cellular mechanisms of apoptosis and identify target molecules for assessing the risk of PFC-induced neurotoxicity.

TP248 Uncertainties in Conducting Ecological Risk Assessments for PFAS Compounds
S.M. Jones, GHD
PFAS compounds have received a great deal of attention in recent years. Whereas strides have been made in analytic technical, advances in our knowledge of toxicity, particularly to ecological receptors, have lagged behind. Because PFAS compounds are known to bioaccumulate and biomagnify in aquatic food webs, regulatory agencies at the federal, provincial, and state levels are requiring ecological risk assessments (ERAs) to evaluate risk to aquatic life and upper trophic level ecological receptors that forage on aquatic prey. Due to absence of a robust database on the ecotoxicity of PFAS, there is a high degree of uncertainty in evaluating risk to ecological receptors, and subsequently, identifying risk management measures. For example, few studies have identified toxicity reference values (TRVs) for avian receptors, with values differing by orders of magnitude among taxonomic groups and feeding guilds. This presentation will discuss the variability in ecological screening guidelines for freshwater and marine water, sediment, soil, and biological tissue from jurisdictions in Canada, Australia/New Zealand, and other countries. Variability in bioaccumulation factors (BAFs), biota sediment accumulation factors (BSAFs) and TRVs for avian and mammalian wildlife will also be presented. Measures to reduce uncertainties in ERAs will be discussed.

Ecological Risk Assessment: What Matters and Prioritization of Resources

TP249 Assimilation of Ash-Related Arsenic and Selenium Contamination in Bubbling Mayflies - Why Tissue Collection for Food Chain Evaluations Matter
H. McChesney, S. Walls, ARCADIS
Benthic invertebrates provide an important food source to aquatic and terrestrial wildlife and, in contaminated water bodies, they also can contribute to the transfer of contaminants from sediments into the aquatic and terrestrial ecosystems. This study focuses on the assimilation of arsenic (As) and selenium (Se) from coal ash into the nymph stages of the common and widespread burrowing mayfly Hexagenia bilineata and compares the measured tissue concentrations to predicted tissue concentrations using literature-derived bioaccumulation factors. Depurated and non-depurated Hexagenia nymphs were collected annually from 2009 to 2017 at up to 11 sites and were analyzed for As and Se. Mean levels of As in Hexagenia tissue ranged from 0.58 to 4.67 mg/kg-dw in depurated individuals and from 2.3 to 19.0 mg/kg-dw in non-depurated tissue. Estimated concentrations of As in tissue based on literature-based bioaccumulation factors and regression models varied widely and both over- and underestimated As tissue concentrations, whereas predicted As tissue concentrations for non-depurated tissue consistently underestimated measured As tissue values. Mean levels of Se in Hexagenia ranged from 3.0 to 9.6 mg/kg-dw in both depurated and non-depurated individuals. Estimated Se tissue concentrations calculated from a literature-based bioaccumulation factors underestimated Se tissue concentrations at low sediment concentrations and overestimated Se tissue concentrations at high sediment concentrations. Differences between measured and predicted tissue concentrations suggest that site-specific conditions may affect the assimilation rates of metals. Differences may also reflect species-specific uptake given that literature-based bioaccumulation factors and models are often based on multiple invertebrate species. Therefore, standard bioaccumulation factors may not accurately predict the contribution of some contaminants to upper trophic level consumers that feed on these organisms. This presentation highlights the importance of understanding uncertainties of key parameters in ecological risk assessments and how collecting site-specific tissue measurements of representative invertebrate species in wildlife diets can alter predicted risk outcomes.

TP250 Ecological Risk Assessment of Heavy Metals from Informal E-waste Processing in Alaba International Market, Lagos, Nigeria
A.A. Adebayo, A.O. Ogunkeyede, Federal University of Petroleum Resources / Environmental Management and Toxicology; O. Oshibanjo, Basel Coordinating Center for Africa / Department of Chemistry, University of Ibadan
Informal electronic waste (e-waste) processing is a crude method of recycling, which is on the increase in Nigeria. The release of hazardous substances such as heavy metals (HMs) into the environment during informal e-waste processing has been a major concern. However, there is insufficient information on environmental contamination from e-waste recycling, associated ecological risk in Alaba International Market, a major electronic market in Lagos, Nigeria. The aims of this study were to determine the levels of HMs in soil, resulting from the e-waste recycling; and also assess associated ecological risks in Alaba international market. Samples of soils (334) were randomly collected seasonally for three years from fourteen selected e-waste activity points and two control sites. The samples were digested using standard methods and HMs analysed by inductive coupled plasma optical emission. Ecological risk was estimated using Ecological Risk index (ER), Potential Ecological Risk index (RI), Index of geoaccumulation (Igeo), Contamination factor (CF) and degree of contamination factor (Cdmg). The concentrations range of HMs (mg/kg) in soil were: 16.7-11200.0 (Pb); 14.3-22600.0 (Cu); 1.90-6280.0 (Ni), 39.5-4570.0 (Zn); 0.79-12300.0 (Sn); 0.02-138.0 (Cd); 12.7-1710.0 (Ba); 0.18-1310.0 (Cr); 0.07-28.0 (V), while As was below detection limit. Concentrations range in control soils were 1.36-9.70 (Pb), 2.06-7.60 (Cu), 1.25-5.11 (Ni), 3.62-15.9 (Zn), BDL-0.56 (Sn), BDL-0.01 (Cd), 14.6-47.6 (Ba), 0.21-12.2 (Cr) and 0.22-22.2 (V). The trend in ecological risk index was in the order Cu>Pb>Ni>Zn>Cr>Ba>V. The potential ecological risk index with respect to informal e-waste activities were: burning>>dis mantling>>disposal>>stockpiling. The index of geo accumulation indices revealed that soils were extremely polluted with Cd, Cu, Pb, Zn and Ni. The contamination factor indicated that 93% of the studied areas have very high contamination status for Pb, Cu, Ba, Sn and Co while Cr and Cd were in the moderately contaminated status. The degree of contamination decreased in the order of Sn>Cu>Pb>>Zn>Ba>Co>Ni>V>Cr>Cd. Heavy metal contamination of Alaba international market environment resulting from informal e-waste processing was established. Proper management of e-waste and remediation of the market environment are recommended to minimize the ecological risks.

TP251 Geospatial approaches to increasing the ecological relevance of chemical risk assessments
For several decades, the prospective risk assessment of chemicals has followed a generic approach of comparing estimated exposures to toxic thresholds designed to be protective of all species (i.e., assessing exposure to the most sensitive species assumed to be located anywhere the chemical may occur in the environment). This approach does not recognize geographic patterns of species distributions or acknowledge that particularly sensitive species may not occupy potentially exposed habitats. Therefore, risk assessments could be overly conservative and restrictive for some uses of chemicals. Approaches for making spatially explicit assessments of chemical exposure are relatively advanced but this is not the case for mapping and assessing ecological data. However, geo-referenced
ecological data appear to be increasingly available at spatial resolutions applicable to chemical risk assessment, potentially facilitating enhanced environmental relevance of such risk assessments. In 2017 a Task Force was initiated by European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) to assess the capability of making chemical risk assessments using available geospatially referenced chemical exposure, ecological receptor and ecosystem services data. Two case studies were developed to illustrate the potential to assess geo-referenced risks to ecological receptors in fresh water and terrestrial environments exposed to i) a chemical used in consumer cleaning products discharged via municipal WWTPs across the EU and ii) a range of representative active ingredients used in plant protection products on selected crops in Germany. After initially compiling a catalogue of available geo-referenced ecological data for Europe, geo-referenced exposure concentrations were derived by combining accessible chemical use and fate data with conventional exposure models. However, use of many ecological data sets over a pan-European range proved problematic due to data access issues, limited geographic coverage and unreliable quality. Nevertheless, several suitable ecological data sets were accessed after making specific requests to various organizations within national authorities and these were integrated with the exposure maps. The results of these case studies give an indication of the potential value of making geo-referenced chemical risk assessments as well as the limitations to current capability.

TP252 Modifying the Ecological Risk Assessment Framework for Managing Environmentally Sensitive Sites
L. McDonald, J. Kirk, B. Hard, M. Whelly, ARCADIS Canada, Inc.; L. Tam, ARCADIS Canada, Inc. / Environment

Point Pelee National Park (PPNP) in southern Ontario includes Middle Island and a mainland portion which is a triangular sand spit formation extending 10 kilometres into Lake Erie. PPNP is located at the centre of two central migratory flyways and provides habitat critical for hundreds of species of migrating birds and insects. PPNP protects a mosaic of ecosystems located in the most biodiverse natural region in Canada, the Carolinian ecozone. 70 COSEWIC-listed (Committee on the Status of Endangered Wildlife in Canada) species are currently found in the park, including 60 federally protected Species At Risk (SAR), as per Schedule 1 of Species at Risk Act, with three SAR found only on Middle Island. The majority of the mainland PPNP is marshland, with remaining 30% composed of dry forest, swamp forest, beach, and savannah habitat. Numerous investigations have documented a variety of contaminants of concern (COCs) in both aquatic and terrestrial media. The objective of the risk assessment (RA) for mainland PPNP was to more accurately represent unacceptable risks to all ecological receptors beyond the capacity of traditional RA models with the goal of more precise characterization of site-specific bio-transfer of contaminants to ecological receptors. This will allow better estimation of exposures and risk for the species that require protection. Given the biodiversity of the park and presence of many SAR, wildlife vertebrate sampling was not advisable, and a more unique approach was recommended. Arcadis developed a site-specific Conceptual Site Model (CSM) in conjunction with Parks Canada Agency (PCA) to more accurately demonstrate the ecological food web interactions and refine recommendations. Arcadis has recommended sampling a variety of primary producers and invertebrates being consumed by SAR to better understand the transfer of COCs from soil, sediment, and water. In particular, the diet of certain SAR required extensive research of receptor characteristics not typically modelled in RAs. Other potential tools may include field surveys related to bio-magnifying compounds and population health assessments. The RA, currently in draft, will enable federal custodians to better understand rates and spatial patterns of COC uptake and transfer within the park to determine whether risk management and/or remediation is appropriate and how it can be implemented most effectively at PPNP, where and if required, to protect this biodiverse ecosystem.

TP253 Practical Advancements in Endangered Species Risk Assessment Efficiency
S. Teed, Intrinsik Corp.; M.E. Kern, Waterborne Environmental, Inc. / Ecotoxicology Risk Assessment; J.L. Cowles, NovaSource / Tessenderlo Kerley, Inc. / Product Safety

With the release of the Environmental Protection Agency (EPA) and National Marine Fisheries Service (NMFS) organophosphate case studies for endangered species risk assessment, it became clear that the methods used in the biological evaluations and biological opinion need refinement for identifying risk to listed species and the critical habitat on which they may depend. With hundreds of pesticide registration actions annually, and more than 1,660 species listed under the Endangered Species Act, it is critical to be able to conduct a scientifically defensible risk assessment efficiently with limited time and resources. However, confidence must be high that the listed species or the critical habitat on which they depend can readily be identified as being not at risk, or at potential risk. The recently released EPA revised method for developing biological evaluations addresses some aspects of these short comings, by recognizing early in the problem formulation process that some listed species will not be exposed to a pesticide for a variety of reasons (e.g., they are extinct or extirpated; only found on federal lands). However, there are many possible additional considerations that matter, can be accounted for, and may vary on a pesticide by pesticide basis. These include label restrictions, simple spatial refinement, specific fate/behavior characteristics, listed species life history information, known and previously evaluated pesticide tolerances, and other factors. In a CropLife America funded project, these practical advancements are being identified and evaluated for use in the problem formulation process. In this presentation, the carbamate pesticide carbaryl is used to evaluate the impact of these factors on the endangered species risk assessment process, along with examples from other chemistries to more clearly show their utility.

TP254 Utilization of a Web-Based Tool ChemTHEATRE in Exposure and Risk Assessments for Chemicals
K. Nakayama, Ehime University / Center for Marine Environmental Studies; B. Lin, National Institute of Advanced Industrial Science / Research Institute of Science for Safety and Sustainability; T. Isobe, National Institute for Environmental Studies / Center for Environmental Research Institute of Science for Safety and Sustainability; T. Kunisue, Ehime University / Institute of Science and Technology; N. Ohno, University of Hyogo / Graduate School of Simulation Studies; T. Kamisue, Ehime University / Center for Marine Environmental Studies (CMES)

A huge number of monitoring data on chemicals in various environmental and biological specimens have been reported in scientific journals. However, comprehensive, public repositories to store such valuable data set of the chemicals do not exist; researchers are forced to spend lots of time and cost in collecting and utilizing the published data, when modelling environmental behavior and fate of, and performing the risk assessment for, the chemicals of interest. Therefore, we have launched a platform to register and visualize the monitoring data of environmental contaminants, named ChemTHEATRE (Chemicals in the THEATRE: Tractable and Heuristic E-Archive for Traceability and Responsible-care Engagement) in 2016. To date, data described in more than 87 projects have been registered on the platform. Users can find e-archived chemical concentration data in the environmental and biological specimens each with associated metadata such as sampling date and location, species, and biometrics, and can download them in text files. Bridging ChemTHEATRE to AIST-MeRAM (Multi-purpose Ecological Risk Assessment and Management Tool) storing chemical property and/or hazard/toxicity information provides us high accurate and transparent assessment of ecological risk of chemicals. AIST-MeRAM can output the results of exposure and risk assessments very easily and quickly just importing the text file containing monitoring data exported from ChemTHEATRE. Much effort is currently being devoted to visualizing e-archived data sets, and enhancing available data-model interfaces to
Bayesian Network Applications for Environmental Risk Assessment and Adaptive Management

TP255 A stochastic framework for estimating freely dissolved concentrations: Implications of variance in observed sediment-porewater partitioning

N. W. Johnson, University of Minnesota, Duluth / Civil Engineering; A. A. Brennan, University of Minnesota, Duluth / Water Resources Science

The use of passive sampling to quantify freely dissolved and bioavailable contaminants (Cfree) in sediment porewater has led to innovative management strategies. However, variance in contaminant partitioning strength in natural systems remains, in many cases, an intractable problem due to a complex environmental conditions. When solid-phase contaminant concentration (Ctotal) is known but direct porewater measurements are not available, variance in sediment-porewater partitioning (KTOC) translates to variance in estimated porewater contaminant concentrations. The variance in estimated C-free has important implications for comparisons to risk-based thresholds. We propose a framework in which a range of Cfree exposure estimates are stochastically paired with effects data, providing a transparent way of quantifying the risk of Cfree exceeding a threshold. The proposed stochastic framework uses passive sampling-derived variance in KTOC as the basis for a continuous estimate of the probability that Cfree will exceed a threshold along a continuum of Ctotal. Our results show that passive sampling-derived KTOC distributions differ markedly among the studies included in our analysis, and that risk curves derived from KTOC distributions depend on the scale of variance present in the partitioning distribution. KTOC probability distributions can be updated for a specific site based on additional site-specific passive sampling-derived porewater measurements. Bayesian analyses can be used to adjust distributions to reflect knowledge of site-specific conditions without the need for wholesale resampling. For assumed parametric KTOC distributions, we apply Bayesian updating to estimate the number of samples needed to quantify site-specific model parameters based on case studies from two contrasting environmental conditions. The proposed methods have applicability beyond sediment contaminant partitioning and advance the basis for understanding and quantifying uncertainty associated with risk management decisions.

TP256 A short introduction to the application of Bayesian networks in ecological risk assessment and decision making

W.G. Landis, Western Washington University / Institute of Environmental Toxicology; J.F. Carriger, Jr., US Environmental Protection Agency / National Risk Management Research Laboratory

Bayesian networks (BNs, also known as Bayesian belief networks) are a means of describing cause and effect using directed acyclic graphs where the interactions between the nodes are described using conditional probability tables. That is a way of saying that there are nodes (steps in a cause-effect model), which are connected by lines of influence, and the interactions are described using probability tables that take into account all possible combinations of inputs to generate the probability distributions for each possible outcome. Bayesian networks inherently incorporate uncertainty and can use wide varieties of data, from precise determinations of molecular interactions to expert elicitation. Since 2010 a number of papers have been published on the use of BNs to evaluate management options, to evaluate risk, to provide a more quantitative framework for the relative risk model, and to become a part of adaptive management. At the 2017 SETAC NA (Sacramento) and the 2018 SETAC EU (Helsinki) this sessions included presentations by developers and users of Bayesian networks to estimate risk, calculate the outcomes of management alternatives and the use of such techniques to make policy decisions. The topics included large scale risk assessments, BNs in QSAR models, the use of BNs to build quantitative adverse outcome pathways, sustainable management of large scale systems, and the management of environmental resources. This session will include presentations integrating the use of pesticides and synthetic biology, multiple stressors, and other applications. The question will be where do we go now that the use of Bayesian networks is part of the mainstream of risk assessment and decision making.

TP257 Risk Assessment Framework for Gene Drive Technology: Example in Integrated Pest Management

E. Brown, Western Washington University / Environmental Sciences; S.R. Eikenbary, W.G. Landis, Western Washington University / Institute of Environmental Toxicology

As of June 2019, there has been no ecological risk assessment which incorporates synthetic biology stressors and potential impacts into a multiple-stressor/multiple-endpoint model. To start developing a framework for this risk assessment scenario, the Relative Risk Model (RRM) was employed in the context of environmental applications of gene drive technology, which aims to spread engineered genes through populations of organisms with relatively short generational times. A conceptual framework and Bayesian Network were constructed for a pest management scenario of non-indigenous mice on the South Farallon Islands. Potential ecological, toxicological, spatial, and temporal influences were incorporated into the Bayesian Network, which quantitatively relates variables using causal knowledge. Two management scenarios are discussed for mouse eradication in the Farallonones: the first is the “Preferred Alternative” put forth by the United States Fish and Wildlife Service (USFWS) in a recent environmental impact statement. The second is deployment of gene-drive-modified mice, which are intended to spread female sterility through the wild non-indigenous mouse population. Integrated pest management, a management goal with the purpose of minimizing the use of chemical pesticides, is discussed in the context of these two potential management strategies, taking into account the possibility of interactions between gene-drive mice and chemical pesticides. The National Academies of Science, Engineering, and Medicine’s (NASEM) report on gene drives outlines a “phased testing pathway” for potential deployment of gene drive organisms into the environment. This testing pathway is discussed in the context of its relation to the risk assessment process and with the scope of developing lab and field experiments for gene drive development. An example of dose-response toxicity data analysis in the context of uncertainty, probability, and gene-drive factors was also outlined to give an example of what experimental design considerations should be accounted for in a risk assessment, as well as a discussion of experimental and modeling assumptions. Additionally, needs for future work is discussed in the context of parameterizing a risk assessment model that incorporates synthetic biology stressor and impact variables in a probabilistic manner.

TP258 A Bayesian network approach for estimating distribution parameters with detected and non-detected environmental concentration data

J.F. Carriger, Jr., US Environmental Protection Agency / National Risk Management Research Laboratory; C. Acheson, US Environmental Protection Agency / National Risk Management Research Laboratory; D. Kleinmaier, US Environmental Protection Agency / Region 5 Analytical Services Branch; R. Herrmann, US Environmental Protection Agency / National Risk Management Research Laboratory

Environmental data often contain non-detects that can bias a data or exposure analysis if mishandled, such as by substituting artificial point
values for the non-detected data. Bayesian analysis is infrequently used with environmental concentration or exposure distributions for handling non-detected data but can incorporate more of the uncertainties for data and parameters than conventional methods. An approach that relies on Bayesian networks for handling non-detects was developed to estimate the parameters of probability distributions built with environmental concentration data. Multiple reporting limits can be used to accommodate the non-detected data and uncertainty ranges can be input to detected data, if useful and appropriate. The approach requires identifying initial prior probability distributions for the distribution parameters and the ranges or point estimates for detected or non-detected data. The uncertainties from the data are propagated to the distributions for parameters using Bayes theorem. The output environmental concentration distribution from the posterior probabilities for the parameters then includes uncertainties from both the parameters and concentration data. We briefly demonstrate the creation of a distribution of environmental concentrations and discuss the application of the Bayesian network distributions in temporal Bayesian learning. Bayesian hypothesis testing, benchmark exceedence calculations, and causal risk-based modelling. The Bayesian network approach to constructing an environmental concentration distribution may be more labor-intensive than classical and other Bayesian approaches as it requires prior probability distributions for parameters and additional time to construct the graphical components of the model. But the Bayesian network approach potentially provides a rigorous and flexible way of including uncertainties from non-detected data and distribution parameters.

TP259 Adaptive management framework and Bayesian network analysis for regional climate change assessments

M. Cains, Indiana University / School of Public and Environmental Affairs

Understanding and planning for climate change is a complex systems problem that is interdisciplinary and requires place-based and impact-specific management practices for communities to become resilient to a changing environment. The greater Charleston Harbor region of South Carolina is highly susceptible to the projected impacts of climate change due to low lying geography, a strongly bimodal socioeconomic spectrum, and invaluable coastal ecosystem services. Using Charleston as an example community, this presentation discusses the application of the Bayesian Network-Relative Risk Model for a system-level, community-focused risk and resilience assessment that aims to enable community involvement in the assessment of and planning for climate change-induced severe weather events, more extreme temperatures, and sea level rise. For climate change assessment, be it for vulnerability, risk, or resilience, to be both contextually and geographically relevant, and be able to foster local commitment to feasible solutions, a holistic assessment approach must 1) employ community-based and community-participatory research methods that acknowledge and treat the community members as collaborators, rather than subjects for observation, 2) integrate regionally-relevant data from disparate disciplines and data sources, and 3) evaluate community-centered solutions through the measurement of qualitative and quantitative resilience metrics that are assessed through the community lens. Effective vulnerability, risk, and resilience assessments do not exist independent of a decision-making framework, such as the adaptive management framework. Adaptive management is an iterative decision-making process that formalizes the qualitative social values (e.g. cultural, well-being) of a community given governing social constraints (e.g. economic resources, legislation) such that relevant management options can be quantitatively evaluated against each other such that system uncertainties are reduced. When paired with Bayesian network analysis, the assessment process within the adaptive management framework allows assessors and decision-makers to parameterize and operationalize system attributes and processes that affect stakeholder endpoints of concern/value. Bayesian network analysis is ideal for such research as it integrates data from diverse sources and probabilistically quantifies spatially explicit risk, thus supporting nuanced decision-making through scenario-based management options.

TP260 Bayesian network model for risk assessment based on fish embryo testing: A probabilistic weight-of-evidence approach

J. Moe, Norwegian Institute for Water Research (NIVA) / Section for Ecotoxicology and Risk Assessment; A. Lillicrap, NIVA / Environmental Toxicology; W.G. Landis, Western Washington University / Institute of Environmental Toxicology; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability; J.M. Rawlings, Procter and Gamble Company / Environmental Stewardship and Sustainability; R. Wolf, NIVA; A.L. Madsen, Hugin Expert

Reduction of animal testing wherever possible is requested by EU Directive on the protection of animals used for scientific purposes (2010/63/EU). Fish Embryo Toxicity (FET) testing can be an alternative to using juvenile fish in acute toxicity testing. However, FET data are currently not accepted as a replacement to juvenile fish acute toxicity data for regulatory purposes such as REACH, without sufficient weight of evidence (WoE). The development of a WoE approach for FET data has been recommended by the European Chemicals Agency to significantly reduce the number of animals required for hazard assessments of chemicals. We propose a Bayesian network (BN) modelling approach for quantifying the lines of evidence demonstrating the relationship between FET data and juvenile fish toxicity results. The purpose of the proposed BN model is to integrate information from large ecotoxicological and physico-chemical datasets, and apply it in a WoE approach to predict fish acute toxicity of chemicals from data on fish embryo toxicity testing in combination with other predictive information. The model has been developed from data on fish embryo and juvenile acute toxicity in combination with other information for more than 200 chemicals. The BN predicts the toxicity level of each chemical to juvenile fish by combining information in four pathways: (1) fish embryo toxicity, (2) physical and chemical properties, (3) toxicity to fish of other chemicals in the same category, and (4) toxicity to other species (algae and Daphnia). The conditional probability tables are quantified either by frequencies of observations or by expert judgement. The current version of the model predicts the correct toxicity interval for 65-80% of the tested chemicals, depending on the criteria for data quality. We aim to improve the model performance by training the model with a larger dataset and by identifying the chemical categories for which the model has high accuracy. This BN model can be used to assess the risk of various contaminants to fish based on fish embryo toxicity data in combination with other available information without the need to perform fish acute toxicity testing. The current version of the BN model has also been implemented as an online tool for testing and demonstration. More generally, this study demonstrates how a WoE approach for predicting risk to unmeasured endpoints can be quantified as a BN model.

TP261 Using structured decision-making-stakeholder engagement to integrate community values with scientific understanding for better decision-making

T. Canfield, B. Dyson, T. Richardson, J.F. Carriger, Jr., US Environmental Protection Agency / National Risk Management Research Laboratory

By the early 1970’s, the state of the environment in the United States had been degraded to the point that the public was raising greater concerns about litter and debris, contaminated waters, beach closures, rivers catching on fire, and deteriorating air quality to their elected officials demanding something be done to address these very visible environmental problems. With the creation of the USEPA, rapid progress was made to address and fix the most egregious and readily tractable environmental pollution problems. While it made sense to address these ‘low hanging fruit’ problems, in the background were many less easily defined (i.e. “wicked”) problems that needed addressing. Such problems were not readily solved by technical solutions and regulations alone due to inter-related socio-economic and environmental constraints. The multi-disciplinary nature of such problems necessitates methods and means to include community stakeholder values to inform management objectives and performance metrics, combined with technical/scientific expertise
for integrated assessment and evaluation of proposed solutions. DASEES (Decision Analysis for a Sustainable Environment, Economy and Society) is a web-based tool predicated on the precepts of decision analysis, aimed at enabling users to better formulate, assess, evaluate, and communicate issues, solution results and trade-offs to address complex problems. The DASEES user-interface provides a suite of tools for structuring and analyzing environmental management problems, that are accessible and understandable to a broad range of stakeholder expertise. DASEES is designed to capture stakeholder provided information and integrate scientific data and expertise, in a transparent and inclusive approach to develop and evaluate solutions. Alternative evaluation, (the stakeholder-derived valuation of data/science-driven metric assessments), is presented through 1) Consequence Tables suitable for more rapid screening evaluations where there is minimal uncertainty, and 2) Bayesian network evaluations where there may be more uncertainty and/or a need to better characterize important socio-ecosystem causal linkages to metrics.

Using Ecological Risk Assessment Frameworks to Determine the Risk of Marine Debris to Marine and Freshwater Ecosystems

**TP262 Alternative Approaches for Estimating Ecological and Human Health Risk of Exposure to Marine Plastics in Data Poor Regions**

B. Polidoro, Arizona State University / School of Mathematical and Natural Sciences; T. Lewis, E. Murphy, Arizona State University

Across the globe, macro and micro sized plastics are increasingly found in marine, freshwater, and terrestrial environments. As a consequence, plastic particles have been shown to incorporate into the food chain, as documented by their presence in humans and in a wide variety of aquatic organisms. However, standardized and/or comprehensive studies on the potential toxicological impacts or adverse outcomes associated with macro or micro plastic ingestion, or other forms of exposure, are widely lacking for the vast majority of species, including humans. As a result, it is difficult to apply a standard risk assessment framework. Based on current projects across the Pacific, two different approaches for estimating risk from ingestion of plastics are presented. In American Samoa, a more traditional, screening-level hazard quotient approach is being employed to estimate potential ecological and human health risks associated with consumption of seafood containing microplastics and other associated contaminants. In the Philippines, a macro and micro plastic assessment of relative risk is being conducted for more than 2,000 marine species, based on life history traits in combination with probability of exposure. Through presentation of preliminary results, the pros and cons of these two different approaches are discussed, including their relevance and application for assessing individual, population and ecosystem risks in data poor regions and developing nations.

**TP263 Risk From Microplastics Exposure To Blue Crab Larvae In Delaware Bay And Its Adjacent Coastal Shelf**

J. Cohen, T. Kukulka, A.o. Mason, A. Internicola, University of Delaware

Plastic marine debris is an emerging pollutant of concern both regionally and globally, with microplastics in particular receiving increasing attention. Microplastic marine debris may present serious hazards to individual marine organisms; however, the impact of microplastics at population, community, and ecosystem scales has yet to be systematically studied through risk analyses. Here, we present a risk assessment framework for understanding microplastics effects on an ecologically and commercially important species: the blue crab, Callinectes sapidus. We are using this approach to test whether microplastic marine debris exposure during larval development in the coastal ocean impacts blue crab survival and recruitment to mid-Atlantic estuaries. Our risk assessment framework includes: (1) determination of spatial and temporal distribution of both microplastics and C. sapidus zoae/megalopae in shelf water of the mid-Atlantic Bight based on a high-resolution hydrodynamic numerical model focusing on the region offshore of Delaware Bay, with field sampling for both microplastic and crab larvae guiding the modeling effort; (2) development of concentration-response functions for mortality and growth upon time-integrated microplastic exposure in C. sapidus zoae/megalopae in the laboratory; and (3) quantification of microplastic exposure risk to C. sapidus zoae/megalopae by analyzing microplastic exposure based on results from distribution modeling (1) and adverse responses functions (2). We are employing ecological risk models at the individual and population levels. This ecological risk assessment will result in a decision making tool for resource managers in the mid-Atlantic region currently evaluating the impact of microplastics on this economically and ecologically important species.

**TP264 Using the commercially valuable black sea bass (C. striata) as a model to assess the risk of microplastic pollution across multiple life stages**

C. Stienbarger, J. Joseph, University of North Carolina, Wilmington / Department of Biology and Marine Biology; S. Athey, University of Toronto / Earth Sciences; A. Andray, NC State University / Department of Chemical and Biomolecular Engineering; B. Monteleone, University of North Carolina, Wilmington / Department of Chemistry and Biochemistry; W. Watanabe, University of North Carolina, Wilmington / Center for Marine Science; A.R. Taylor, University of North Carolina, Wilmington / Department of Biology and Marine Biology; P. Seaton, University of North Carolina, Wilmington / Department of Chemistry and Biochemistry; S.M. Brander, Oregon State University / Environmental and Molecular Toxicology

Microplastics have emerged as a global threat to aquatic ecosystems. Coastal and estuarine waters that serve as critical habitats for commercially important fish species are susceptible to microplastic pollution due to their proximity to terrestrial inputs and tidal processes that provide favorable conditions for accumulation. As such, we explored the occurrence and effects of microplastic exposures on the commercially valuable black sea bass (Centropristis striata). Fish were exposed in the laboratory to virgin and contaminated microplastics across larval (10-14 dph), early juvenile (50-60 dph), and late juvenile (320-330 dph) life stages. Larval fish obtained more plastics from their prey, and juvenile fish from some treatments appeared to have a decrease in immune response and increased respiration at high plastic concentrations. Other measured effects of the laboratory microplastic exposures include condition index, hepatosomatic index, gene expression, and chemical desorption into fish tissues. Wild-caught adults were also analyzed to investigate the potential effects of microplastic ingestion on individual hepatosomatic index and condition factor. A major goal of this work was to examine the consequences of these individual-level exposures and effects on overall population dynamics. Thus, we used weight-of-evidence approaches to integrate data collected across different life stages, and also use empirical data supplemented with data from similar fish species to parameterize an integral projection model (IPM). This approach is commonly used in fishery stock assessments. We quantified the effects of exposures to a range of microplastic concentrations, accounting for both population persistence and population variability. Model predictions indicate that microplastic exposure may have longer-term effects on population variability. The projected effects will elucidate the degree to which microplastic pollution affects a commercially valuable species across several life stages, highlighting the need for more commercial fishes to be considered in risk assessment.
Site-Specific Risk Assessment of Soils Impacted by Petroleum Hydrocarbon Mixtures: State of Science and New Approaches

TP265 Developing Site-Specific Petroleum Hydrocarbon Guidelines for a Site in the Taiga Ecozone: Initial Research and Development Stages

L. Eastcott, Imperial Oil Limited / Environmental & Property Solutions

Imperial Oil is currently progressing remediation and reclamation at the Norman Wells operating field (the Site). Remediation work includes excavating soils to meet the Canadian Council of Ministers of the Environment (CCME) environmental quality guidelines. A large portion of petroleum hydrocarbon (PHC) affected soils are amenable to bioremediation, and where possible these soils are treated on-site biocells. However, in some cases the residual PHC Fraction (F3) concentration is the limiting factor, as concentrations remain above CCME eco-contact guidelines. There is some uncertainty around application of the CCME guidelines for eco-contact under Site conditions because of the manner in which they were derived. Toxicity testing was done using agronomic species and earthworms that are not native to or not present in subarctic areas where the Site is located. In addition, the toxicity testing was carried out with fresh crude oil or oil distillates, and not the specific PHC composition of weathered and/or biotreated soils. Thus, Imperial Oil has undertaken to develop Site-specific guidelines for the soil eco-contact pathway using toxicity testing under CCME protocols, which is an option within the regulatory framework of the Northwest Territories for management of contaminated sites. The intent is to assess the toxicity of Site soils to native plant species and a number of invertebrate species using conventional organism toxicity testing, and potentially reduce bioremediation times while providing the same level of protection. The process of developing these risk-based guidelines has involved a number of phases of Research & Development (R&D) work in collaboration with government and academic research teams. The work began with initial field surveys undertaken approximately 10 years ago to identify plants native to the region and to characterize plant root length and invertebrate communities and distributions with depth in soil at the Site. We will share results and lessons learned from the initial R&D stages, and summarize work that is currently ongoing.

TP266 Developing site-specific petroleum hydrocarbon (PHC) guidelines for a site in the Taiga Ecozone

A. Pang, Queen’s University / Environmental Studies; B. Zeeb, Royal Military College / Chemistry Chemical Engineering Dept; A. Rutter, Queen’s University / School of Environmental Studies

Current Canada-wide petroleum hydrocarbon guidelines are derived from toxicity tests using species commonly found in the temperate region, which may misrepresent actual risk scenarios in colder subarctic sites where these species do not reside. Additionally, the toxicity tests were performed using either fresh crude oil or specific sub-fractions of crude oil that do not accurately represent sites contaminated with weathered petroleum hydrocarbons (PHCs). Hence, generic Canada-wide guidelines may be too conservative for a site contaminated with weathered PHCs in subarctic areas and may lead to over-management of northern sites, with measures such as excessive excavation of site soils. Where site conditions significantly modify exposure and risk scenarios, the Canadian Council of the Minister of the Environment (CCME) allows for the derivation of site-specific PHC guidelines. Toxicity tests were conducted following Environment Canada’s biological test methods but with modified summer climate conditions (17°C for 20h Light / 14°C for 4h Dark) for five plant species and four soil invertebrates native to the subarctic ecoregion. For species not listed in Environment Canada’s test methods, similar test protocols were developed. Fine- and coarse-grained reference and contaminated soils were collected and homogenized for testing. Preliminary range-finding tests were conducted using dilutions of contaminated soil mixed with reference soil to determine a concentration range at which the plants and soil invertebrates are being affected. For plants, the endpoints evaluated were root and shoot length and percent emergence. Mortality rate and reproduction were evaluated for the soil invertebrates. Following the range-finding tests, definitive tests were conducted to verify results. The outcome of this research will assist in the derivation of site-specific PHC guidelines for the site in the subarctic ecoregion. Findings and evolving alternative toxicity tests will be discussed during the presentation.

TP267 Evaluating the effectiveness of select biomimetic passive sampling methods for estimating the toxicity of petroleum contamination in soils

R. S. Koster, Royal Military College; A. Rutter, Queen’s University / School of Environmental Studies; B. Zeeb, Royal Military College / Chemistry Chemical Engineering Dept

The derivation of site-specific remediation guidelines for contaminated sites often requires the use of labour-intensive and time-consuming toxicity tests using indicator organisms. The toxicity of petroleum hydrocarbon (PHC) contamination to soil-dwelling invertebrates has been correlated to the bioaccessible fraction of the hydrocarbon mixtures dissolved in soil pore water. Chemical analytical methods that mimic biological uptake (biomimetic methods) of contaminants from soil pore water can be used to estimate the toxicity to organisms without the need for costly toxicity testing. A selection of biomimetic passive sampling methods, including polyoxymethylene (POM) and solid-phase microextraction (SPME) were compared using contaminated field soils of various concentrations. The test soils for this comparison were characterized using standard chemical extraction methods for total PHCs and individual constituents (e.g. volatile organic compounds, and alkyl/aryle-polyaromatic hydrocarbons) as well as total organic carbon, which is known to affect bioaccessibility. The selected passive sampling methods will be used to determine the bioaccessible soil pore water concentrations of total PHCs and individual compounds known to contribute substantially to the toxicity of PHC mixtures such as alkyl- and oxy-polyaromatic hydrocarbons. Each passive sampling method will be evaluated based on consistency, time commitment, resource use, labour requirements, and correlation to toxicological results from concurrent studies. Preliminary results will be discussed in the presentation.

TP268 Acute Toxicity of Water Accommodated Fractions (WAFs) of three Nigerian Crude Oils to Clarias gariepinus (Burchell, 1822)

H. Omogoriola, Nigerian Institute for Oceanography and Marine Research / Fishery Resources

Oil industry activities such as exploration, transportation, storage, use and disposal, as well as oil spills are sources of major contamination problems in Niger Delta, which have significant deleterious effects on aquatic organisms. The objective of this study was to report LC50 values obtained from acute toxicity tests on the African Catfish, C. gariepinus exposed to Water Accommodated Fraction (WAF) -heavy (Ebo), light (Meji) and medium (Erha) crude oils. Acute toxicity concentrations of 0%, 2%, 4%, 6% and 8%, 0%, 15%, 20%, 25% and 30% and 0%, 40%, 60%, 80% and 100% were used to determine the 96h Lethal Concentration (LC50) of heavy, light and medium crude oils respectively. The analysis of variance (ANOVA) showed that there was a significant (p<0.05) differences in the quantal response of C. gariepinus to different concentrations of the various crude oil types at 24, 48, 72 and 96 hours exposure. These results showed that 96LC50 values for heavy, light and medium crude oils on C. gariepinus were 0.028 mg TPH/1, 0.177 mg TPH/1 and 0.742 mg TPH/1 respectively. The 96LC50 of WAF showed that the heavy crude oil was six times more toxic than light and twenty six times more toxic than medium and on toxicity categorization, the heavy, light and medium crude oils were very highly toxic, highly toxic and highly toxic on C. gariepinus. Based on the acute toxicity tests, heavy with lower API (< 22.30C) gravity was more toxic than other crude oils on C. gariepinus. All crude oils are toxic to aquatic organisms especially the fish; their discharge into the water bodies during crude oil exploration, transportation, storage and even sabotage should be discouraged to protect the environment.
TP269 Organic carbon normalization and relevance of species assemblages for soil ecological risk assessments of petroleum hydrocarbon-contaminated soils

A. Gainer, SNC-Lavalin / Soil Science, Toxicology; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; K.E. Bresee, Intrinsic Corp.; S. Siciliano, University of Saskatchewan / Department of Soil Science

Sediment toxicity studies and ecological risk assessments on organic contaminants routinely apply organic carbon normalization to toxicity data; however, no studies examine its potential for use in soils with petroleum hydrocarbon (PHC) contamination. Limited studies in soil ecotoxicology assess the influence of species assemblages used in species sensitivity distribution curves provided influenced more by soil cation exchange capacity. Incorporating organic carbon into species sensitivity distribution curves provided a higher level of protection to soil dwelling receptors in low organic carbon normalization into species sensitivity distribution curves provided influenced more by soil cation exchange capacity. Incorporating organic carbon normalization into species sensitivity distribution curves provided a higher level of protection to soil dwelling receptors in low organic matter soils as well as reduce the variability of PHC soil toxicity data. Soil remediation guidelines derived for protection of soil dwelling organisms using a diverse species assemblage provided similar levels of protection as guidelines developed with test species specific for remote, forested land uses in Canada. We conclude that: (i) Canadian hazard concentration values for PHC contamination of soils should be revisited as they may not be protective and (ii) that soil PHC guidelines for protection of soil dwelling organisms should be expressed as carbon normalized values.

TP271 Post clean-up analysis of crude oil contaminated agricultural soil at Emede Isoko south local government of Delta state, Nigeria

A.O. Orgukevede, Federal University of Petroleum Resources / Environmental Management and Toxicology; A.A. Adedayo, Federal University of Petroleum Resources Effurun Nigeria / Environmental Management & Toxicology

Emede community in Isoko South local government of Delta state, Nigeria has had a fair share of oil spillage from pipeline leakage. After many years of clean-up by the multinational oil company that owns the pipeline, crude oil is visible on the soil surface of the agricultural area. Hence, the major farm products (cassava and maize) from the farmlands or grazing of goats on plants are of serious concern. This research seeks to examine the concentration of the petroleum hydrocarbon in the soil and Cyperus rotundus (Nutgrass) (indigenous plant on the farmland) at uncultivated farmland in Emede town. Four sampling points were picked at random based on the dark grey colour intensity of the soil surfaces. The surface soil (0 - 15 cm) and subsoil samples (15 cm - 30 cm) were collected using soil auger at same sampling points where Cyperus rotundus were picked. The soils analysed for the following parameters: pH, total organic soil and total petroleum hydrocarbons (TPHs), while TPHs is the only parameter analysed in plants samples. The results of soils sample revealed that the values of TOC ranges from 13.26 ± 1.21 to 19.23 ± 1.21 for surface soil and subsoil samples were 18.13 ± 1.30 to 22.11 ± 4.20. The gas chromatograph-flame ionisation detector (GC-FID) result of the surface soils TPH ranges from 7463.62 ± 8.26 to 37201.30 ± 4.47 mg/kg while subsoil 32368.31 ± 5.32 to 81115.36 ± 48.21 mg/kg. The shoot samples result ranges from TPH 2866.23 ± 5.75 to 15636.52 ± 2.78 mg/kg, and roots values were 1915.06 ± 4.47 to 51448.80 ± 2.78 mg/kg. These soil TPH results were higher than the intervention limit of 5000mg/kg set by the Department of Petroleum Resources (DPR). The nut grass results were very high, and they can find their way into the food chain through goats (common animal within the community) grazing on them. Crude oil contains benzene and toluene that can cause aplastic anaemia, acute leukaemia, bone marrow abnormalities, DNA strand breaks, nausea, weakness, confusion, and at high doses leads to unconsciousness and even death. It further contains 32 polycyclic aromatic hydrocarbons, which includes benzo(b) fluoranthene that is carcinogenic. The cassava tuber products may be harmful to Emede people because it can absorb crude oil. This research revealed that the agricultural area requires urgent remediation.

Pesticides and Pollinators: Assessing Potential Risks at Colony and Population Level

TP272 Pollinator Research Task Force: Overview of Accomplishments and Upcoming Projects

V.J. Kramer, Corteva Agriscience / Ecotoxicology; B. Sharma, FMC Corporation / Global Regulatory Sciences

Research on pollinators is an active area of scientific inquiry. However, there is a paucity of research devoted to improving the fundamental aspects of pesticide risk assessment for pollinators. The Pollinator Research Task Force (PRTF) was formed in 2015 by a group of US pesticide registrants to facilitate improvement in pollinator risk assessment paradigm jointly created in 2014 by the United States Environmental Protection Agency (USEPA), Health Canada Pest Management Regulatory Agency and the California Department of Pesticide Regulation. The research projects conducted by the PRTF are developed in collaboration with the USEPA insuring relevancy to pollinator risk assessment needs in the United States, while remaining cognizant of and generally applicable to regulatory issues regarding pollinators globally. This presentation will summarize completed, ongoing and planned PRTF projects. Completed and published projects include: a ring-test of improvements to the honey bee larval repeat-dose test methodology, a literature survey and analysis of the relevance of guttation water as a potential source of pesticide exposure to honey bees, and; results of an international workshop on non-Apis exposure pathways. Completed projects that are in the manuscript submission/review phase include: a literature review and analysis of honey bee colony-level consumption of pollen and nectar and of nectar consumption by nectar foragers particularly; Monte Carlo model development and evaluation of nectar consumption by honey bee nectar foragers, and; a literature review and analysis of pesticide active ingredient acute toxicity to honey bees compared to formulated product toxicity. PRTF projects that are in progress include: evaluation of the BEEHAVE model parameterized to North American conditions for prediction of over-wintering survival of honey bee colonies; refinement, standardization and ring-test of the “Toxicity of Residues on Foliage: RT25 Test;” and laboratory evaluation of alternative solvents for use in honey bee larval tests. Outlines for future research projects will also be presented.

TP273 Honey bee risk assessment: Are two larval studies better than one (2019 update)?

M.A. Feken, Syngenta / Ecological Risk Assessment; S. Hinarejos, Sumitomo Chemical Agro Europe / AgroSolutions Division International; R. Hummel, Landis International Inc.; V.J. Kramer, Dow Agro Sciences LLC / Ecotoxicology; B. Neill, DuPont Crop Protection; D. Schmelch, Bayer Crop Science; R. Singh, BASF Corporation / Ecotoxicology

After the publication of the Guidance for Assessing Pesticide Risk to Bees (USEPA, PMRA, CDPR 2014), USEPA began requesting a suite of honey bee Tier 1 laboratory toxicity studies to support registration and the registration review process of new and currently registered crop protection chemicals, respectively, including the 8-day acute, single exposure and the 22-day chronic, repeat exposure larval toxicity studies. For the acute larval study design (OECD Test Guideline 237), the primary goal is to determine the LD50/LC50 following a single exposure to a test chemical (on Day 4) and mortalities are evaluated on days 5-8 of the larval developmental phase. In contrast, in the 22-day chronic larval study design (OECD Guideline No. 239), honey bee larvae are exposed to the test
chemical on Days 3-6 with mortality recorded on Days 4-8 during the larval phase, on Day 15 during the pupae phase, and on Day 22 during adult emergence. Given the 22-day larval study design covers all phases of honey bee brood development up to adult emergence and the larval endpoints LD$_{50}$/LC$_{50}$ can be calculated, the European Food Safety Authority (EFSA) only requires the 22-day larval study to derive larval endpoints for their bee risk assessments. However, USEPA requires the acute, single exposure study to calculate a dose-based endpoint (i.e., LD$_{50}$) that can be incorporated into the current screening-level risk assessment model (i.e., BeeREX). In 2018, a preliminary review of LD$_{50}$/LC$_{50}$ endpoints from both study designs indicated that similar endpoints (< 2x difference) are derived based on dose (i.e., LD$_{50}$) for both study types but lower endpoints (greater sensitivity) are typically derived in the repeat exposure design when based on concentration (LC$_{50}$). Likewise, converted daily dose (e.g., LDD$_{50}$) endpoints from the repeat exposure designs are often lower (40% where >2x lower) than single exposure endpoints. Additional data (approximately 50 studies total) have been incorporated into this most recent evaluation to further corroborate or refute our previous finding. If confirmed, we propose that the acute, single exposure study design should not be required considering the 22-day larval study provides the necessary larval endpoints required for Tier 1 bee risk assessments.

**TP274 The utility of a weight-at-emergence endpoint in the 22-day larval assay for a pollinator risk assessment**

B. Sharma, FMC Corporation / Global Regulatory Sciences; D. Schmehl, Bayer Crop Science; J. Collins, F. Abi-Akar, Waterborne Environmental Inc

USEPA has identified the 22-day honey bee larval assay as a Tier 1, screening-level toxicity study for assessing pesticide risk to bees. This repeat-dose larval study is based on the Organization for Economic Co-operation and Development Guidance Document 239, and methodology provided by Schmehl et al.(2016). During this study, first instar larvae are transferred from healthy colonies to grafting cells (day 1) and treated diet is administered between days 3 and 6. Survival is assessed at multiple stages of the test: daily between days 4 and 8 for larvae; day 15 for pupae; and day 22 (emergence time) for adults. However, at the request of the USEPA, adult weight at emergence has also been included as a study endpoint. The Pollinator Research Task Force (PRTF) is conducting an endpoint evaluation to compare the sensitivity of adult weight at emergence to that of the survival endpoint in this study design. A database was developed based on anonymized study data from PRTF member companies, as well as applicable studies from the open literature. The compiled data were evaluated both empirically and statistically with regard to endpoint sensitivity. Statistically significant effects based on survival and adult weight at emergence were compared. No- and Lowest-Observed-Effect Dose (NOED and LOED) values, as well as 50% lethal and effect dose (LD$_{50}$ and ED$_{50}$) values were also compared between the endpoints. Coefficients of variation (CVs) were compared graphically and statistically to quantify the variability in each metric and determine significant differences. A pairing structure was also used to assess correlation, which could be graphed and statistically analyzed. This presentation outlines the methods used during this project, the results of the endpoint analyses, and concluding findings on the endpoint sensitivity comparison between survival and adult weight at emergence.

**TP275 Comparisons of Neonicotinoid Residue Data When Considering Potential Exposures to Pollinators**

Historically, data has been sparsely available to quantify the concentrations ("residues") of pesticides in food matrices relevant to honey bees, (i.e., pollen and nectar). As part of the registration review of the nitroguanidine-substituted neonicotinoid insecticides (imidacloprid, clothianidin, thiamethoxam, and dinofuran), registrants submitted data to the U.S. Environmental Protection Agency (EPA) on neonicotinoid concentrations in pollen and nectar for a variety of crops and application methods. Registrants also submitted data for other matrices that could potentially be used as surrogates for pollen and nectar (e.g., anthers, flowers). Each neonicotinoid active ingredient has its own set of registered crops and corresponding rates and methods, leading to many possible chemical-crop-application scenarios to consider when assessing potential honey bee exposures. To understand potential influences of geographic location on residues, studies for the same crop and application scenario were carried out at multiple locations. Since residue data were not available for every crop and application scenario registered for a single neonicotinoid, EPA analyzed residues for the same chemical and application method to determine potential bridging among crops (i.e., whether residues in floral matrices of one or more crops are suitable surrogates for an entire crop group). In addition, EPA analyzed residues for the same crop and application method (e.g., foliar applications to cotton) among different neonicotinoids to determine the potential for bridging across neonicotinoids. We summarize the available residue data, provide comparisons across chemicals and crops, and describe the scientific justification for extrapolating residue data among neonicotinoids, crops, and plant matrices when assessing risks to bees.

**TP276 Quantifying insect pollinator exposure and effects from pesticides for risk and impact assessment**

E. Crenna, European Commission - Joint Research Centre / Directorate D - Sustainable Resources, Bioeconomy Unit; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division; O. Jolliet, University of Michigan

Pollinator populations are suffering significant declines worldwide. The use of agricultural pesticides has been identified as one of the main contributing causes. The impact pathway associated with pollinators' exposure to pesticides, however, is currently missing in various assessment frameworks, including comparative risk screening and life cycle impact assessment (LCIA) to characterize various impacts contributing to damages on humans, ecosystems and natural resources associated with product and service life cycles. To address this gap, we developed a model to quantify field exposure of honey bees—chosen as most relevant pollinator species—to pesticides and related potential ecotoxicity impacts. As exposure metrics, we defined bee intake and dermal contact fractions for oral and dermal exposure, respectively. We tested our model to characterize bee impacts of two pesticides, namely lambda-cyhalothrin (insecticide) and boscalid (fungicide) applied to oilseed rape. We observed that dermal contact and oral intake fractions vary according to the specific type of forager honey bees, with the highest dermal contact fraction of 1.27x10^-5 kg dermal contact/kg applied found in pollen foragers for the fungicide boscalid, and the highest intake fractions of 3.21x10^-5 and 1.90 x10^-5 kg oral intake/kg applied found in nectar foragers for both boscalid and lambda-cyhalothrin respectively. Hive oral exposure fraction is higher than forager oral exposure fractions in both pesticides. For boscalid it is 7.4 to more than 100 times higher, while for lambda cyhalothrin it is 2.1 to 32.4 times higher than the intake fraction of foragers. We observed a higher impact of the insecticide, being the impact score two orders of magnitude higher compared with the fungicide, and the impact per unit application three orders of magnitude higher. Overall, nectar foragers are the most affected forager type for both pesticides, emphasizing the oral pathway dominating overall bee exposure. Considering the in-hive exposure, CFs for hive bees are up to two orders of magnitude higher than CFs of foragers for boscalid, and at least twice the CF of foragers for lambda-cyhalothrin. This is based on the assumption of the same toxicity between adults and larvae. This model and the calculation of bee intake fraction constitutes an important first step toward integrating pollinator impacts in risk screening and LCIA, whereas we also identified areas of further model refinement to fully operationalize our approach in comparative frameworks where quantifying impacts on pollinators is relevant.
TP277 Assessing the uptake of pesticides from soil by ground-nesting solitary bees
S. Rondeau, D. Willis Chan, N. Raine, University of Guelph / School of Environmental Sciences

Risk assessments of the impacts of pesticide exposure are currently only tested on social honeybees as the model pollinator species. However, honeybees are atypical of most bee species in their ecology and life history and may be more resilient to pesticide exposure than solitary bees. While research on the impact of pesticides on pollinators typically focusses on the consumption of contaminated pollen and nectar, exposure may also occur via nesting materials and sites, such as leaves, wood or mud. As more than 70% of all bee species nest underground, prolonged contact with contaminated soil may represent an important yet overlooked route of pesticide exposure. While female ground-nesting bees are repeatedly exposed to soil during nest excavation and maintenance, larval stages experience long-term contact exposure as they develop underground. In most ground-nesting bee species, however, the nest cells in which bees develop are thought to be lined with a water-resistant lining that may reduce larval exposure to pesticide residues from soil. The extent to which these linings actually prevent exposure is an important research gap to be addressed. Here we report results from a new method developed in our laboratory to study squash bees (Peponapis pruinosa) under ecologically-realistic conditions used for the first time to evaluate the uptake of three widely used pesticides (imidacloprid, boscalid, difenoconazole) by adult female and developing larvae of this agriculturally important ground-nesting solitary bee. Mated female squash bees were introduced into mini hoop houses (meshed enclosures) containing zucchini plants as sources of pollen and nectar. Bees were allowed to nest in contaminated or uncontaminated bare soil. Samples of bees (adults and larvae) and soil were then analyzed for pesticide residues, allowing us to calculate an uptake factor for each pesticide. We predict uptake will occur for all pesticides tested, with a positive correlation between uptake levels and pesticide lipophilicity. These results will allow us to determine whether pesticide residues in soil can be taken up by the most vulnerable developmental stages of ground-nesting bees, and the extent to which residues can accumulate in bees. Our semi-field exposure paradigm represents a valuable addition to the field of bee ecotoxicology research, by providing a novel tool to study ground-nesting bees under semi-controlled, yet environmentally-realistic, conditions.

TP278 Nest bundles used to characterize agrochemical exposure to native pollinators near cattle feed yards and row crop agriculture
E. Peterson, Texas Tech University / Environmental Toxicology; C. Tomlinson, Texas Tech University / Plant and Soil Science; P.N. Smith, Texas Tech University / Environmental Toxicology

Insect pollinators are declining worldwide due to a variety of factors such as habitat loss, disease, non-native species, and pesticides. However, knowledge of specific agrochemicals present in the environment is still incomplete. Beef cattle feed yards and row crop agriculture are the foremost agrochemical end-users in the Southern High Plains of the United States. In an effort to characterize agrochemicals availability in this region and potential risk to pollinators, phragmites reed nest bundles were deployed alongside beef cattle feed yard boundaries and row crop agriculture. Nest bundles were installed prior to pollinator emergence in February and collected in November, to span an entire field season. Reeds were opened to determine which cavity nesting insect species were present and reed cell matrices (mus, feces, leaves, pollen, and larvae) were analyzed via liquid chromatography mass spectrometer for agrochemicals commonly used in this ecoregion. Initial screening of reed matrices revealed a variety of agrochemicals including thiamethoxam, imidacloprid, clothianidin, dicrotophos, diazinon, malathion, ivermectin, and boscalid. Over 60% of mud caps and larvae from reeds located near feed yards contained agrochemical concentrations above the limit of detection. Native bee monitoring strategies like that used in this study may allow for more accurate determination of agrochemical distributions in the environment and enhance assessment of risk among native pollinators.

TP279 A semi-field tunnel study using the common eastern bumble bee (Bombus impatiens)
L. Richardson, J. Hanzas, Stone Environmental, Inc. / Agrochemical Fate and Exposure; S. Perez, Adpen Laboratories, Inc.

Ecological risk assessment is a key component of the regulatory process required for registration of crop protection products in the US and elsewhere. The western honey bee (Apis mellifera) is the established test organism for assessing pesticide exposure risk to pollinating bees, yet there is concern that it is not a suitable surrogate for other bees in all circumstances. Accordingly, efforts are underway in Europe to adapt honey bee test methodologies for two types of native bees, bumble bees and mason bees. The buff-tailed bumble bee (Bombus terrestris), a test species in Europe, may not be imported to North America, meaning that such risk assessment studies will have to be conducted here using a species native to the area, the common eastern bumble bee (B. impatiens). To address this need, in 2019 we are conducting a higher-tier field study with B. impatiens. Adapting semi-field study guidelines for honey bees (e.g., EPPO 170 and OECD 75) and benefiting from similar work with B. terrestris in Europe, we grew 3 hectares of the bee-attractive plant curly phacelia (Phacelia tanacetifolia) on a Vermont, USA farm. We constructed 18 caterpillar tunnels, each 60 m², above the crop, and at the onset of flowering, introduced one commercial B. impatiens colony to each tunnel. Six replicate tunnels were randomly assigned to each of three treatments: a negative control where plants were sprayed only with water, and low and high concentration applications of the insecticide dimethoate. Following applications made with a handheld spray boom, analytical samples will be collected to verify application rates, nectar and pollen residues, and realized dietary exposure to bees. After 14 days of confinement to tunnels, all colonies will be moved outside to forage on untreated floral resources. The primary endpoint to be quantified is number and mass of new gynes (queens) produced by colonies. In addition, we are collecting data on production of male offspring, worker mortality, foraging behavior, and colony growth. Our work is novel in that it is the first fully-replicated semi-field tunnel study to be conducted using B. impatiens, a key component of future risk assessment research for non-Apis bees in North America. We anticipate that our methods and results can guide future efforts to develop a standard test paradigm to assess risk of crop protection products to bumble bees.

Understanding Risks from Exposures to Per- and Polyfluoroalkyl Substances (PFAS)

TP280 A Framework for Assessing Bioaccumulation and Exposure Risks of Per- and Polyfluoroalkyl Substances in Threatened and Endangered Species
B.C. Kelly, Simon Fraser University / Civil & Environmental Engineering; F. Gobas, Simon Fraser University / Resource & Environmental Management

For several decades, the U.S. Department of Defense (DoD) widely used aqueous film forming foams (AFFF) formulations for training and operations related to fire suppression. These AFFF formulations contained relative high quantities of perfluorooctane sulfonate (PFOS), as well a range of other of per- and poly-fluoroalkyl substances (PFAS). The objective of the present study is to develop a framework for conducting scientifically sound risk assessments for PFAS in T&E species at these sites. The study involved (i) a comprehensive literature review of physical-chemical properties, bioaccumulation metrics and environmental concentrations, (ii) development of a risk assessment framework for assessing PFAS bioaccumulation and exposure risks in T&E species and (iii) application of the proposed framework to select AFFF-impacted DoD sites. The proposed approach utilizes a combination of field-based
measurements and bioaccumulation modeling to evaluate exposure in T&E species. Toxicity reference values (TRVs) are derived from conventional toxicity assay data for surrogate test species, as well as in vitro assay data (e.g., ToxCast assays). A chemical activity-based approach is utilized for exposure and effects characterization, where chemical activity (a, unitless) in a given medium is determined as the ratio of the concentration (C, mol/m³) and the corresponding solubility (S, mol/m³) of the chemical for a given phase or compartment (i.e., a = C/S). T&E species with habitat ranges overlapping AFFF-impacted DoD sites included the Bog Turtle (Clemmys muhlenbergii), Northern Long-Eared Bat (Myotis septentrionalis), Red-cockaded Woodpecker (Picoides borealis) and E. Massasauga Rattlesnake (Sistrurus catenatus). For sites with relatively high PFAS concentrations risk quotients (RQs) of PFOS for T&E species often exceeded 1. For sites with relatively low concentrations, RQs of PFOS for T&E species were generally well below 1. Omnivorous and carnivorous birds, mammals and reptiles are shown to exhibit a higher degree of PFAS bioaccumulation and hence exposure risk, compared to aquatic organisms at a given site. Lastly, key uncertainties and knowledge gaps related to bioaccumulation behavior and exposure assessment of PFAS will be highlighted and discussed. This study will help guide future research efforts and risk assessment initiatives related to exposure of legacy PFAS in T&E species at AFFF-impacted sites.

**TP281 Assessing the effect of Per- and Polyfluoroalkyl Substances on the expression of epigenetic machinery-associated genes in the placenta**

*J.T. Bangma, UNC Chapel Hill / Marine Biomedicine and Environmental Sciences; J. Szilagyi, C. Meakin, University of North Carolina at Chapel Hill / Environmental Science and Engineering; J. Reiner, National Institute of Standards and Technology; T. Manuck, University of North Carolina / OB/GYN; R.C. Fry, University of North Carolina at Chapel Hill / Environmental Science and Engineering*

Per- and poly-fluoroalkyl substances (PFAS) are a group of chemicals that have been widely used in stain repellents, paints, protective coatings, and firefighting foams. While some of these chemicals, including perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), have been discontinued in the United States, their persistence in the environment and continued use internationally make them a toxicological concern. Moreover, hexafluoropropylene oxide dimer acid (HFPO-DA, ammonium salt with trade name: GenX), a modern replacement for PFOA, and continued use internationally make them a toxicological concern. As demonstrated with 8:2 fluorotelomer alcohol (FTOH), these intermediates can form covalent adducts with cellular proteins. Consequently, identifying the protein targets of these compounds is paramount to elucidating their toxic mechanisms of action. To this end, we have developed a proteomics method for the identification of proteins covalently modified by PFAS. Our method combines solid phase fluoruous separation (FSPE) and a modified nanoliquid chromatography gradient with existing proteomics infrastructure for the identification of targets via high-resolution mass spectrometry-based shotgun proteomics. When applied to the analysis of tryptic bovine serum albumin peptides modified with a cysteine reaction fluoruous tag, our FSPE enrichment enables a 30% increase in the number of identified fluoruous-modified peptides. Likewise, our modified proteomics gradient was able to compensate for the increased hydrophobicity of fluoruous-modified peptides and we report a two-fold increase in detected fluoruous-modified peptides over traditional proteomics gradients. We then applied our method to investigate the protein targets of 8:2 FTOH in rat liver S9 fractions. As our described methodology can only enrich PFAS-modified peptides, we combine the downstream analysis with a traditional proteomics analysis of the unmodified flow-through fraction to identify 8:2 FTOH adducts at both the peptide and protein levels. Our developed method will help to better understand the toxic mechanism of 8:2 FTOH. Lastly, we will discuss our plans to identify PFAS with structurally unknown peptide modifications for a better understanding of the toxic mechanisms of action for numerous, structurally varied, PFAS.

**TP282 Development of a Chemical Proteomics Method for the Enrichment and Identification of Poly- and Per-Fluorinated Covalently Modified Proteins**

*D. Hall, J. Han, S. Joudan, H. Peng, University of Toronto / Department of Chemistry*

Per- and poly-fluoroalkyl substances (PFAS) are not only environmentally ubiquitous and capable of significant bioaccumulation, but can often undergo biotransformations into more reactive, and toxic, intermediates. As demonstrated with 8:2 fluorotelomer alcohol (FTOH), these intermediates can form covalent adducts with cellular proteins. Consequently, identifying the protein targets of these compounds is paramount to elucidating their toxic mechanisms of action. To this end, we have developed a proteomics method for the identification of proteins covalently modified by PFAS. Our method combines solid phase fluoruous separation (FSPE) and a modified nanoliquid chromatography gradient with existing proteomics infrastructure for the identification of targets via high-resolution mass spectrometry-based shotgun proteomics. When applied to the analysis of tryptic bovine serum albumin peptides modified with a cysteine reaction fluoruous tag, our FSPE enrichment enables a 30% increase in the number of identified fluoruous-modified peptides. Likewise, our modified proteomics gradient was able to compensate for the increased hydrophobicity of fluoruous-modified peptides and we report a two-fold increase in detected fluoruous-modified peptides over traditional proteomics gradients. We then applied our method to investigate the protein targets of 8:2 FTOH in rat liver S9 fractions. Our developed method will help to better understand the toxic mechanism of 8:2 FTOH. Lastly, we will discuss our plans to identify PFAS with structurally unknown peptide modifications for a better understanding of the toxic mechanisms of action for numerous, structurally varied, PFAS.

**TP283 PFOA induces liver and serum dyslipidemia in a humanized PPARα mouse model fed an American diet: A risk assessment relevant model**

*W. Heiger-Bernays, T.F. Webster, Boston University / Dept Environmental Health; T. Hyytyläinen, Orebro University; C. Boston, J.J. Schlezinger, Boston University School of Public Health / Department of Environmental Health*

Americans are exposed daily to mixtures of perfluoroalkylated substances (PFAS) in their drinking water, food, air, dust in their homes, and direct use of consumer products. Increased concentrations of serum total cholesterol and low density lipoprotein cholesterol (LDL-C) are among the best supported outcomes by epidemiology studies. Dyslipidemia (elevated tri-glycerides, decreased high density lipoprotein cholesterol) and increased serum LDL-C are major contributors to cardiovascular disease, the leading cause of mortality in the US. Despite evidence that human PFAS exposure is associated with dyslipidemia, these effects of PFAS have received little focus as a basis for risk assessment, largely due to the lack of a suitable animal model. Notably, the European Food Safety Authority has proposed Tolerable Daily Intakes for PFAS based on epidemiological data. Mechanisms by which PFAS cause lipid-disrupting metabolic effects are not well understood, but given their structural similarity to fatty acids, interaction with human peroxisome proliferator activated receptor α (PPARα) is a logical molecular initiating event. PPARα is an essential mediator of cholesterol and lipid homeostasis. Moreover, polymorphisms in human PPARα are associated with changes in serum cholesterol. Thus, PPAR activation is relevant and important as a likely PFAS mechanism of action. Humanized PPARα mice were exposed to PFOA in drinking
water (8 µM) for 6 weeks and fed a custom diet based on “What we eat in America.” Serum was analyzed for ALT by activity assay, triglycerides by UHPLC/QTFMS, and cholesterol by enzymatic assay. Liver was collected, weighed and analyzed for triglycerides by chemical conversion to glycerol. Liver lipidome was analyzed by UHPLC/QTFMS. Liver mRNA expression was determined by RT-qPCR. Perfluorooctanoic acid (PFOA) exposure in drinking water (8 µM) for 6 weeks resulted in a serum PFOA concentration of 78.8 ± 5.4 µg/ml, a level approximately 4-fold higher than serum levels found in fluorochemical workers. PFOA exposure increased liver mass, increased lipid content, perturbed the lipidome and induced PPARα target gene expression. PFOA increased serum triglycerides and total cholesterol, while also perturbing the serum lipidome. Sex-dependent effects were evident. A literature-based analysis of effects of PFOA on serum triglyceride and cholesterol across multiple mouse models suggests a non-monotonic dose response. The humanized PPARα mouse model fed an American diet is an important new model for examining PFAS-induced dyslipidemia to prioritize PFAS of concern for human risk assessment.

**TP284 PFOA Physically Targets >500 Lipid-Interacting Proteins as Revealed by Chemical Proteomics**

*J. Sun, H. Peng, University of Toronto / Department of Chemistry*

Perfluorooctanoic acid (PFOA) has been reported to induce diverse toxicities such as lipid homeostasis. While several potential protein targets of PFOA including peroxisome proliferator-activated receptor alpha (PPARα) have been reported, but the vast majority toxicities of PFOA was found to be mediated via PPARα-independent pathways. In this study, a chemical proteomics method was developed to identify the protein targets of PFOA by employing photo-reactive palmitic acid probe. >500 lipid-interacting proteins were detected by quantitative proteomics, by spiking lipid probe to HepG2 and HEK293 cell lines, two major bioaccumulation organs for PFOA. In-gel fluorescence was adopted to characterize the protein targets of PFOA, and dose-dependent (30, 160, 800 µM) competition was observed. Particularly, all >500 lipid-interacting proteins were competed by PFOA at the highest concentration (800 µM). Quantitative proteomics was performed on two lower concentrations, and >100 proteins were physically targeted by PFOA at medium concentration (160 µM), while only ~20 proteins were targeted at low concentration (30 µM). The proteins targeted at low concentration were enriched in several pathways including mitochondria fatty acid beta-oxidation. Several proteins including acetyl-coenzyme A synthetase were purified in E. coli and their interactions with PFOA were validated by thermal stability assay. This study reported, for the first time, that PFOA could physically target hundreds of proteins, which provides an important mechanistic basis to understand their toxicities. The unbiased method also provides a unique opportunity to investigate the potential toxicities of other PFAS such as PFOA/PFOS replacements.

**TP285 Polymeric PFAS: Advances in Toxicology, Grouping Criteria, Essential Uses and Alternatives Assessment**

*S. Korzeniowski, BEC; J. Bowman, FluoroCouncil*

Per- and polyfluoroalkyl substances (PFAS) is a term that describes a wide and diverse array of chemistry containing carbon and fluorine. It is noteworthy that the chemistry and properties are vastly different across the various PFAS categories and classes. The primary focus of this presentation will be on polymeric PFAS including both fluoropolymers and side-chain fluorotelomer-based polymers. We will describe why fluoropolymers should be regarded as polymers of low concern and provide clear compelling examples of essential uses. Moreover, robust criteria for PFAS grouping will be proposed and discussed considering mode of action, potential for toxicity, critical toxicological endpoints, human and animal half lives, bioavailability, bioaccumulation and biomagnification. Recent advances pertaining to side-chain fluorotelomer-based polymers will be described including degradation, toxicity, fate, transport and water treatment. This presentation will summarize a number of these critical and significant advances and present the results in the context of the overall risk in using the subject fluoropolymer-based products. In addition, we will discuss decision criteria to help in the assessment of alternatives (risk vs. exposure vs. hazard vs. precaution), as well as the true value-in-use including some critical end use examples. The decision criteria will include persistence, mobility, end-use need (concept of essential use), function, precaution, toxicity, performance and emission control amongst the various elements.

**TP286 Machine learning approaches to inform classification of toxic impacts of diverse PFASs**

*W. Cheng, University of Pittsburgh; C.A. Ng, University of Pittsburgh / Civil & Environmental Engineering*

Recent estimates of the diversity of per- and polyfluoroalkyl substances (PFAS) suggest more than 4700 different substances and technical mixtures may have been used in processes and products, potentially resulting in environmental release and human and wildlife exposure. As the extent of environmental contamination with PFAS becomes apparent, the lack of available data on the properties and potential toxic impacts of the vast majority of these substances is a major concern to scientists, regulators, and impacted communities. At the same time, high throughput screening (HTS) has become increasingly common in risk assessment for chemicals used in a wide variety of products and applications. As a consequence, databases of HTS data for chemicals are growing in scope and coverage of the universe of chemicals. In this study, we seek to exploit existing chemical hazard classification databases to develop machine learning based models for PFAS effects. In this talk, we will first present an analysis of coverage of PFAS chemicals in two important chemical activity databases: the PubChem Bioassay database (PCBA), and the EPA’s ToxCast database. First, we evaluate the number of fluorinated substances (containing at least one CF2 group) present in PCBA and ToxCast, as well as all substances that fall under the definitions of PFASs set out in OECD’s 2018 report. We then assess the overlap between the PFAS found in the OECD database (the subset of the 4730 substances for which a SMILES code could be found or defined). Finally, we use the fluorinated substances found in the PCBA and ToxCast databases to develop a set of machine learning models of PFAS activity. We optimize and validate their performance, and use them to predict biological activity (active/inactive classification) of the non-overlapping PFASs in the OECD database. We discuss what structural features and potential bioactive pathways emerge from this analysis and the implications for identifying and prioritizing PFAS effects.

**TP287 Effects of Chronic Dietary Exposure to Aqueous Film Forming Foam on Japanese Quail (Coturnix japonica)**

*S.J. Bursian, M. Crawford, J. Link, Michigan State University / Animal Science; M. McCarty, M.F. Simcik, University of Minnesota / Division of Environmental Health Sciences*

Aqueous film forming foam (AFFF) containing perfluoralkyl substances (PFAS) has been used by the Department of Defense for over 40 years for fire-fighting and emergency response activities. This has resulted in contamination of ground and surface water, soil and biota near relevant military bases with perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA) as well as other PFASs. In order to develop an avian toxicity reference value for these chemicals, the effects of a 3M AFFF formulation (containing primarily PFOS with a lesser concentration of PFOA and other PFAS) on egg production, embryo development, hatchability and chick survivability and growth were determined in Japanese quail (Coturnix japonica). Hatching Japanese quail were raised on 6 dietary concentrations of AFFF for 140 days (0, 2.1, 5, 11, 19, and 21 µg/g feed). At 4 weeks of age, 16 male/female pairs were assigned, within treatment, to breeding/laying cages (1 pair per cage). At 8 weeks of age, photoperiod was increased gradually to induce the females to start laying eggs at 10 weeks of age. Eggs were collected daily, set weekly and incubated for 18 days for the following 10 weeks. Hatchlings were fed uncontaminated feed for 2 weeks and then euthanized and sampled for blood and liver. Unhatched eggs were opened to determine stage of development. At the
end of 10 weeks of egg collection, the adult quail were euthanized to collect blood, liver and kidneys. Results indicated that dietary exposure of Japanese quail to 3M AFFF had an adverse effect on egg production, hatchability, chick survivability and chick body weight. There were significant histological changes in the liver and kidney, but these changes were not dose-dependent. Of the endpoints evaluated, chick survivability was determined to be the most sensitive. EPA benchmark dose software was used to determine the dose at which chick survivability was decreased by 20%. A daily dose of 0.58 mg PFOS/kg body weight/day derived from 3M AFFF could pose a threat to avian wildlife.

TP288 Chronic Toxicity in Northern Bobwhite Quail Exposed to Perfluorooctane Sulfonate (PFOS) or a 2:1 Mixture of PFOS and Perfluorohexane Sulfonate (PFHxS)

N.M. Dennis, Texas Tech University / Environmental Toxicology; M.L. Dennis, A. Karpjanapiboonwong, S. Subbiah, S. Lasee, Texas Tech University / Department of Environmental Toxicology; T.A. Anderson, Texas Tech University / Environmental Toxicology

Per- and polyfluoroalkyl substances (PFAS) are a broad class of environmentally persistent chemicals that include thousands of synthetic organic molecules which are potentially toxic. There is a lack of terrestrial toxicity data on individual PFAS for comprehensive risk assessment and therefore a lack of data to inform regulations of these chemicals. We utilized a common avian species (Colinus virginianus) with known chemical sensitivity and amenability to laboratory conditions to perform sub-chronic (90-day) toxicity studies via oral exposure to perfluorooctane sulfonate (PFOS) and a simple mixture of PFOS and perfluorohexane sulfonate (PFHxS) (2:1) at three increasing and environmentally relevant concentrations (0.1 ppb, 1.0 ppb, and 20 ppb). Adult bird survival was 92% over the 90 days with only one death possibly treatment related (Female: 1.0 ppb PFOS). Our endpoints included: average number of eggs laid, hatch success rate, average day of arrested embryo development, adult weight change over the 90-day exposure, chick weights (hatch, 7-day, and 21-day), and chick survival rate. We calculated individual adult daily doses from amount of water consumed during the studies, then sought to determine if any dose-response relationships existed among these variables. After the 90-day exposure, adult doses varied 1.38 ± 0.06(10-5), 1.28 ± 0.10(10-4), and 2.62 ± 0.08(10-3) mg/Kg body weight (bw) for the PFOS study and 1.34 ± 0.06(10-5), 1.36 ± 0.09(10-4), and 2.70 ± 0.13(10-3) mg/Kg bw for the mixture study. Average egg production (69 ± 2 eggs) was statistically similar among treatments (p = 0.70). Hatching success ranged from 48 to 72% and was significantly associated with treatment (p = 0.009). The average day of arrested embryo development was significantly different among all treatment groups (p << 0.001). There was no treatment effect on adult weight change overall, however, females gained significantly more weight in both the 0.1 ppb PFOS and 20 ppb PFOS treatments than in the 20-ppb mixture treatment (p = 0.04, p = 0.01). Chick hatch, 7-day, and 21-day weights were all unequal among treatments (p << 0.001, p = 0.001, p = 0.001), respectfully. Chick survival from hatch to 21 days ranged from 91 to 99% and was not significantly associated with treatments (p = 0.10). Completion of this study fulfills gaps in chronic toxicity data necessary for establishing toxicity reference values (TRVs) used to better estimate ecological and human health risk.

TP289 Environmental Risk Assessments for PFAS Contaminated Sites; The Role of the Total Oxidizable Precursors Analysis

H.L. Lord, Bureau Veritas Laboratories / Scientific Services; P. Benvenuto, Bureau Veritas Laboratories / Mississauga Operations; T. Obal, Bureau Veritas Laboratories / Corporate

Background/Objectives. Per- and polyfluorinated alkyl substances (PFAS) are ubiquitous, persistent, anthropogenic chemicals that bioaccumulate in both humans and biota. An understanding of the toxicity of certain PFAS such as perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS) and several of their shorter carbon-chain analogues has developed in recent years. In response, along with a recognition of the wide presence and environmental impacts of these compounds, contaminant guidelines for selected PFAS in environmental matrices have been introduced in many jurisdictions. While significant effort has been focused on identifying priority impacted sites and delineating PFAS contamination extent, an additional consideration expected to influence risk assessment efforts is the potential for in situ oxidative transformation of PFAS precursor compounds to the currently reported PFAS of concern. At many sites, the pool of potential precursor compounds is large and poorly characterized. As a result it is difficult for stakeholders to quantify, assess or mitigate the potential risk posed by the presence of these precursor compounds. Approach/Activities. In 2012 Erika Houtz and David Sedlak of the University of California, Berkeley published a laboratory-based oxidative conversion of PFAS precursors in water by persulfate thermolysis. By measuring a standard suite of PFAS from the same sample before and after oxidation, the presence of a potential PFAS precursor pool could be determined, and by extension, the potential magnitude of uncharacterized risk inferred. Bureau Veritas Laboratories (Bureau Veritas) has implemented the total oxidizable precursors (TOPs) assay as published for water samples. A parallel assay to measure the presence of PFAS precursor compounds (often referred to as PFAS “dark matter”) in contaminated soils and sediments has been developed and validated by Bureau Veritas. Results/Lessons Learned. During this presentation, we will share our experiences and “lessons learned” over the past two years of processing soil and water samples with the TOPs assay from multiple sites throughout North America, including:-Characterization of the types and magnitudes of additional PFAS compounds that are commonly seen with the assay; -Correlations between types of precursors observed and resulting new PFAS generated; -Examples of observed changes in toxic potential based on amount total PFAS normalized to relative toxicities of individual species.

TP290 Estimates and perspectives on the risk of PFAS to terrestrial and aquatic ecological receptors

A. East, Towson University / Environmental Sciences; R.H. Anderson, US Air Force / AFCEC; C.J. Salice, Towson University / Environmental Science & Studies Biology

Per- and polyfluoroalkyl substances (PFAS) have been detected in a wide variety of terrestrial and aquatic environmental samples as well as organisms. Estimating risk to ecological receptors, however, remains a significant challenge. One important challenge lies in identifying priority PFAS for research and risk assessment given the wide variety of existing PFAS. As well, there are generally a lack of toxicity data for most PFAS other than a few well studied chemicals (e.g., Perfluorooctane sulfonate (PFOS), Perfluorooctanoic acid (PFOA)). From an exposure perspective, there is considerable variability regarding uptake and accumulation for terrestrial and aquatic receptors for even well-studied PFAS. To better understand the ecorisk landscape of PFAS, we used a large dataset of PFAS-contaminated soil and surface waters on DoD installations, available toxicity data for prominent PFAS, and uptake/accumulation estimates to explore the potential risk to ecological receptors. Careful analysis of the environmental data point to the prominence of mostly PFOS followed, in many cases, by perfluorohexane sulfonate (PFHxS). Hence, we used data for PFOS as our estimate of toxicity and because PFOS was the dominant PFAS (by an order of magnitude in some cases), we used maximum PFOS concentrations as a basis for exposure estimates. The analysis indicated that exposure and effects are relatively likely but the magnitude was organism- and location-specific. In aquatic systems, exceedance of the HC5 (50th percentile most sensitive species) was 26% and exceedance of the lower confidence level of the HC5 was 65%. These two estimates suggest that many aquatic sites may contain PFOS concentrations that exceed current toxicity thresholds. In terrestrial systems, we used two example avian species with different life histories. Time-on-site and life history had large effects on risk—pesticides, for example, were in exceedance in greater than 5% of sites at any level above 1% time-on-site while granivores were in exceedance at 5% of sites only when time-on-site was greater than 32%. Collectively, the data point to the potential for environmental concentrations of PFAS to result in exposures to ecological receptors that...
exceed current toxicity thresholds. However, there are considerable uncertainties regarding the toxicity of even well-studied PFAS such as PFOS. We are refining methods to better characterize ecological risk in light of the ambiguities and inconsistencies in PFAS toxicity data.

TP291 An evaluation of multiple approaches to derive threshold values for the protection of aquatic organisms exposed to perfluoroalkyl acids

J.L. Newsiedl, Ramboll / Environmental and Health Sciences

Perfluoroalkyl acids (PFAs) are synthetic fluorinated organic compounds that can be released to the environment during manufacturing processes, from commercial products and applications, or indirectly via oxidation of precursor molecules containing perfluoroalkyl chains. While PFAs have received increased attention in monitoring programs, the assessment of the potential risks PFAs pose to aquatic organisms is still being investigated. Currently, water quality values including predicted no-effect concentrations (PNECs) have been derived for several PFAs using two regulatory approaches, application of assessment factors (AF) to the “most sensitive” species, and species sensitivity distributions (SSD). Another less utilized approach is the application of models to establish PNECs that are based on ecological and toxicological principles. AQUATOX is an aquatic ecosystem model that incorporates environmental fate and trophic processes as well as toxicant lethal and sublethal effects that can be evaluated through food webs and ecosystems. In this study we evaluated the ecological risks posed by perfluorooctane sulfonate (PFOS) and perfluorobutane sulfonate (PFBS) using all three approaches in Lake Ontario. Laboratory acute and chronic toxicity data were used to derive PNEC values based on the AF and SSD approaches. For the model approach, PNECs were estimated as the lowest PFAS concentration resulting in non-significant changes in taxon-specific biomasses as compared to control results. Results showed that while the AF approach produced the most conservative PNEC for PFBS, the model approach produced the most conservative PNEC for PFOS. Uncertainties related to all three approaches will be discussed.

TP292 Reviewing Current Toxicity Literature to Evaluate Data to Support the Development of Draft PFOS and PFOA Aquatic Life Ambient Water Quality Criteria

A. Jarvis, US Environmental Protection Agency / Office of Water; J. Justice, US Environmental Protection Agency; M. Elias, B. Schnitker, K. Gallagher, US Environmental Protection Agency / Office of Water

Perfluorooctanoic acid (PFOA) and Perfluorooctane sulfonate (PFOS) contamination of aquatic ecosystems is widespread. PFOA and PFOS are part of a broader group of polyfluorinated compounds, which are synthetic and have unique chemical and physical properties, including thermal stability, water and oil repellency, and surfactant properties. PFOA and PFOS were incorporated into a wide range of industrial and consumer products for decades until the production of PFOA and PFOS was phased out by their major global manufacturers in 2000 and 2002, respectively. However, both PFOA and PFOS are highly persistent in the aquatic environment and, therefore, still pose a potential risk. Acute and chronic effects to a relatively wide diversity of aquatic and aquatic-dependent taxa have been reported in the current toxicity literature for both PFOA and PFOS. Additionally, bioaccumulation of polyfluorinated compounds consisting of long carbon chains (generally eight or more) like PFOS, occurs through the aquatic food web. This presentation will provide an overview of current toxicity literature evaluated for data quality to support development of PFOA and PFOS aquatic life and aquatic-dependent wildlife effect values and will identify existing data gaps for aquatic and aquatic-dependent species.

TP293 A Novel Approach for Assessing Hazard Associated with Firefighting Foams

A. Luz, C. Hutchings, J. Anderson, Integral Consulting, Inc.; P.E. Goodrum, GSI Environmental, Inc.; J. Field, Oregon State University / Environmental and Molecular Toxicology

A mixture of per- and poly-fluoroalkyl substances (PFAS) are found in most Class B firefighting foams used at O&G facilities. Past use of firefighting foams has resulted in the release of PFAS into the environment where they may mobilize and persist. Concern over potential health risks to humans and ecological receptors has generated substantial interest in developing next generation foams, such as short-chain (C6) and fluoro-free foams (3F), that potentially have more favorable risk profiles. As a critical first step towards quantifying the relative risks of these foam types, we developed hazard profiles following the general guidelines outlined in the GreenScreen for Safer Chemicals hazard assessment method. Constituents detected in at least one C6 foam included perfluorocarboxylic acids (PFCAs; C3-C8), 4:2, 6:2, and 8:2 fluorotelomer sulfonates (FTS); 4:2, 6:2, and 8:2 fluorotelomer thiiaoamido sulfonates (FITAoS); 4:2, 6:2, 8:2, 10:2, and 12:2 fluorotelomer sulfonamide betaines (FIsaB); and 4:2 and 6:2 fluorotelomer sulfonamido amines (FiSaAM) and 6:2 fluorotelomer thiohydroxy ammonium (FiTHN). The detection of long-chain PFAS was limited to one C6 foam sample and at orders of magnitude lower concentrations compared to short-chain PFAS. Similar classes of hydrocarbon surfactants were detected in both C6 and 3F foams and included alkyl sulfates, linear alkyl benzene sulfonates, alkyl ethoxy sulfates, linear alkyl ethoxylates, glucosides, cocamidopropyl hydroxysulfates, and alkyl amido dipropionates. A comprehensive literature review yielded varying amounts of toxicity data for the majority of PFCAs, 6:2 FTS, and 6:2 FiSaB including data for systemic mammalian toxicity, mammalian reproductive and developmental endpoints, and aquatic toxicity. However, for many detected fluorotelomers, toxicology study data gaps remain for parent compounds, expected degradation intermediates, and terminal products. In these cases, the longest chain PFCA that could form following fluorotelomer degradation was used as a surrogate. This approach facilitated the development of a hazard profile for each foam type. The proposed hazard assessment approach and results of this study can help to guide further research to address key data gaps on analytical chemistry standards and toxicology of complex mixtures present in current and future foam formulations.

TP294 Estimating PFAA exposure from consumption of vegetables grown in contaminated soils

S. Lasee, S. Subbiah, W. Thompson, A. Karnjanapiboowanong, Texas Tech University / Department of Environmental Toxicology; P. Payton, USDA Agricultural Research Service; Cropping Systems Research Laboratory / Plant Stress and Germplasm Development; T.A. Anderson, Texas Tech University / Environmental Toxicology

In 2017, the FDA conducted a study measuring per- and poly-fluoroalkyl substance (PFAS) concentrations in American foodstuffs. Among their results, they found concentrations of perfluorooctanesulfonic acid, a member of a sub group of PFAS know as per- and polyfluoroalkyl acids (PFAAs), in leafy greens as high as 1,000 parts per trillion; PFAAs have been known to bioconcentrate in plants grown in contaminated soils. The potential risk from consuming these plants is currently not well defined. Using a combination of our own research and literature data on plant uptake of PFAAs from soil, we developed an equation for predicting PFAA bioconcentration factors (BCFs) for plants grown in soils with a known percent organic carbon. This calculated BCF was then used with measured soil PFAA concentrations to estimate PFAA concentrations in harvested plants and the potential exposure to humans and animals consuming them. This equation could be a useful tool for estimating exposure to PFAAs in soils through trophic transport.
TP295 Development of Ambient Perfluorooctane Sulfonate (PFOS) and Perfluorooctanoate (PFOA) Concentrations in Soil and Groundwater

H. Loso, AECON / Remediation; K. Schwach, AECON / Environmental Remediation; C. Wong, AECON / Modelling/Statistics Dept.

Poly-and perfluoralkyl substances (PFAS) are a group of emerging anthropogenic compounds that are environmentally persistent, ubiquitous, and are used in a wide variety of consumer products and industrial applications. Perfluorooctane sulfonate (PFOS) and perfluorooctanoate (PFOA) are two of the most studied PFAS and have been documented to be present in both abiotic and biotic media worldwide. Some risk-based screening benchmarks and preliminary remediation targets have been developed for selected PFAS and are extremely low. The combination of widespread prevalence and low screening levels introduces considerable uncertainty and potential costs in the characterization and remediation for PFAS at sites contaminated from known sources. Thus far, characterization of ambient (i.e. background) has been limited and the development of quantitative background threshold values (BTVs) have not been calculated that could be applied on a national or regional level. BTVs can be especially useful at sites in the initial characterization phase when site-specific background concentrations may not be well understood. This presentation compiles the available U.S. background datasets from primary literature and governmental publications and attempts to develop national and regional BTVs for soil and groundwater for PFOS and PFOA by using documented and well-established statistical procedures available in the environmental statistical literature and governmental guidance. The upper tolerance limit (UTL95-95) was selected as the BTV for this evaluation. The UTL95-95 is a value that represents the upper limit of a tolerance interval such that 95% of the observations from the background population will be less than or equal to that upper-limit value with a confidence coefficient of 95%. Availability of statistically-based BTVs provides for a better understanding of national and regional ambient levels of PFOS and PFOA in soil and groundwater, which may contribute valuable information to remedial project decision-making at sites throughout the U.S.

TP296 Development of Generic Risk-Based Soil Screening Values for Perfluoroalkyl Substances (PFAS) Applicable to Biosolid Amended Agricultural Lands

N.C. Garisto, ARCADIS Canada, Inc. / Risk and Radioactivity; E. Arbaban, ARCADIS Canada, Inc.; S. Dunn, ARCADIS

PFAS may be present in biosolid amended agricultural lands (BAAL). PFAS in such soil can enter the terrestrial agricultural food chain and result in human exposure. This study develops risk-based soil screening values (SSVs) protective of human health exposure to PFAS due to both direct soil contact and food consumption. The SSVs can be used as interim values for assessing soil quality at BAAL. We have followed the USEPA biosolids risk assessment (RA) guidance for the derivation of SSVs for three agricultural land uses: (i) Farm: a crop producing farm, where residents (i.e., farmers) consume local crops and store-bought meat; (ii) Ranch: a cattle ranch, where residents (i.e., ranchers) consume local meat and store-bought crops; and (iii) Mixed Farm and Ranch: a crop producing farm and ranch, where residents consume local crops and meat. The PFAS concentrations in seven groups of vegetables/crops were estimated using transfer factors (TFs) from literature studies on BAAL. The PFAS concentration in beef was modeled using feed to muscle TF and cattle’s daily dietary intake. The short chain PFAS (C4-C7) were not detected in the muscle tissue samples of the literature study, therefore, the human exposure to the short chain PFAS via beef ingestion was assumed to be negligible. The exposure to short chain PFAS via food was assumed to occur only through crop ingestion pathway. Generic human exposure characteristics were used. No irrigation was assumed. A hazard quotient target level of 0.1 was used to be consistent with up-to-date RA and to ensure conservatism. The SSVs were derived for perfluoroalkyl carboxylic acids (PFCAs) (C4-C14) and perfluoroalkane sulfonic acids (PFSA) (C4, C6, C8 and C10). The results indicate that the derived risk-based SSVs are more stringent for long chain PFCAs for a “Ranch” than for a “Farm” agricultural land use, while the SSVs for short chain PFAS (C4-C7) are more stringent for a “Farm” than for a “Ranch” land use. These observations are consistent with limited data on the chain length and functional group dependency of TFs for PFAS. Further studies are recommended to improve the understanding of short chain bioaccumulation potential in farm animals. As expected, the “Farm and Ranch” land use has the most restrictive SSVs. The concentration of PFAS in BAAL reported in the literature was compared to the derived SSVs. The soils meet the SSVs depending on the historical biosolids loading rates.

TP297 Employing the SeqAPASS tool to inform bioaccumulation potential of per- and polyfluorinated alkyl substances across species

C. LaLone, US Environmental Protection Agency / Office of Research and Development; J. Doering, NRC USEPA / Mid-Continent Ecology Division; W. Cheng, University of Pittsburgh; H. Peng, University of Toronto / Department of Chemistry; C.A. Ng, University of Pittsburgh / Civil & Environmental Engineering

Per- and polyfluorinated alkylated substances (PFAS) are synthetic chemicals used in a variety of industrial applications and consumer products, notably fire-fighting foams and stain and oil repellents. Due to the ubiquitous nature of PFAS in the environment, they have been measured in tissues from species as diverse as whales, birds, fish, and even invertebrates, covering a range of trophic levels. The ability of these chemicals to bioaccumulate is largely due to protein binding, with both serum albumin in the blood and fatty acid binding proteins in the liver capable of important interactions. Due to the involvement of proteins in bioaccumulation, the US Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) tool was used to evaluate protein conservation and predict similarities and differences in bioaccumulation potential across species. This approach serves as a case study in using SeqAPASS for advanced in silico and chemical prototoxic evaluations. Level 1 of SeqAPASS compared human primary amino acid sequences for serum albumin and liver fatty acid binding protein (LFABP) to all other protein sequences that exist in publicly available protein databases. These results provide a line of evidence that serum albumin and LFABP are conserved across the majority of vertebrate species. Based on knowledge of amino acid residues identified as critical for the interaction of PFAS with LFABP, Level 3 of SeqAPASS was used to compare individual amino acids. From these results, two positions, 50 and 94, were identified as potentially important for differences in PFAS bioaccumulation due to the differences observed when comparing across taxonomic groups. For example, a substitution of phenylalanine at position 93 for threonine predicted that zebrafish may differ from human LFABP in interactions with PFOS therefore leading to potential differences in bioaccumulation. Results from SeqAPASS were then used to guide molecular homology modeling and molecular dynamics simulations to further evaluate species similarities and differences to predict potential for bioaccumulation of PFAS across species. Cross-species chemical proteomic studies will be used to confirm and expand upon in silico results. The contents of this abstract neither constitute nor reflect official policy of the USEPA.

TP298 Field-Based Terrestrial Bioaccumulation Factors for PFAS

N.C. Garisto, ARCADIS Canada, Inc. / Risk and Radioactivity; E. Arbaban, A. Dawe, ARCADIS Canada, Inc.; F. Cooper, ARCADIS Canada, Inc. / Risk and Radioactivity; C. Guay, ARCADIS Canada, Inc.

Human health and ecological risk assessments require data on the levels of contaminants in both the abiotic and biotic environments. If such data are missing in the biotic environment, it is often possible to derive them, using abiotic concentrations and Bioaccumulation Factors (BAFs). For many organic contaminants, it is possible to derive BAFs from their octanol-water partitioning coefficient (KOW). However, this method is not suitable for per- and polyfluoroalkyl substances (PFAS) compounds that are strong acids i.e., for perfluorooalkyl carboxylic acids (PFCAs) and perfluoroalkane sulfonates (PFSA). The PFCAs and PFSA typically exist in nature as anionic species and the KOW method is not relevant for such species. Furthermore, as many PFAS bind to proteins rather than...
to lipids, KOW would not be an appropriate measure of their bioaccumulation potential. Therefore, we derived terrestrial BAFs using field measurements. These measurements were used to assess the behavior of PFAS in the environment and develop an understanding of the main parameters that control the transfer of PFAS from the abiotic to the biotic environment. Co-located soil samples and the following terrestrial biota tissue samples were collected and analyzed for PFCAs (C4 -C14) and PFSAs (C4, C6, C8 and C10):(a) Terrestrial plants species: grass, leaves, forage, and berries; (b) Terrestrial invertebrates: earthworm BAFs were only calculated for parameters with detected concentrations in soil samples. The BAFs were developed for soil to terrestrial plants (BAFs-plant) and soil to earthworms (BAFs-earthworm). The derived BAFs-plant suggest a decreasing bioaccumulation potential with increasing chain length for both PFCAs and PFSAs, while the BAFs-earthworm increase with chain length for long chain PFCAs and decreases with chain length for PFSAs. These findings are consistent with previous studies. An exponential correlation was observed between PFOS and PFOA concentrations in plants and soil. A linear correlation was observed between the concentration of PFOS and PFOA in earthworms and soil. It is interesting to note that the calculated terrestrial BAFs were within an order of magnitude of literature values. These derived regression models can be applied to estimate the concentration of these parameters in plants and earthworms, providing the soil concentrations are known for these parameters and are within the range applied in the derivation of field based BAFs.

TP299 Development of a marine PFAS bioaccumulation model

Per- and polyfluoroalkyl substances (PFAS) are a broad class of widely produced anthropogenic chemicals that have been detected in ecosystems globally. As a chemical class, PFAS are often referred to as bioaccumulative substances. However, mechanisms driving uptake and accumulation in aquatic food webs for various PFAS are still poorly understood. Here we present a new food web bioaccumulation model for PFAS that is based on both phospholipid partitioning and serum protein binding in tissues. Our research goal is to develop a generic model that can help inform biotic monitoring and risk assessment guidance for PFAS. We parameterize the model to two marine food webs: 1) North Atlantic pilot whales and their prey, and 2) a highly polluted coastal estuary (Charleston Harbor). We will present results comparing modeled and field-measured PFAS concentrations and discuss physical and chemical factors driving accumulation in biota. These results will include a quantitative assessment of contributions to variance in model results, including sensitivity analyses that are used 1) to assess the impact of uncertainty in literature-derived partitioning coefficients and 2) to infer the relative importance of active protein transport. We will also present results of a novel assessment of the bioaccumulation potential of unidentified organofluorine.

TP300 Accumulation of Per- and Polyfluoroalkyl Substances in Fish Downstream of a Fire-fighting Training Area and Determination of the Risk to Human Health

Environmental investigations completed for the fire-fighting training area (FTA) of an airport (the Site) identified elevated concentrations of per- and polyfluoroalkyl substances (PFAS) in surface water and sediment in a river that flows across the Site. PFAS are persistent and can bioaccumulate in fish, representing a potential risk to people that may consume fish from the river. The objectives of the study were to: (1) collect and analyze fish tissues from the river to assess the bioaccumulation of PFAS; (2) derive Site-specific fish tissue guidelines for PFAS protective of human health; and (3) compare the measured fish tissue concentrations to the derived fish tissue guidelines to determine if the concentrations of PFAS in fish pose a health risk to people consuming fish from the river. Fish tissues were collected from the river from locations downstream (i.e., exposure areas) and upstream (i.e., reference areas) of the FTA. Surface water and sediment were primarily impacted by perfluorooctane sulfonic acid (PFOS), perfluorohexane sulfonic acid (PFHxS) and perfluorohexanoic acid (PFHxA). PFHxS, PFOS and perfluoropentanoic acid (PFPeA) were detected in muscle tissue collected downstream of the FTA, with PFOS dominating PFAS uptake. Fish tissue guidelines protective of human health were derived for all PFAS analysed in fish tissues using receptor characterizations, exposure and toxicity assumptions recommended by Health Canada or based on Site-specific information. The derived fish tissue guidelines for the most sensitive receptor (toddler) ranged from 11 ng/g (for perfluorodecanoic acid [PFDA], perfluorododecanoic acid [PFDoA] and perfluoroundecanoic acid [PFUnA]) to 6883 ng/g wet weight (for perfluorobutanoic acid [PFBA]). Except for PFOS, maximum measured muscle tissue concentrations of PFAS in rainbow trout, creek chub, rock bass and white sucker were below the fish tissue guidelines derived for a toddler. For PFOS, the maximum measured concentration in rock bass of 232 ng/g wet weight was greater than the derived fish tissue guideline of 138 ng/g wet weight, suggesting that concentrations in rock bass may pose a health risk to people consuming fish from the river. Fish consumption advisories were recommended to address the potential risk. The fish consumption advisories will be developed in collaboration with the Ministry of the Environment based on their analyses of splits of the fish tissue samples collected from the Site.

TP301 Biotransformation and Bioconcentration of 6:2 and 8:2 Polyfluorooalkyl Phosphate Diesters in Common Carp (Cyprinus carpio)

L. Zhu, M. Chen, T. Guo, Nankai University / College of Environmental Science and Engineering

Polyfluorooalkyl phosphates esters (PAPs) are widely used in a variety of commercial products and detected in many aquatic organisms. To investigate their bio-accumulation and transformation in fish, common carp (Cyprinus carpio) were exposed to 6:2 and 8:2 diPAP in water. Several degradation products, including fluorotelomer unsaturated carboxylic acids (6:2 and 8:2 FTUCA), 5:3 and 7:3 fluorotelomer carboxylic acids (5:3 and 7:3 FTCA), perfluorooalkyl carboxylates (PFCAs) were identified in the carp liver. In addition, several phase-II metabolites, such as glutathione- and glucuronide-conjugated compounds were detected in the carp bile. 8:2 diPAP displayed lower accumulation potential than 6:2 diPAP probably due to its relatively large molecular size. However, 8:2 diPAP experienced more extensive transformation and produced more phase I metabolites than 6:2 diPAP, with higher transformation rate of 8:2 diPAP (6.78-14.6 mol%) compared to 6:2 diPAP (0.49-0.66 mol%). The in vitro incubation with the liver S9 fraction confirmed that biotransformation of 6:2 and 8:2 diPAP took place in the carp liver. Further analyses of enzyme activities indicated that acid phosphatase (ACP) could be involved in mediating phase I while glutathione S-transferase (GST) involved in phase II metabolism of 6:2 and 8:2 diPAP in carp.

TP302 Development of a Risk Framework for Threatened and Endangered Species potentially exposed to PFAS on military installations

Per- and polyfluoroalkyl substances (PFAS) are emerging contaminants of concern on many DoD sites. As such, there is growing interest regarding the potential effects of PFAS to public and environmental health, as
well as concern from the DoD regarding liability under federal statutes such as the Endangered Species Act (ESA). ESA requires federal agencies to ensure that any actions conducted by that agency are not likely to jeopardize the continued existence of threatened and endangered species including their respective habitat. Given the lack of information concerning the potential risk of PFAS to T&E species on DoD lands, we are developing a spatially-informed framework to conduct screening-level risk assessments for listed species on DoD installations. Using Joint Base McGuire-Dix-Lakehurst (JB MDL) as a model installation, percent of PFAS-impacted habitat per species was estimated using geospatial analysis by overlaying the areas of impacted soil/surface water with species-specific habitat (landscape layer(s)). Additionally, to determine if there are specific, at-risk taxa based on dietary preferences we developed a GIS layer that extrapolates transport of PFAS from the release location and overlaid this with taxa-diet landscape layers and found that species with insectivorous dietary preferences likely experience increased PFAS exposure. Currently, we have preliminary data for the screening-level risk assessment for Osprey and the Northern Pine Snake (both state listed in NJ) at JB MDL. These preliminary estimates indicate that osprey and snakes may be exposed to 0.003 and 0.03 - 2.15 mg PFOS/kg/d, respectively. The working Toxicity Reference Value (TRV) for avian and reptilian species is 0.021 and 0.2 mg/kg/d, respectively. Taken together, the high exposure estimate of 2.15 mg/kg/d at a former fire training area on the installation would likely pose a risk to Pine Snakes. Importantly, many assumptions are built into these screening-level risk estimates and there are critical uncertainties (i.e. fish tissue concentrations vs whole body) that we identify as data needs.

TP303 Guidance for Assessing the Ecological Risks of Threatened and Endangered Species at Aqueous Film Forming Foam (AFFF)-Impacted Sites

J.M. Conder, J. Arblaster, E. Larson, Geosyntec Consultants; J.B. Brown, C.P. Higgins, Colorado School of Mines / Department of Civil and Environmental Engineering

Per- and Polyfluoroalkyl Substances (PFAS) have been widely used in numerous applications since the 1950s, including aqueous film forming foams (AFFFs) used for fire suppression at airports, firefighting training facilities, and other industrial locations. PFAS are routinely-detected in a wide variety of environmental media impacted by AFFF, and have prompted regulatory focus on exposures and risks. Many AFFF sites host ecological habitat or, due to the offsite transport potential for PFASs, PFAS-impacted AFFF sites may affect nearby and downgradient habitats. As part of a Strategic Environmental Research and Development Program project, a guidance document was developed to provide a current state-of-the-practice overview of methods, practices, and key data gaps for assessing the potential for risks from exposure to PFAS for threatened and endangered (T&E) species at AFFF-impacted sites. The guidance is intended to provide clear guidance to quantitatively evaluate ecological risks and enable site managers to make defensible, risk-based management decisions using the best available information and approaches. The key objectives are: 1) to provide a framework for the evaluation of T&E species during ecological risk assessments (ERAs) at AFFF-impacted sites; 2) to provide the reader with an understanding of the specific T&E species or general feeding guilds typically expected to be considered most at risk at AFFF-impacted sites; 3) to provide the reader with recommended parameters (exposure factors, toxicity reference values [TRVs], uptake factors) to perform a food web model-based ERA for wildlife T&E species; and 5) to provide the reader with a recommendation of key data gaps and uncertainties when evaluating T&E species at AFFF-impacted sites. Several hundred toxicity values and over 1000 bioaccumulation parameters were assessed in the guidance review effort, resulting in 150 recommended values for use in ERAs. In addition to providing a review of the available literature and recommendations for ERA parameters, the guidance reaches the following key conclusions: 1) ERAs for AFFF sites are feasible; 2) off-site habitats are most at risk; 3) aquatic habitats are critical to address; 4) terrestrial habitats may be important at some sites; 5) risks from mixtures is uncertain; and 6) the exposures and effects of many PFAS-constituents in AFFF are unknown.

TP304 Selection of Toxicity Reference Values (TRVs) for Use in Ecological Risk Assessment of Threatened and Endangered Species at AFFF Impacted Sites

As part of a Strategic Environmental Research and Development Program project, a guidance document was developed to provide a current state-of-the-practice overview of methods, practices, and key data gaps for assessing the potential for risks from exposure to Per- and Polyfluoroalkyl Substances (PFAS) for threatened and endangered (T&E) species at AFFF-impacted sites. A key part of this guidance focused on a state-of-the-science review of Toxicity Reference Values (TRVs) for use in ecological risk assessments of avian and mammmalian wildlife. Over 70 regulatory and peer-reviewed documents were reviewed for both mammalian and avian toxicity studies (lethality, growth, and reproductive endpoints) for 18 target PFAS, primarily the environmentally-stable perfluoroalkyl acids (PFAAs). To reflect a high level of conservatism for T&E species (consistent with general USEPA T&E ecological risk assessment guidance), TRVs from exposure doses associated with an absence of statistically detectable differences in effects from controls (termed no observed effect level [NOEL] values) were prioritized. Doses associated with ecologically adverse effects (No Observed Adverse Effect Levels (NOAELs) and Lowest Observed Adverse Effect Levels (LOAELs) were also highlighted where available. Each wildlife toxicity study was reviewed and scored on a 10-point scoring system modified from USEPA Ecological Soil Screening Level (Eco-SSL) review approaches. The overall TRV selection process considered several different aspects of each study including duration of exposure, endpoint, and magnitude of the TRV to ensure a robust and, a conservative value was selected for each PFAS. Recommendations were identified for 11 mammalian TRVs and 2 avian TRVs for use in ecological risk assessment. In addition to providing recommended PFAS wildlife TRVs, the guidance also identifies critical data gaps for PFAS lacking robust TRVs and highlights cases in which further research is warranted.

TP305 Selection of Bioaccumulation Metrics for Use in Empirical PFAS Food Web Modeling for Threatened and Endangered Wildlife Species

As part of a Strategic Environmental Research and Development Program project, a guidance document was developed to provide a current state-of-the-practice overview of methods, practices, and key data gaps for assessing the potential for risks from exposure to Per- and Polyfluoroalkyl Substances (PFAS) for threatened and endangered (T&E) species at AFFF-impacted sites. A key part of this guidance focused on a state-of-the-science review of bioaccumulation metrics (e.g., bioconcentration factors, bioaccumulation factors, biota-sediment accumulation factors, etc.) for use in empirical bioaccumulation modeling to estimate concentrations of (PFAS) in diet items of threatened and endangered (T&E) wildlife species. Organic carbon-water partitioning coefficients (Koc) values were also reviewed, as these values can be critical components in PFAS bioaccumulation and fate modeling. Over 1000 bioaccumulation parameters in over 100 regulatory and peer-reviewed documents in aquatic and terrestrial food webs were reviewed for 18 target PFAS, primarily the environmentally-stable perfluoroalkyl acids (PFAAs). After compilation, metrics and studies were reviewed to provide recommended values for each PFAS (where available), resulting in a final compilation of 82 bioaccumulation values for predicting uptake by aquatic biota and 35 bioaccumulation values for predicting uptake by terrestrial biota.
Selection of recommended values followed a pre-determined approach, including preferential selection of values from laboratory studies using PFAS-spiked media, concentrations determined at steady state, and use of standardized testing organisms, resulting in robust values with a high level of conservatism for modeling bioaccumulation exposures to T&E wildlife species. The resulting recommended bioaccumulation metric values can be applied to measurements of PFAS in abiotic media to estimate concentrations in plants, terrestrial invertebrates, benthic invertebrates, pelagic invertebrates, and fish. In addition to providing recommended bioaccumulation factors for PFAS, the guidance also identifies critical data gaps for PFAS lacking robust bioaccumulation factors and highlights where further research is warranted.

TP306 Framework for Assessing Risks to Threatened and Endangered Aquatic Life at PFAS Impacted Sites

J. Arblaster, J.M. Conder, E. Larson, Geosyntec Consultants; C.P. Higgins, J.B. Brown, Colorado School of Mines / Civil and Environmental Engineering

The United States Department of Defense is one of the primary stewards of Threatened and Endangered (T&E) species on Federal lands. As part of a Strategic Environmental Research and Development Program (SERDP) project, guidance on the current methods for assessing risks to T&E aquatic life from exposure to per and polyfluoroalkyl substances (PFAS) was developed. To evaluate risks to aquatic T&E species, over 50 laboratory aquatic toxicity studies on PFAS were reviewed. To reflect a high level of conservatism for T&E species, no observed effect concentrations (NOEC) or 10% effective concentrations (EC10) were compiled for U.S. resident species and reviewed for inclusion in a Species Sensitivity Distribution (SSD) for PFOS and PFOA (other PFAS met minimum data requirements for SSDs). A total of 82 NOECs for freshwater aquatic species and 14 NOECs for marine aquatic species were included in SSDs for PFOS and PFOA. One percent and five percent hazardous concentrations (HC1 and HC5) were calculated from the SSD using USEPA guidance. HC1 values for PFOS were 0.56 µg/L and 2.57 µg/L for freshwater and marine species, respectively. HC5 values for PFOS were 5.8 and 7.7 µg/L for freshwater and marine species, respectively. The HC1 and HC5 value for PFOA were 537 µg/L and 1,110 µg/L for freshwater species, respectively (data were insufficient for marine species). HC5 values are typically accepted as protective thresholds for aquatic life. Based on the inclusion of NOEC values as the basis for the SSD, the HC5 values reported here are expected to represent conservative thresholds for evaluating risks to aquatic T&E species and aquatic life.

TP307 Case Study: Risk-based remedial criteria for per- and polyfluoroalkyl substance (PFAS) contamination in soil and groundwater in Ontario

W. Lau, Pinchin, Ltd. / Environmental Due Diligence & Remediation; C. Thorne, E.B. Chorostkowska, T. Phillips, Pinchin, Ltd. / Environmental Due Diligence and Remediation

A case study on a fire site in southern Ontario is presented and highlights challenges encountered during environmental evaluation work and the undertaking of a risk assessment wherein risk-based criteria were derived as remedial goals for per- and polyfluoroalkyl substances (PFAS), e.g. perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA). The fire occurred at an industrial property and was extinguished using a water and aqueous film-forming foam (AFFF) mixture, likely containing PFAS. Suitable containment of douse water was not achieved, and the runoff discharged to a neighboring property. Following the fire, subsurface investigations were conducted to delineate and remediate off-site fire-related impacts. The results indicated that PFOS and PFOA concentrations of up to 0.01 µg/g and 0.0028 µg/g, respectively, were present in soil. In groundwater, PFOS and PFOA concentrations of up to 0.12 µg/L and 0.24 µg/L, respectively, were also detected. In the absence of generic Site Condition Standards (SCS) in Ontario, a risk assessment was conducted to derive site-specific risk-based remedial criteria for PFAS contamination in both soil and groundwater. The challenges for risk assessors included, but are not limited to, 1) adequate identification of PFAS substances of concern; 2) selection of appropriate screening criteria and toxicity data; 3) managing the evolving science of PFAS toxicity; 4) defining uncertainties in a space with very limited regulatory consensus; and 5) recommending risk management of PFAS contamination protective of both human and ecological receptors. The human health risk assessment of PFOS and PFOA relied upon toxicity reference values (TRVs) provided by the United States Environmental Protection Agency and Health Canada, and the ecological risk assessment of PFOS relied upon toxicity benchmarks provided by Environment and Climate Change Canada. The final risk-based criteria in soil were 0.01 µg/g for both PFOS and PFOA, and a risk-based criterion in groundwater, of 0.07 µg/L for total PFAS, was also recommended. This case study showcases the approach adopted at a fire site in southern Ontario in consultation with provincial regulators, and the measures taken to ameliorate environmental and liability risk associated with PFAS contamination in soil and groundwater. The challenges encountered during the risk assessment of PFAS contamination at this fire site are relevant to similar sites across Canada.

TP308 Per- and Polyfluoroalkyl Substances (PFAS) Regulatory Values for Soil in the Context of Background Concentrations

C. Faith, K. Hathaway, Barr Engineering Co.

PFAS regulatory values for soil are being set below one part per billion (ppb) in several jurisdictions. At the same time, recent regional and global background studies have detected PFAS in soils at background levels exceeding one ppb. The methods used and considerations given to set the PFAS regulatory values for soil vary greatly between agencies including recent regulatory directives from certain agencies to evaluate the potential for PFAS to leach from soils using Synthetic Precipitation Leaching Procedure (SPLP). The presentation will compare and contrast established or proposed PFAS regulatory values for soils, how these values have been developed, causes for variability in these values and how these values relate to background levels. A compilation of hypothetical groundwater protection values, based on the methods used by various regulatory agencies, will be also be presented. The information presented will illustrate the relevance of background PFAS levels in the investigation and risk assessment at PFAS-impacted sites.

TP309 A review of four per- and polyfluoroalkyl substances to inform surface water standards in New Hampshire

M. Rardin, NH Department of Environmental Services / Permitting and Environmental Health Bureau; J.M. Ali, New Hampshire Department of Environmental Services / Environmental Services

Per- and polyfluoroalkyl substances (PFAS) have a long history of global industrial use, but their persistence in ecosystems and bioaccumulation within organisms and their environments pose risks to human and environmental health alike. In 2018, the State of New Hampshire was tasked with developing a plan for the regulation of four PFAS (perfluorooctanoic acid [PFOA], perfluorononanoic acid [PFNA], perfluorooctanesulfonic acid [PFOS], and perfluorohexanesulfonic acid [PFHxS]) in its diverse surface waters. The objective of this project was to review PFAS toxicity data relevant to the protection of aquatic life and human-health-based surface water criteria. This information will be used to make recommendations to the state regarding surface water standards, and most importantly, will delineate what further research is needed to support a more formal recommendation. A systematic literature review was conducted to collect data relevant to the state’s designated uses. These designated uses include but are not limited to: fish and shellfish consumption, aquatic life integrity, human recreational use, and a source of drinking water. After consideration of these designated uses and the current research on chemical, biological, and toxicological impacts of PFAS in surface water, fish consumption has been determined to be the driver of surface water standards. This is due to markedly different toxicokinetics between humans and most studied aquatic organisms, which is summarized in this poster. Therefore, using fish consumption as the main determinant of surface water standards will not only protect human
health, but will be sufficiently protective of wildlife. This work has direct applications to the challenging issues unique to New Hampshire—as well as other states—looking to establish surface water standards for PFAS. Additionally, this work can provide a broader scope of existing PFAS data which can inspire further PFAS research projects within the fields of academia and industry.

**Systematic Review for Robust Reporting and Evaluation of Environmental Toxicology Data for Risk Assessment**

**TP311 Combining best practices in Weight of Evidence and Systematic Review**

*G.W. Suter, US Environmental Protection Agency / ORD/NHEERL*

Environmental assessments often require inference by combining multiple pieces of evidence. Conventionally, this has been done by weight of evidence (WoE), but too often this process has consisted of informal narratives. Better practices for WoE are guided by Hill’s, or equivalent, considerations. Recently, more structured and transparent WoE processes have been developed by the USEPA and others. In parallel, clinical medicine developed Systematic Review (SR) as a more structured and transparent approach, including meta-analysis. As developed by the Cochrane Collaborative, SR combined a systematic review of the literature with meta-analysis of the extracted data. More recently, SRs for human health hazard assessments (e.g., OHAT) have adapted and expanded methods to include qualitative methods. The best practices from WoE and SR can be identified by distinguishing two steps: assembling the evidence and making the inference. SR is characterized by a structured process of searching, screening, and extracting formation from the literature. WoE has focused less on the literature review but has, in some cases, formalized the generation of sets of new evidence. Inference processes are more heterogeneous. If only one type of evidence is used (e.g., rat carcinogenicity tests), some version of meta-analysis can be used. If multiple types of evidence are used (e.g., laboratory tests, mechanistic studies, mesocosm tests, field observational studies, or models), some version of WoE must be used. The SETAC community should consider how best to make SR and WoE fit for our purposes. One approach is represented by our framework for making inferences in environmental assessment that combines best practices in WoE and SR. Depending on the case, it may direct the assessor to a classic SR with meta-analysis of assembled data, or to a transparent and structured WoE with the evidence assembled in a rigorous and transparent manner.

**TP312 Comparing apples to pomegranates: Development of toxicology-based systemic review criteria using evidence integration techniques: TCE case study**

*M.S. Johnson, T.E. Sussan, US Army Public Health Center / Toxicology*

Development and derivation of toxicology-based criteria are rarely straightforward. This process often requires systematic review using data collection for different purposes, integrating a wide range of endpoints from diverse study designs, and searching for patterns of corroboration, biological plausibility, coherence, and dose-response relationships. Despite the direct applicability of human data to criteria derivation, rarely are there opportunities for application of specific human environmental data, primarily because of imprecise exposure estimates, assumptions and confounding factors. Here we present a framework for evaluating epidemiological, controlled in vivo, mechanistic/in vitro and computational evidence that can help in toxicology criteria development. We begin with a documented systematic review of the literature according to precise problem formulation guidelines, followed by sorting of data into either controlled laboratory in vivo, mechanistic/in vitro, or epidemiological/field data categories. Strict weight of evidence criteria are used to assess controlled in vivo data that includes an assessment of risk of bias. Epidemiological and in vitro data are used to help inform points of departure or human-equivalent concentrations that are system-based. Bayesian uncertainty factors are then employed to develop preliminary criteria, and these values are again compared with epidemiological data to support for the toxicity reference values.

**TP313 Identifying and Curating Ecologically- Relevant Toxicity Data with the ECOTOXicology Knowledgebase Literature Search and Review Processes**

*C. Elonen, J. Olker, US Environmental Protection Agency / Office of Research and Development; A. Anderson, A. Pomplun, B. Kinziger, C. Suomi, T. Karschnik, A. Pilli, General Dynamics Information Technology; D.J. Hoff, US Environmental Protection Agency / Office of Research and Development*

The ECOTOXicology Knowledgebase (ECOTOX, https://www.epa.gov/ecotox/) is a nationally and internationally recognized source of curated single-chemical toxicity data for aquatic life, terrestrial plants, and wildlife. This publicly available database provides private industries, federal and state regulators, and researchers with a cost-effective, non-duplicative means of locating high-quality ecological effects data to support chemical decision making. Through its 30+ year history, ECOTOX has developed systematic and transparent procedures to conduct comprehensive literature searches, title/abstract screening to identify references that meet ECOTOX applicability and initial acceptance criteria (e.g., ecologically-relevant species, verifiable CASRN, endpoint and control reported), and data extraction of all pertinent study and effects information (e.g., species, chemicals, test methods and conditions, toxicity results). Currently, the ECOTOX Knowledgebase includes data for more than 11,000 chemicals from over 48,000 references, with additional data uploaded quarterly. This well-established protocol is completed for 35-50 chemicals each year, as requested by various Program Offices. Some recent data updates were: a) Aluminum for EPA’s Office of Water, b) Uranium for the Office of Land and Emergency Management, c) Ziram for OCSP’s Office of Pesticide Programs, d) Decabromodiphenyl ethers for the Risk Assessment Division in the Office of Pollution Prevention and Toxics, and e) over 250 per- and polyfluoroalkyl substances (PFAS) for the Office of Research and Development and others. The curated data within ECOTOX can be searched and refined by 19 parameters (e.g. Species, Chemical, Effect, Control, Year, etc.), with customized output selections from over 100 data fields for users’ specific applications. These data results are readily available for use in scoping reviews, evidence mapping, systematic reviews, risk assessments, and regulatory decisions. Updated and enhanced functionality was recently added to the ECOTOX user interface, with interactive queries and data visualization capabilities; and efforts are on-going to enhance the interoperability with other databases and tools such that environmental regulatory agencies, the regulated industry, and researchers can more effectively and efficiently search and use existing toxic effects data. This abstract does not necessarily reflect USEPA policy.

**TP314 The Evidence Ecosystem: Present and Future Innovations For Systematic Review Automation**

*I. Stefanison, P. O’Brien, J. Tetzlaff, Evidence Partners*

Today’s systematic review software evolved from the need to automate the many manual tasks involved in conducting a review. Reviews are process intensive and data heavy, but, until recently, the ecosystem of tools to support them have been unsophisticated, inefficient and prone to error generation. Further, they failed to provide the level of transparency and reproducibility expected in reviews. Recent innovations have allowed many parts of the systematic review process to be automated to varying degrees, to the point that an entire electronic ecosystem now exists for evidence generation and curation. These evidence ecosystems enable unstructured text to be converted to structured data that can easily be searched, analyzed, and re-used. In addition, artificial intelligence is increasingly being used to accelerate and enhance the screening, classification, quality assessment, and data extraction processes, with enormous potential for even greater impact in the near future. This overview of the emerging evidence ecosystem will highlight the various technologies and
tools currently available as well as new developments on the horizon that allow for more efficient, higher quality, human-in-the-loop conversion of unstructured content into structured, high quality evidence.

**TP315 Harnessing literature-based evidence to support nutrient criteria development in rivers and streams: Applying systematic review**

C. Ridley, US Environmental Protection Agency / Office of Research and Development; M. Bennett, US Environmental Protection Agency / Region 5; S. Lee, K. Schofield, US Environmental Protection Agency / Office of Research and Development

Eutrophication from nitrogen and phosphorus pollution is a major stressor of freshwater ecosystems globally. Despite recognition of this problem by scientists and managers, qualitative and quantitative synthesis of scientific evidence is still needed to inform nutrient-related management decisions and policies, especially for streams and rivers. We conducted systematic reviews of the literature on nutrient stressor-response relationships and potential confounding environmental factors to support identifying, managing, and restoring aquatic resources impaired by eutrophication. We asked two questions: (1) What are the responses of chlorophyll-a (chl-a), diatoms, and macroinvertebrates to total nitrogen (TN) and total phosphorus (TP) concentrations in lotic ecosystems? (2) How are these relationships affected by other environmental factors? Consistent with best practice in systematic review, we published our review protocol before the review began and established data searching, screening, extraction, and evaluation methodologies to increase transparency and reproducibility and reduce bias. Our preliminary results are based on ~300 publications (screened from >20,000 initial search results) that document quantitative stressor-response relationships between relevant nutrients and endpoints around the world. Overall, we found that chl-a has stronger relationships than diatoms or macroinvertebrates to nutrients. This confirms a common understanding in stream ecology that autotrophic indicators are better predictors of nutrient enrichment. However, certain macroinvertebrates show broadly consistent responses to both TN and TP: burrowers, chironomids, and dipterans show consistent positive responses, while coleopterans, plecopterans, and EPT index show consistent negative responses. For studies that report relationships between chl-a and both TN and TP, those that show a strong response to TN also tend to show a strong response to TP. This reconfirms the importance of controlling both nitrogen and phosphorus to limit eutrophication. When completed, our dataset will be publicly available via an interactive database to facilitate user-driven data exploration and analysis. Disclaimer: Views expressed are the authors’ and not views or policies of the USEPA.

**TP316 Systematic review criteria used in polychlorinated biphenyl fish toxicity meta-analysis for ecological risk assessment and injury determination**

The legacy of environmental contamination by polychlorinated biphenyls (PCBs) continues even decades after their production ban. We conducted a meta-analysis on mortality, growth and reproductive toxicity thresholds of PCB-related effects on fish to facilitate assessment of potential impacts on aquatic life (Berninger and Tillitt 2019 Environ Toxicol Chem 2019;38:712-736). The goal of the meta-analysis was to evaluate data on PCB-induced toxicity in fish and develop tissue concentration-based thresholds useful for ecological risk assessments and injury assessments. A strategy for data retrieval, extraction and analysis was initially developed based on our objectives. We developed and documented a set of six criteria to identify appropriate primary data for inclusion into or exclusion from the meta-analysis. The rationale for these criteria were clearly defined to be consistent with the quantitative nature of the meta-analysis. A data extraction protocol, including predetermined data fields for each data type and worksheets were developed. Key data fields were lowest observable adverse effect residue (LOAER) concentrations for mortality, growth impairment, and reproductive impairment, and the corresponding effect levels (% of controls). This presentation details the planning, conduct and reporting of our systematic review of PCB-induced toxicity thresholds in fish.

**TP317 A meta-analysis of acute toxicity tests in fish**

H. Pluegg, N. Das, Verisk 3E / Safer Chemical Analytics; J. Kostal, George Washington University

Very little information is available regarding the overall statistical variability of the universe of acute fish toxicity tests, a necessity for its use in the regulatory community. Add to this the need for comparative data for computerized in silico modelling of acute fish toxicity, and the need for a meta-analysis becomes ever clearer. Based on publicly available data we obtained acute fish toxicity tests; approximately 70,000 results for 7400 chemicals. As the quality of the data (entry) varies widely; data cleanup and normalization are essential. The data were filtered to eliminate duplicates (from multiple entries), implement quality control parameters and standardize exposure/test duration and taxonomy. The resulting databases were separated into a number of component/sub-databases. The sub-databases include o A 10% subsample to determine statistical stability o Chemicals for which the raw number of LC50 assays exceeds 50 (N 180 chemicals!) o Specific data bases for chemical classes e.g. metals Based on preliminary data analysis we determined that data, i.e. LC50’s (for select chemicals), even at n=100 were not normally distributed. Given that many evaluations in ecotoxicology use normally distributed statistical methodologies, this already identifies a major problem. We thus focused on non-normal distribution based statistics i.e. using geometric means, which assume a log-normal data distribution. In order to demonstrate log-normal vs normal data distribution we used simple parameters such as mathematical mean, median and geometric mean, the latter of which tend to converge when a log-normal distribution is present. Graphical analyses were also performed, again in order to demonstrate typical data distribution. We calculated these statistics including a geometric mean confidence interval for all of the databases including many of the individual chemicals. Selected classes e.g. metals were analysed. Species-specific analyses were performed to determine relative sensitivity. We evaluated the ratios of effects based on various standard exposure times e.g. 24 vs 96 hours. Novel and highly sophisticated uncertainty analyses of the same data are presented elsewhere.

**TP318 Recommended versus inappropriate procedures for the interpretation of histopathology data from environmental toxicity studies**

J.C. Wolf, EPL, Inc.

Histopathology is a key endpoint for many environmental toxicological bioassays, as it can provide information relevant to hazard identification, risk assessment, the elucidation of disease mechanisms, monitoring of contaminant remediation efforts, and the general health of animal test subjects. Additionally, morphologic tissue changes can serve as critical links between initiating molecular events and apical effects in adverse outcome pathways. Despite the long established use of this venerable endpoint as a research tool, published recommendations concerning the appropriate collection, interpretation, and reporting of histopathology data for hypothesis-based ecotoxicological challenge studies are not widely available. In particular, issues arise when attempts are made to convert descriptive microscopic findings and semi-quantitative ordinal categorizations of lesion severity to quantitative data. Increasingly evident in the literature are papers in which the histopathology data are reduced to numerical index values per organ type and test organism. Although seemingly scientific, this inherently biased approach relies on a variety of unsupported assumptions and statistically invalid mathematical calculations. More importantly, because they promote the recording of numerous unrelated finding types, many of which are incidental to the study outcome, index systems are highly prone to the generation of false positive and false negative results. One very real danger is that inaccurate conclusions resulting from such analyses will be used in characterizations of hazard or risk to establish policy. This presentation will illustrate...
the shortcomings of index systems, and then describe an algorithmic, weight-of-evidence approach for the recording, interpretation, and statistical analysis of histopathology data from toxicological studies that utilize fish as test subjects.

TP319 Microplastic Soil Pollution: Key Knowledge Gaps and Research Needs
I. Bamgbose, Gradient

In recent years, microplastics have become emerging persistent contaminants of increasing concern with ecological consequences. Microplastics (plastic particles < 5 mm in size) are a diverse heterogeneous group of particles that differ in size, shape, color, and have chemical composition with specific densities that come from many various sources. Despite the ever increasing scientific documentation on the widespread presence, fate, and ecological adverse effects of microplastics in aquatic environments (marine and freshwater), their fate and impact on the soil ecosystem still remains largely unexplored. Soils are essential components of terrestrial ecosystems that experience strong pollution pressure. Soils have widely known to be sinks for various organic and inorganic contaminants and potentially sinks for microplastics. Given the paucity of information about microplastics in soil, the poster aims to assess the state of science in the exposure and effects assessment of microplastics in soil by drawing from the marine and freshwater literature to summarize current understanding of microplastics in soil, identify knowledge gaps, and suggest future research priorities.

Poster Only: Policy, Management and Communication

TP320 A study of chemical accident cases for determination of the restoration endpoint
S. Lee, E. Jho, Hankuk University of Foreign Studies / Department of Environmental Science

The number of chemical substances distributed in Korea is about 45,000 to 50,000, among which 43,500 kinds are registered as existing chemical substances, and 200 to 400 new chemical substances are reported every year. When chemical accidents break out, there will be huge impacts on human and environment, and there have been several large spill accidents in Korea. Assessment of the effects of chemical accidents is mostly based on human risks, but assessment techniques that take into account the impacts of ecosystems such as water quality and soil are very important. In addition, it is very important to determine the endpoint of the disaster due to the chemical accidents. In developed countries such as the United States and the United Kingdom, emergency response plans for chemical accidents and various guidelines for environmental pollution are available. However, there are only few studies on domestic chemical accident response regulations. Therefore, recognizing international chemical regulatory trends is very important for safe maintenance and development of the domestic chemical industry. In this study, the present situation of domestic and foreign spill accidents and regulations on restoration of chemical accidents are studied, compared, and analyzed to contribute towards determining the endpoint of disaster recovery considering the aquatic ecosystem.

TP321 Development of contaminated site management decision support program based on human health risk in Republic of Korea
K. Yang, K. Kim, M. Lee, Korea Environment Institute / Environmental Assessment Group; J. Kim, Greencos Inc; K. Nam, Seoul National University / Department of Civil and Environmental Engineering

In the Republic of Korea, contaminated site management has been based on the total concentration of contaminant in the soil and its removal to meet the soil regulatory level. The concept of ‘risk’ assessment for contaminated site was introduced about 20 years ago, and the relevant guidance was prepared about 10 years ago with the revision of related law. However, risk-based contaminated site management is still not a common practice. The major reasons are the technical difficulties of determination of exposure factors, lack of a consensus of risk mitigation practices, and the absence of guidance on risk-based site management strategy. The project developing guidance on detailed technical risk assessment process and method, and how to build risk-based management strategy for contaminated site is underway. This study included in the project is for developing software to support risk managers of contaminated site when they assess human health risk and make a risk management plan. The main features of the software are statistical analysis of site survey results, determination of human health risk, and decision support. Statistical analysis tool includes sample size determination, goodness-of-fit test, and 95% upper confidence limit determination. Human health risk assessment tool includes default exposure factors and toxicity values, simple estimation of exposure concentration of contaminant in environmental media (i.e., groundwater, fugitive dust, outdoor and indoor vapor), and risk determination. Decision support tool includes cleanup goal determination to meet target risk level, determination of area of concern, geospatial analysis including creation of concentration, risk, area of concern maps. The software is developed in Microsoft .NET Framework using C#. For statistical analysis tool, R programming language was used. R codes for sample size determination, goodness-of-fit test, and 95% upper confidence limit determination were written based on ‘EnvStats’ which is R package for statistical analysis of environmental data, and connected with C#.

TP322 Pesticide use in Colombia and future policy needs in the sustainable agriculture framework
J. Gallego Zapata, J. Olivero-Verbel, University of Cartagena / Environmental and Computational Chemistry Group / School of Pharmaceutical Sciences

Agriculture is among the greatest contributors to environmental pollution in developing countries due to the high dependence on pesticides and their misuse. Achieving the food security goals involves the sustainable management of agroecosystems and the assessment of the risks of agrochemicals. Hence, the increasing use of pesticides requires policies and regulatory actions aimed to minimize the impact on human and environmental health. The objective of this study was to examine the trends in pesticide use in horticultural systems in Colombia, emphasizing on environmental issues, health risks, policies, and regulations. The analysis was carried out using data from official databases and the recent literature. In this country, the agricultural production is rising as a result of a growing national and international demand, a process linked to an increase in pesticide use, in particular organophosphates, carbamates, pyrethroids, neonicotinoids, and azoles. An average of 4.6 kg of pesticides is applied annually per hectare, resulting in 14588 tons of fungicides and bactericides, 9401 of insecticides, and 30038 of herbicides. It was found that there are more than 500 different active ingredients, which are commercialized as individually or mixtures formulations in 2292 officially registered products. Some of them are prohibited in the European Union, United States, and China, among others. Despite the fact that there are general regulations for the production, transport, storage, and application of pesticides, recent studies highlight health and environmental concerns. Genotoxicity and neuronal disorders related to pesticides have been reported in rural communities, as well as accidental and self-inflicted poisoning. In terms of environmental impact, few local studies have been conducted; however, pesticides have been found in water, soils, and foods. The different field application approaches used for agrochemicals are also of great concern for human and environment health, demanding attention from the national government. The results suggest that to reduce human and environmental health risks from pesticide use it is necessary to insist on sustainable agriculture. Policies should be focused to improve institutional capacities to provide support to smallholders, increase environmental monitoring strategies to obtain more reliable data on pesticide exposure, protect vulnerable groups, in particular women, and update the regulations for high toxicity pesticides.
TP323 The Use of Flow Studies in Arid West Streams to Determine Impacts on Downstream Waters

S. Skigen-Caird, GEI Consultants, Inc. / Ecology; S. Pargee, GEI Consultants, Inc. / Ecological Division; B. Bertelmann, GEI Consultants, Inc. / Ecology; S. Struck, J. Kurz, P. Staub, Geosyntec Consultants, Inc. / Environmental

When developing permit limitations for sites in Colorado the State considers both the water quality standards for the receiving stream and next downstream segment in order to ensure protection of the designated uses. Where it is determined that effluent has reasonable potential to reach the downstream waterbody, the downstream segment water quality standards must be considered. The more restrictive limitations are adopted in the permit to protect the uses of both the immediate receiving waterbody and downstream waterbodies. Sites discharging effluent to ephemeral and intermittent stream systems can present unique challenges for regulators. If reasonable potential exists, permit writers will incorporate the more stringent standards of downstream waters, no matter the distance between discharge and perennial waterbody, and it is then the responsibility of the discharger to prove otherwise. GEI Consultants, Inc. (GEI) and Geosyntec Consultants, Inc. (Geosyntec) collaborated to design and implement a flow study appropriate to determine whether discharge into an ephemeral stream bed would reach downstream perennial waters. For this study we evaluated discharge rates from three outfalls of particular concern, surveys were then conducted to characterize both the existing conditions as well as the extent of flow generated by active discharge. Conditions were documented pre- and post-discharge, as well as for one outfall not yet active but being considered for future permitting. Pre-discharge data collected for each drainage included: precipitation data, underlying geology and soils, surface water condition/type and flow rate, dominant vegetation type, and substrate composition. Post-discharge data collected for each drainage focused on documentation of flow lines from point of discharge to the point at which flow terminated. Field conditions and flow data from each outfall were then input into the U.S. Environmental Protection Agency’s Stormwater Management Model (EPA SWMM, v. 5.1.013) to assess whether flows would reach downstream perennial waters under varying conditions. The results from both field and associated modeling efforts will be presented with a particular focus on presenting alternative compliance strategies for arid environments.

TP324 Fish Tissue Monitoring Recommendations for Implementation of the Environmental Protection Agency’s 304(a) Freshwater Aquatic Life Selenium Criterion

K. Kesler, US Environmental Protection Agency / Office of Science and Technology; L. Guenzel, US Environmental Protection Agency / Office of Wetlands, Oceans, and Watersheds; J. McLaughlin, US Environmental Protection Agency / Office of Science and Technology

The 2016 304(a) recommended freshwater chronic selenium criterion for aquatic life is composed of four criterion elements, two fish tissue elements (egg-ovary and whole body/muscle) and two water column criterion elements (monthly average exposure for toxic and lentic waters and intermittent exposure). This criterion is the Environmental Protection Agency (EPA)’s first tissue-based criterion for the protection of aquatic life. To support the implementation of this criterion, the EPA is developing Technical Support for Fish Tissue Monitoring for Implementation of EPA’s 2016 Selenium Criterion. This document would provide recommendations and considerations for designing a fish tissue monitoring plan for the assessment of the selenium criterion and for the development of site-specific water column criterion elements. It would provide information to help states and authorized tribes decide which fish species it should target for sampling, which type of fish tissue to sample (egg-ovary, whole body, or muscle), how to collect fish samples (individually or as composites), and what to consider when selecting sampling locations. In addition, it would provide considerations for how to utilize existing tissue monitoring programs that are typically designed to assess human health risks. Lastly, this document would present information on analytical chemistry methods and data analysis. One of the recommendations that is unique to this criterion is the recommendation to collect egg-ovary samples for assessments. While states and authorized tribes have considerable discretion when selecting the fish tissue type to be used in their sampling protocols, EPA recommends sampling egg-ovary for assessment of the selenium criterion, if possible, and this document would provide monitoring considerations specific to egg-ovary sampling. This document is being developed in tandem with three other documents that address recommendations for the implementation of the selenium criterion, including for criterion adoption, National Pollutant Discharge Elimination System permitting, and Clean Water Act sections 303(d) and 305(b) assessments, listings, and total maximum daily loads. The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

TP325 Envisioning an International Validation Process for New Approach Methodologies

M. Mondou, G. Hickey, G. Pain, McGill University / Natural Resource Sciences; S. Maguire, The University of Sydney / Business School; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences

After 30 years of discussions within the global toxicology community, New Approach Methodologies (NAMs), such as in vitro, in silico, and ‘omics-based approaches, still lack the standardized protocols and procedures that govern conventional in vivo testing methods routinely used to test the human and environmental risk of chemicals. Questions about the validity of NAMs compel their proponents to envision a validation process that could bolster the trust of the toxicology community and increase the acceptance of NAMs for regulatory purposes. To generate expert evaluations of options for the validation of NAMs, we conducted a Delphi study - a group communication process that solicits expert judgments through iterative questioning and feedback - with 13 expert panelists from government, industry, and non-governmental organizations in Europe and North America. To aid and accelerate the validation of NAMs, our panelists emphasize the development of common data collection, reporting and sharing procedures for new test methods, along with the improvement of knowledge about new test methods in the regulatory community. Both solutions suggest the need for a common regulatory science infrastructure that would enable toxicology stakeholders to generate and share the benefits of collaboration amongst themselves. Ranking novel testing approaches from the most to the least beneficial and easily implemented within a 3-year timeline, our panelists prefer the Ecological Thresholds of Toxicological Concern (eco-TTC), followed by fit-for-purpose validation, Integrated Approaches to Testing and Assessment (IATA), adverse outcome pathways (AOPs), and the replacement of existing assays with new standardized tests. However, our experts reach no consensus on implementation in risk management, as some favor flexibility, whereas others wish for more structure and less interpretation. This may reflect the broader lack of consensus on the best way to validate NAMs internationally. Our study highlights the need for stakeholders to rally around a shared collaboration infrastructure based on trust across many sites - laboratories, regulatory agencies, contract research organizations, chemical producers, and the public. To build this trust, stakeholders need to agree on what matters (content in relation to context), how it is communicated (data format), and how it is measured (metrics). This work supports the EcoToxChip project (www.ecotoxchip.ca).

TP326 The importance of a legislative framework; linking science to decision making in climate change mitigation and adaptation

I.C. Ezeugo, N. Nwafor, University of Nigeria, Enugu Campus / International Law; I.N. Onwurah, University of Nigeria / Biochemistry

Climate change phenomenon has motivated an extensive body of research across a diverse array of topics including ecological niche theory. A lot of debate or scientific papers have appeared in several journals or News papers concerning climate change with some governments
viewing it as a political weapon while some as a myth. The overwhelming lines-of-evidence now has necessitated the call for approaches or actions that will mitigate or check climate change which is now known to be global in nature. Since avoidance of environmental harm and compensation for environmental damage are incorporated in sustainable principle, certain measures should be put in place to deal with or minimize the effects climate change. As such adaptation and mitigation should encompass a legal framework that will support or help in translating or giving insight on the complicated scientific principles and results for the lay public and non-scientific community or managers. This may ameliorate some of the challenges in linking science to decision-making. Essentially scientific data on climate change need to be consolidated, sorted and transformed into meaningful recommendations for influencing management decisions without losing the accuracy of the findings. However, this should be supported by a legal framework for policy making so that there is little chance of misconstruing the intent of the science. Substantive involvement of all disciplines and stake holders is needed for successful communication of results and actions but apart from the involvement of a communication expert, a legal framework which may facilitate a two-way push and pull of dialogue is vital; it may protect managers and decision-makers in a the manner they convey the scientific report where there are speculations and possible consequences of management decisions that should be made on the basis of what may not be clear or unknown. Hence in this work milestone for a legal framework that may lead to the foundations on which today’s climate change policy could be based is discussed. It is hoped that the hypothesis so derived if successfully implemented will engender an effective mechanism that could integrate information into a sound foundation for welcome decisions on climate change mitigation and adaptation.

TP327 Safer chemicals and materials: Exposing values in green design tools
A. Kokai, University of California, Berkeley / Environmental Science, Policy, and Management; C. Rosen, University of California, Berkeley / Haas School of Business; A. Iles, University of California, Berkeley / Environmental Science, Policy, and Management

The sustainability and health issues of everyday materials are increasingly provoking public debate. Pervasive problems such as the toxicity of commonly used chemicals raise questions about the contributions of designers and engineers, alongside lawmakers and consumers, to creating potential solutions. Technology and design professionals, as well as policymakers, are turning to new tools to operationalize material sustainability goals: “green design tools” are assessment methods and frameworks that help to structure decision-making about chemicals and materials with environmental health concerns in mind. Tool developers (including NGOs, scientists, governments and industry groups) play an important but largely uninvestigated role in mediating technical knowledge in sustainable production initiatives. We argue that green design tools are a way for designers, engineers, and policymakers to operationalize an ethics of sustainable materials. Using toxics issues in the building industry and the green building movement as a case study, we consider specific examples of green design tools that focus on chemicals and materials: the GreenScreen for Safer Chemicals, Pharos, and the Health Product Declaration. We analyze how these tools encode ethical reasoning and instill their developers’ particular perspectives and values. We also examine how the tools are adopted and debated by an extended network of stakeholders. We find that key points of conflict reveal contested values in relation to the ethical questions that the tools are trying to address.

TP328 Themes and Typologies in Supply Chain Sustainability Management and Reporting in the Information and Communication Technologies (ICT) Industry
L. Shi, Stanford University / E-IPER

The growth of the information and communication technologies (ICT) industry has increased its environmental and human health impacts globally. However, we have limited contextual and empirical understanding of how sustainability management practices have developed in the ICT industry, as well as the role of public and private policies. Based on existing theoretical and empirical research in sustainable supply chain management (SSCM) literature, we use content and interview analysis to identify the main themes, specific practices, and attitudes towards risks by ICT companies. We collect over 2000 annual sustainability reporting data from the Global Reporting Initiative (GRI) Database, the largest global sustainability reporting database and supplemented it with in-person semi-structured interview of managerial personnel in the ICT industry. To analyze emerging themes in ICT supply chain sustainability management, we use machine-based text analysis tool Structural Topic Modeling (STM) to identify themes that are frequently reported by companies. In addition, we built a classification model to predict if ICT companies’ sustainability management practices are driven by risk or non-risk factors using machine-learning approach LASSO to categorize the ICT companies. Based on preliminary analysis, we observe that companies from certain geographic regions have high correlation in their reporting semantic use. The emerging themes reported by ICT companies include 1) finance and performance; 2) management and service; 3) employee and operation; and 4) accountability and risk. Lastly, machine learning methods such as LASSO can be applied to classify corporate sustainability reporting typology. However, small hand-labeled sample size results in low recall rate.

TP329 ScienceBites: An Online Blog Network and Community for Early-Career Scientist Writers
C.A. McDonough, Colorado School of Mines / Civil and Environmental Eng; L. Schifman, Boston University; N. Sanders, ComSciCon

Early career scientists (graduate students and postdoctoral researchers) in STEM fields are an untapped source of very enthusiastic science writers, eager to share their research stories with the broader public. However, they often lack confidence in communicating with broader audiences, and they may have difficulty finding training resources to guide them in honing messages for non-experts, or platforms where they can publish their non-scientific writing. The ScienceBites family of blogs (astrobites.org, oceanbites.org, envirobites.org, chembites.org, and many others) provide a platform to connect early-career scientists with non-expert audiences by sharing compelling, bite-sized research summaries in a wide variety of scientific fields. At the ScienceBites blogs, these scientist writers regularly publish articles translating recent research articles in their field into engaging blog posts written for broad audiences, with undergraduate students specifically in mind. ScienceBites is working to form a centralized online hub to aggregate work from early-career scientists writing at many different Bites Sites, and to provide support and advice to students looking to start new Bites Sites in additional disciplines. When our website is launched, we also plan to disseminate free online resources that will help to train new Bites writers and other science writers to communicate effectively with non-experts. Here, we will introduce SETAC attendees to our growing network of science blogs, which currently features 14 websites in 3 languages. We will also summarize what we have learned this far about creating engaging science blogs, outline our future plans to grow ScienceBites, and provide information for any graduate students interested in joining an existing site, or starting a new one!
Multiple Stressors and Their Impact in Complex Ecosystems Within and Across Ecosystem Boundaries

TP330 Microbial Metatranscriptomic Investigations Across Contaminant Gradients of the Detroit River
N. Falk, T. Reid, A. Skoyles, A. Grgicak-Mannion, K.G. Drouillard, C.G. Weisener, University of Windsor / Great Lakes Institute for Environmental Research

It is well documented that microbial assemblages in sediments respond to exogenous anthropogenic contaminants via alterations in community structure and cell function. However, how these processes proceed in fresh water ecosystems across pollution gradients is unclear, particularly with regards to holistic microbial gene expression. The advancement of culture-independent, meta-omic techniques is bridging this research gap by enabling whole transcriptome-level sequencing of microbial samples collected at contaminated sites, adding to the understanding of bottom-up ecosystem responses to pollution. This approach was applied to sediments collected from the Detroit River; a region with a complex history of industrialization, urbanization and agricultural land use. Previous sediment surveys and modelling have delineated the river into contaminant zones based on concentrations of polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and metals, and comparative microbial metatranscriptomics was performed on sediments sampled within these regions. Differential gene expression analysis revealed that microbial function varied from natural to contaminated sites, with legacy-polluted sediments showing increased catabolic and anabolic cycling associated with nitrate reduction, methanogenesis, and beta-oxidation, despite decreases in community alpha-diversity. Transcripts involved in cell gluconeogenesis and polyester synthesis also showed high abundance in contaminated zones, along with increased expression of stress response genes and genetic transfer mechanisms. Aromatic cleavage genes were detected, but in low abundance across the contaminant gradient. These results suggest that microbial communities within the Detroit River exploit unique pathways to derive and store energy through the degradation of legacy organic contaminants and contribute to ecosystem services at work in the benthic environment.

TP331 Effects of the co-presence of the anionic surfactant sodium lauryl ether sulphate and pesticide chlorpyrifos on a natural soil microbial community

Chlorpyrifos (CPF) is an organophosphate insecticide currently used in agricultural practices characterized by a P-O-C linkage. Natural biodegradation can play an important role in its environmental removal; the main metabolite due to its hydrolytic processes is 3,5,6-trichloro-2-pyridinol (TCP). Surfactants are able to solubilize hydrophobic contaminants through their incorporation into the hydrophobic core of micelles in solution, improving the bioavailability of pesticides for natural microorganisms. Sodium lauryl ether sulphate (SLES) is an anionic surfactant widely used in excavation industry, as it is the main component of foaming agents used as lubricants. SLES residual concentrations can occur in the spoil materials reusable as by-products for different environmental purposes, including its mixing to agricultural soils. To date, no studies have been carried out on the interactions between SLES and CPF in soils. The aim of the present study was the evaluation of the persistence and bioavailability of both the anionic surfactant SLES and the pesticide CPF when they simultaneously occur in an agricultural soil. CPF and SLES half-lives (DT50s) were evaluated and the soil natural microbial community were also studied. For this purpose, various soil microcosms were treated with only SLES (70 mg/kg) or only CPF (2 mg/kg) or with both SLES and CPF; moreover, uncontaminated soil were used as microbiological controls (Con). At selected times (0, 7, 14, 21, 28d) soil sub-samples were collected for chemical and microbiological analysis. SLES was analysed by the Methylene Blue Active Substances (MBAS) method, while the pesticide CPF and TCP with a GC-MS, preceded by a Pressurised Liquid Extraction (PLE) from soil. Microbiological analyses were performed in order to assess microbial abundance (DAPI counts), cell vitality (live/dead method), dehydrogenase activity and structure (ELFA analysis). The results showed that both CPF and SLES concentrations decreased during the experimental time, but their halving times were not significantly affected by the presence of the other compound. On the other hand, the formation of TCP was favoured in the co-presence of SLES. In presence of both compounds, the microbial populations were more active and abundant, however the presence of the pesticide caused a shift in the microbial community structure, favouring the Gram-negative bacteria, main responsible of its degradation.

TP332 A multidisciplinary approach for evaluating fate and effects of mixtures of emerging compounds on aquatic and soil ecosystems

Aquatic and terrestrial organisms are continuously being subject to chronic exposures by mixtures of xenobiotics that can affect the population dynamics. A multidisciplinary approach, combining microbiology, ecotoxicology and chemistry makes it possible to assess direct and indirect effects of mixture on natural ecosystems. The natural attenuation capacity of ecosystem versus emerging contaminants such as pharmaceuticals, pesticides and surfactants was studied in microcosms containing natural water and soil samples (comprising the autochthonous microbial communities). The biotic and abiotic degradation of each pollutant alone or in mixture was evaluated comparing the chemical persistence in microbiological active versus pre-sterilized microcosms. At the same time, changing in microbial community structure and functioning, (e.g. loss or inhibition of bacterial populations which could be involved in key ecosystem functions), were also assessed. Non-treated microcosms were used as microbiological controls. The analytical determinations (GC or LC-MS/MS) of the xenobiotic residues in the soil/water over the experimental times period (0d, 7d, 14d, 21d, 28d), made it possible to assess both their half-lives (DT50) and transformation product formation. At the same time, microbiological parameters, related to functional (microbial activity and vitality) and structural (abundance and phylogenetic composition) characteristics of the microbial autochthonous communities, were analyzed. Finally, the effects of the multi-contaminated environmental matrix were also evaluated using standard target species by ecotoxicological bioassays. Ecotoxicological tests on the model organisms V. fisheri (water) and H. incongruens (soil), made it possible to assess the toxicity of both target compounds and un-target products, which may not be detected by chemical analysis. This work reports and discuss the overall chemical, microbiological and ecotoxicological data get from various microcosm experiments, showing the different knowledge obtained by this multidisciplinary approach.

TP333 The effects of the neonicotinoid pesticide imidacloprid and temperature on an ecological relevant springtail (Collombola) species
S. Kristiansen, H. Leinaas, University of Oslo / Department of Biosciences; C. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; K. Borgå, University of Oslo / Department of Biosciences

Springtails (Collombola) play an important role in decomposition and the cycling of nutrients and energy in soil ecosystems, and provide good soil quality needed for the production of food. Although a non-target species, Collombola suffer sub-lethal and lethal effects from exposure to pesticides used on crops. The agricultural pesticide group neonicotinoids are used to protect crops against grazing insects, and is applied widely and heavily worldwide. When applied, commonly more 90% of the pesticide enters the soil from the crops. In addition to pollution has also climate change been identified as a major threat to the natural environment. Effects of pollution and temperature may interact to produce
unpredictable, potentially synergistic, negative responses. Our aim was to study the effects of the neonicotinoid imidacloprid and temperature on an ecologically relevant Collembola species. A major part of the available toxicological data is on the standardized test species, which have parthenogenetic reproduction and usually only found in very special habitats. By comparison, the sexual species Hypogastrura viatica is widely distributed in temperate and Arctic coastal habitats. We exposed $H. \text{viatica}$ to the neonicotinoid imidacloprid through their ambient environment (soil) at two temperatures, and observed the physical effects and mortality, and life history traits such as time and size at reproduction, and egg production. The animals were exposed to 7 concentrations of imidacloprid between 0.01 to 100 mg/kg dry soil, in addition to the control (0 mg/kg dry soil). The exposure lasted 35 and 26 days, before the animals were kept in a clean environment for 60 and 45 days, respectively for 15 and 20°C; i.e. physiological age. We determined lethal effects of imidacloprid already at the low concentration of 0.01 mg/kg dry soil, and increasing mortality with increasing concentrations. The animals did not recover when moved to a clean environment. The mortality was higher at 20°C compared to 15°C, while egg production of surviving animals and subsequent hatching size did not differ between treatments. However, Collembola exposed to higher concentration of imidacloprid started reproduction later. Understanding the responses in life history traits when exposed to multiple stressors can lead to better extrapolation of results from laboratory studies to field conditions. This is essential to improve ecological risk assessment.

TP334 Ecological Legacy of DDT Archived in Lake Sediments from Eastern Canada

J. Kurek, Mount Allison University; P. MacKeigan, McGill University; S. Veinot, University of New Brunswick; A. Mercer, University of New Brunswick / Biology; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute

Past forest management practices led to widespread aerial application of insecticides, such as DDT, to North American forests. Lake basins thus provide an important archive of inputs and aquatic responses to these organochlorines. We used dated sediment cores from study lakes in multiple watersheds in New Brunswick, Canada, to provide a regional perspective on this legacy stressor in remote lake ecosystems. Peak sedimentary levels of p,p'- and o,p'-DDT (ΣDDT) and breakdown products ΣDDE and ΣDDD occurred during the 1970s to 1980s. Sediments exceeded probable effect levels (PELs) by ~450 times at the most impacted lake. Modern sediments in all study lakes still contained levels of DDTs that exceed PELs. We show that aerial applications of DDT to eastern Canadian forests likely resulted in large shifts to primary and secondary consumers within several lake food webs. Modern pelagic zooplankton and benthic invertebrate communities are now much different compared to those present before DDT use, suggesting that a regional organochlorine legacy may exist in the modern food webs of many remote lakes in watersheds where DDT was applied widely.

TP335 Predation-controlled populations are more vulnerable to stressors than food-controlled populations

M. Vaugoues, University of Minnesota, Twin Cities / Ecology, Evolution, and Behavior; P. Venturelli, Ball State University / Department of Biology; S.E. Hummel, US Fish and Wildlife Service; C. Accolla, V. Forbes, University of Minnesota / Ecology, Evolution & Behavior

Stresses on ecological systems can result in species population declines and even extinctions. Detecting stressor impacts at the population level is consequently very important but challenging due to the natural variability of populations, and the large spatiotemporal scales that are needed to detect changes in population dynamics. Therefore, stressor impacts are frequently measured at individual and sub-individual levels. However, methods are needed to extrapolate from effects on individuals to impacts on populations because population-level impacts are not necessarily proportional to individual-level responses. Scaling from individual- to population-level impacts is challenging because a stressor can impact the survival, growth, and/or reproduction of an individual, as well as how individuals interact with each other and their environment. Population dynamics emerge from these individual-level interactions, often nonlinearly, as a result of positive or negative feedbacks. Closed populations are regulated through reproduction and death, both of which depend on the balance between bottom-up forces (e.g., food availability) and top-down forces (e.g., predation). Few studies consider both regulating forces when evaluating effects of stressors. Therefore, there is a pressing need for studies that systematically assess the stress responses of populations under top-down versus bottom-up control. We used an Individual-Based Model to infer population-level impacts of a hypothetical, sublethal stressor that can affect an individual’s metabolism (growth, reproduction, maintenance, or assimilation) in systems in which population size is controlled by different combinations of food availability and predation. Our results confirm that population-level effects increase with stressor intensity, and are rarely directly proportional to individual-level effects. However, we also found that population-level effects were greater when the stressor impacted assimilation, and when populations were predation-controlled. Our results suggest that individual-level measurements alone are insufficient for inferring population-level impacts of stressors, and that accurate inference hinges on insight into how populations are regulated. We suggest incorporating individual-level data into mechanistic models that take into account population regulation.

TP336 Can the SPrEcies At Risk of pesticides (SPEARpesticides) index selectively quantify pesticide impacts within artificial ecosystems?

J. Bray, S.J. Nichols, R. Mac Nally, O. ’Rilley-Nugent, University of Canberra / Institute for Applied Ecology; G. King Kon Kam, University of Turin; S. Kaserzon, University of Queensland / QAIEHS; B.J. Kefford, University of Canberra / Institute for Applied Ecology

Pesticides are increasingly recognised as a threat to freshwater biodiversity, but their effects among co-occurring stressors and environmental gradients remain difficult to quantify. The SPrEcies At Risk indices designed for pesticides (SPEARpesticides) and corrected for use within mesocosms (SPEARpesticides-mesocosms), attempt to selectively quantify pesticide effects on communities among co-occurring stressors. We directly tested the efficacy of SPEARpesticides and SPEARpesticides-mesocosms, using 24 independent 1000L re-circulating outdoor mesocosms. We examined the effects of malathion, and other agricultural stressors, i.e. sediment, nitrate and phosphate, on stream invertebrate structure in an orthogonal pulsed design. Stream invertebrate communities were subjected to two pulses of sediment, nitrate and phosphate combined into one treatment (mimicking eutrophic conditions), and malathion (Pulse 1: 0.1 and 1ugL$^{-1}$; Pulse 2: 2.5 and 25 µgL$^{-1}$). SPEARpesticides failed to establish effects despite sensitive taxa declines during Pulse 1. In contrast, during Pulse 2 SPEARpesticides responded in the opposite direction in high pesticide treatments than expected. Both examination of species tolerances and the use of SPEARpesticides-mesocosms as opposed to SPEARpesticides help to correct this result. However, results identified that misclassification of taxonomic tolerances, low abundance, and low richness, especially in combination can cause unusual variation in SPEARpesticides indices. Simulation supports varying abundance, sample richness, sensitivity error, all cause declining index performance. We suggest the use of both multivariate and univariate (SPEARpesticides) analysis, accounting for co-occurring gradients both physical and chemical, coupled with experimentation and toxicity tests will best elucidate pesticide effects within complex freshwater systems.
TP337 Understanding Insect-Mediated Contaminant Flux: When, Where, and How to Look for Contaminant Export by Emergent Aquatic Insects

G.B. Beaubien, R.R. Otter, Middle Tennessee State University / Biology; C. Olson, Middle Tennessee State University; D. Walters, US Geological Survey / Columbia Environmental Research Center; M. Mills, US Environmental Protection Agency / National Risk Management Research Laboratory

The exchange of subsidies across the land-water interface is a key driver of community dynamics and ecosystem processes in both aquatic and riparian habitats as organic matter, nutrients, and animals flow across these systems. However, biological vectors can also transport contaminants across the land-water boundary. A classic example of contaminant-linked subsidies came from early studies of egg shell thinning in birds. In these studies, reproductive failure in piscivorous birds (e.g., eagles and pelicans) was linked to DDT exposure from consumption of fish that had accumulated in the aquatic ecosystem. Like birds, adult aquatic insects have been shown to transport significant quantities of contaminants such as PCBs out of aquatic environments, thereby linking aquatic contamination to terrestrial predators via a phenomenon called insect-mediated contaminant flux. Here, we present a decision-making tool to assess the likelihood of terrestrial risk via insect-mediated flux. This tool, named the Riparian Impact Test, integrates the technical science of the conceptual model into a step-wise series of four questions to aid risk assessors. We also discuss practical considerations for risk assessors, including how to best sample for insect-mediated contaminant flux at a specific site.

TP338 The effect of complex life histories on Hg accumulation and exposure in linked aquatic-terrestrial food webs

Many animals such as insects and amphibians have complex life histories that involve metamorphosis from an aquatic to a terrestrial life stage. Aquatic systems tend to concentrate contaminants such as mercury (Hg), so animals that accumulate Hg during their aquatic life stage are potential vectors of Hg transport to terrestrial ecosystems. Some amphibians are particularly interesting for assessing mercury flux from one system to the next because they feed on algae as tadpoles, do not feed during the process of metamorphosis, feed on aquatic and terrestrial insects as adults, then do not feed at all during hibernation which can last 7-8 months at high elevations. We measured total Hg (THg), methylmercury (MeHg), and isotopic composition (δ13C, δ15N) in chorus frogs (Pseudacris maculata) at two subalpine ponds (2775 and 2960 m elevation) in the Rocky Mountains in Colorado, USA. We sampled various life stages including spawning adults (‘starved’ adults just emerging from hibernation), eggs, tadpoles, metamorphs (recently emerged aquatic environment,) and mid-summer adults that remained and fed around ponds after spawning. We found large differences in MeHg concentrations and percent MeHg among life stages as a function of maternal transfer to eggs, diet switching, and catabolism during metamorphosis and hibernation. Starved spawning adults had the highest mean MeHg concentration (274 ng/g dry mass) of any life stage. Maternal transfer of mercury to eggs was minimal (22 ng/g) and remained low in tadpoles (36 ng/g) but roughly doubled at the metamorph stage (71 ng/g). This large increase was accompanied by a 33% loss of body mass during metamorphosis. Adults that remained around ponds during summer had concentrations roughly half (146 ng/g) that of the starved, spawning adults. The percent of MeHg and isotopic signatures also showed similar pronounced step changes across life history. Percent MeHg was high (~8%) for both adult life stages and remained high in eggs (52%) due to maternal transfer. After hatching, this percentage declined to only 23% in tadpoles and then doubled to 50% during metamorphosis. Isotopic signatures also changed substantially and abruptly between egg, tadpole, and metamorph life stages. Our findings show that key transition periods in animals with complex life histories are an important consideration in understanding environmental exposures to contaminants. Further, factors such as catabolism can dramatically alter the typical trajectory of trophic transfer and accumulation of contaminants such as mercury.

TP339 A Recommended Framework for a Great Lakes Early Warning System - Characterizing and Responding to Stressor Interactions

M. Donahue, AECOM / Water Resources; J.F. Bratton, T. Slawecki, LimnoTech

The Science Advisory Board of the Canada/US International Joint Commission funded the development of a framework for a Great Lakes Early Warning System; a means to allow the Great Lakes scientific and management communities to “get ahead of the curve” in addressing emerging and anticipated issues before they threaten the ecological integrity of the Great Lakes - St. Lawrence River Basin. Toward that end, a multi-faceted approach consisting of a literature review, interviews, survey and Experts Workshop was taken to 1) identify and prioritize emerging and anticipated threats and stressors; and 2) develop a conceptual framework for a GLEWS to characterize these threats and stressors and link them to response actions. Project outcomes included the identification and prioritization of several dozen current, emerging and anticipated threats and stressors adversely impacting ecological integrity. In addition, structural and operational alternatives of a recommended framework were explored, with the recommended alternative being a distinct and formalized entity within the International Joint Commission structure. A related follow-on project examined the nature of interactions among priority stressors, noting that some approaches to multiple stressor impact assessment have assumed that impacts are additive. While synergistic stressor interactions have been hypothesized to further degrade ecosystem conditions within the Great Lakes, there is little documented evidence of non-additive effects of stressors, let alone ternary or quaternary stressor interactions. This project explored the potential for nonlinear effects and ecological changes associated with multiple interacting stressors. Outcomes included a characterization and prioritization of stressor interactions by 1) identifying and describing commonly documented stressor combinations; 2) describing the nature of non-additive effects; 3) identifying stressor combinations of greatest concern; 4) characterizing the strength of stressor interactions across different aquatic environments and scales; 5) assessing underlying data quality and strength of evidence; and 6) identifying and describing research, surveillance and monitoring needs. The development of a Great Lakes Early Warning System, coupled with an investigation into stressor interactions, has laid a foundation for more informed, science-based management of the Great Lakes system.

TP340 The Montreal Protocol and Kigali Amendment: Actions for a sustainable Earth

K.R. Solomon, University of Guelph / School of Environmental Sciences

Global problems need global solutions and there are few examples of successful actions leading to changes for the better other than the Stockholm Convention on POPs and the Montreal Protocol (MP) and the Kigali Amendment to the MP. Depletion of stratospheric ozone has serious consequences to humans and the global ecosystem. Under the MP (initiated in 1987), the release of ozone depleting substances (ODSs) has been successful in mitigating depletion of stratospheric ozone and thus contributed to a sustainable earth. The Kigali amendment has begun the process for mitigating the release of gases with global warming potential (GWP) that will reduce global warming. Under the leadership of the United Nations Environmental Programme (UNEP) all but two nations have become parties to the MP. This has come about because of overwhelming scientific evidence of depletion of stratospheric ozone, a detailed understanding of the mechanisms involved, and the resultant increased intensity of damaging UV-B at the surface of the earth. While UV-B is the primary...
Wildlife Ecotoxicology: Assessing Effects of Chemical Stressors at Multiple Scales

TP341 Elevated Persistent Organic Pollutant Exposure in St. Lawrence Estuary Belugas (Canada): Relationships with Lipid Profiles and Body Condition

A. Bernier-Graveline, Université du Québec à Montréal / Biological Sciences; S. Lair, University of Montreal; R. Michaud, Group for Research and Education on Marine Mammals; V. Lesage, Fisheries and Oceans Canada / Maurice Lamontagne Institute; M. Rosabal, Université du Québec à Montréal / Department of Biological Sciences; J. Verreault, University of Quebec, Montreal / Sciences Biologiques

Exposure of St. Lawrence Estuary (SLE) belugas (Delphinapterus leucas) to elevated levels of persistent organic pollutants (POPs) was identified as environmental stressor that may contribute to affect SLE beluga health, and potentially be associated with certain causes of death in this endangered population. Several POPs (e.g., PCBs and PBDEs) are known to disrupt thyroid functions, lipid metabolism and ultimately alter body condition in mammals. However, limited information exists on the impact of contaminant exposure on energetic metabolism in cetaceans. The main objective of this study was to investigate the relationships between blubber concentrations of POPs (several flame retardants and organochlorines), lipid profiles (fatty acids, phospholipids, acylcarnitines) and body condition (scaled mass index) of SLE beluga males and females (n = 51; 1998 to 2016). A second objective was to investigate the linkages between these variables and the causes of death of these animals determined by necropsy. SLE female belugas that died as a result of dystocia were younger and were in better body condition than other females, whereas those that died by starvation had a lower body condition. SLE belugas that died from cancer exhibited greater concentrations of medium-chain fatty acids (C14:0, 16:0, and 18:0) compared to those that died from other causes. Concentrations of PCBs and organochlorine pesticides were 8- and 42-fold greater in male than female SLE belugas, respectively. Male and female belugas that died from bacterial infection showed the greatest PCB and organochlorine pesticide blubber concentrations, which could be explained by POPs exposure-mediated suppression of the immune system. SLE beluga females that died following dystocia, also exhibited the greatest polyunsaturated:monounsaturated fatty acid ratios that have been associated with metabolic disorders, oxidative stress, and lipid metabolism perturbation. Preliminary results of this study showed that energetic metabolism and general health of endangered SLE belugas is potentially affected as a result of their elevated POP exposure, which would warrant further investigation.

TP342 Effects of early-life stage exposure of double-crested cormorant embryos to 4 environmental chemicals on apical outcomes of regulatory relevance

D. Cramp, Environment and Climate Change Canada / National Wildlife Research Centre; A. Farhat, Environment and Climate Change Canada; E. Boulander, McGill University / Natural Resource Sciences; M. Becker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; J. Head, McGill University / Natural Resource Sciences

Environmental risk assessment is often challenged by a lack of toxicity data for ecological species of relevance. Although avian species are sensitive indicators of ecosystem health, toxicity data for many chemicals of ecological and regulatory concern are lacking. The overall goal of this research project was to employ an avian early-life stage toxicity test to determine the effects of 4 chemicals (benzo[a]pyrene [BaP], chlorpyrifos [CPF], ethinylestradiol [EE2], fluoxetine hydrochloride [FLX]), which are commonly detected in Canadian ecosystems and have well-characterized modes of toxic action. The chemicals were dissolved in DMSO and administered via air cell injection to fertilized, unincubated eggs collected from double-crested cormorant (DCCO) nests, at 3 nominal concentrations (BaP - 5, 0.5, 0.05 ng/g; CPF - 40, 4, 0.4 µg/g; EE2 - 33, 3.3, 0.33 µg/g; FLX - 30, 3, 0.3 µg/g) plus a solvent control. The highest concentration of each chemical was selected based on LD20 values from the literature and previous egg injection studies conducted by our group with Japanese quail (JQ) embryos. Liver tissue was collected from a sub-set of embryos at mid-incubation (day 14) for subsequent 'omics and analytical chemistry analyses, while the remaining embryos were examined on day 26 (1-2 days prior to hatch) for apical outcomes of regulatory relevance. Data are currently being analyzed to permit species sensitivity comparisons between JQ and DCCO. Ultimately, we aim to link 'omics endpoints with apical measures of regulatory relevance and demonstrate the utility of early-life stage toxicity tests as alternatives to traditional animal tests in the realm of chemical screening. The study supports the standardization of this early-life stage test in Canada and a large-scale Genome Canada project (EcoToxChip project; www.ecotoxchip.ca) aimed at transforming ecological risk assessment.

TP343 Health Assessment of Bighorn Sheep and Elk Populations on a Mine using GPS tracking and Tissue Sampling

In wildlife ecotoxicology studies, directly sampling chemical concentrations in individuals of free-ranging wildlife and monitoring their movements and diets provides an opportunity to identify population-level patterns of exposure and effects. This information can be used to inform remedial decisions. To assess effects from metals exposure to bighorn sheep populations that forage on a large mine and to elk populations that forage on the mine tailing facility, bighorn ewes and elk cows were captured. They were fitted with GPS collars to monitor herd foraging patterns on and off site for one year. Blood, hair and feces were collected from each collared individual to provide an indicator of metal uptake and overall health of each herd. Blood analyses included cell counts and biochemical parameters. The health of nearby reference herds was monitored at the same time through tissue collection. A dietary analysis of the elk herd for each season was conducted using DNA in feces. Tracking results indicate that bighorn sheep spent 13 to 22% of their time on the mine, depending on the season. They had elevated molybdenum levels in tissues but showed no indication of adverse effects on measured health parameters. Changes in exposure after mine reclamation were then predicted using landscape-scale habitat modeling. Planned reclamation will convert molybdenum exposure areas from waste rock piles to a seeded mine cover designed to transition to shrubland vegetation. Using innovative techniques, the habitat models predicted new home range contours and use patterns for post-reclamation populations. These models predicted that, after shrub development on the cover post-reclamation, bighorn sheep will spend approximately 16 to 20% of their time on the reclamation cover, which is similar to time spent on the mine prior to reclamation. Tracking results indicated that the elk herd foraged on the tailing facility 14% of the time. Tissue analysis indicated that elk had marginal copper deficiency in their blood and/or liver. However, the elk experienced no ill effects on their health as determined by a veterinarian and one necropsy.
TP344 Sublethal Effects of Neurotoxic Pesticides on Tropical Bats: from Cells to Behaviour

N. Sandoval Herrera, University of Toronto, Scarborough / Ecology and Evolutionary Biology; K.C. Welch, University of Toronto, Scarborough / Biological Sciences

Bats play vital roles in our ecosystems and economies as pest control agents, seed dispersers, and pollinators. Insectivorous bats, for example, control insect populations including agricultural pests. However, agricultural intensification and the consequent increase in pesticide use may represent an increasing threat to bat populations, thereby affecting the ecosystem services they provide. Some pesticides such as organophosphates (OPs) are highly neurotoxic for non-target organisms but have low persistence in the environment. Nevertheless, even low doses can impair essential processes such as immune function, locomotion, and cognition, threatening animal survival and its ecological function in a longer term. This study seeks to determine what sublethal effects of organophosphates have on bat physiology and behavior. We used an integrative approach to study the toxic effects of OPs on captive and wild bats. We measured multiple biomarkers in wild population roosting close to croplands in Mexico and Belize. We evaluated molecular (enzyme activity), physiological (metabolic rate, immune response) and behavioral (spatial memory) endpoints, aiming to extrapolate these responses across levels of biological organization. We present evidence of the suitability of some of these biomarkers to monitor wild populations and we propose a simple, yet sensitive behavioral test to evaluate spatial memory as an ecologically relevant behavior in bats. Understanding the sublethal effects of pesticides at different scales will enable to better predict the implications on bat populations and help to inform conservation strategies.

TP345 Micronucleus assay, a suitable tool to evaluate genotoxicity in wild bats

J.T. Castillo, University of Toronto, Scarborough; N. Sandoval Herrera, University of Toronto, Scarborough / Ecology and Evolutionary Biology; K.C. Welch, University of Toronto, Scarborough / Biological Sciences

Micronuclei were identified after a differential hematological staining as small, basophilic round inclusions inside the erythrocytes. We found that the bats from caves surrounded by commercial crops irrigated year-round have the highest number of MN, followed by bats from caves surrounded by seasonal crop lands, with bats from the cave proximal to deciduous forest having the lowest number of MN. We find evidence that MN assay is a useful biomarker for evaluating variation in genotoxic damage among wild animal populations.

TP346 Getting Buzzed: Use of Honey Bees (Apis mellifera) as an Alternate Model for Behavioral Effects of Alcohol Toxicity

T.E. Black, Oklahoma State University / Psychology; A. Chicas-Mosier, Oklahoma State University / Integrative Biology; C.I. Abramson, Oklahoma State University / Psychology

The current predominant model for examining effects of alcohol toxicity on behavioral and neurochemical outcomes in invertebrates is the fruit fly, Drosophila melanogaster. We propose that honey bees (Apis mellifera) have much to recommend them as a potential alternate organism to fill this research niche. Past research illustrates that honey bees readily consume alcohol, from both fermented nectar products, as well as in laboratory settings. Research into Drosophila has included both latent variables such as captive life span and general activity, as well as more controlled behaviors such as target oriented movement. In addition, the Drosophila literature has suggested a number of candidate genes which are affected by acute and chronic ingestion of alcohol. Past research in our laboratory, as well as genetic sequencing suggests that many of these genes are conserved in the honey bee genome. Here we present an initial assessment of the effects of chronic alcohol exposure on gross behavioral function and mortality in Apis mellifera ligustica.
**Advantages of Using Field Collected Invertebrates in Ecotoxicology and Ways to Standardize Their Collection and Testing**

WP001 Parallel Native Biota and Culturable Species Testing at EPA's Experimental Stream Facility

C.T. Niethe, US Environmental Protection Agency / Water Supply and Water Resources Division; J.M. Lazorchak, US Environmental Protection Agency / ORD/NERL/Systems Exposure Division; P. Weaver, US Environmental Protection Agency

The USEPA's Experimental Stream Facility (ESF) conducts meso-scale ecotoxicology studies that account for both structural and functional responses of whole stream communities to contaminants or other stressors. A macroinvertebrate community is established for each test by colonizing gravel baskets in field streams of the East Fork Watershed of Southwestern, Ohio where the ESF is located, and by allowing for recruitment from a continuous flow-through of natural river water over the course of each test, which are typically run for 90 days. Procedures have been developed for conducting parallel single-species exposure assays at the bench-scale using traditional test organisms and a culturable mayfly species, as well as using ex situ/in situ to the mesocosm formats that assess fish survival and fecundity and bivalve survival and growth. The 16 mesocosms of ESF are indoors and consist of a tiled run section (0.152 m W x 4.268 m L x 0.105 m D) that widens to a gravel riffle section (0.305 m W x 4.268 m L x 0.19 m D). They are intermediate size among studies reporting stream mesocosm results. Their set-up is unique for their size, with a high degree of engineering controls for continuous flow-through dose-response designs, yet fixed, chronic exposures to contaminants under conditions that quantifiably mimic real stream riffle/run habitat using standardized collection and measurement methods. With this framework of parallel native biota and standard test organism measures studies at ESF support the evaluation of proposed aquatic life criteria. This presentation will present the standardized methods used to colonize the mesocosms, measure biotic endpoints, physiochemical parameters and toxicity tests. In addition, present results on how single species toxicity tests compare with community responses.

WP002 Mesocosm testing of naturally colonized stream insect communities produces sensitive, reproducible, and ecologically-relevant effects concentrations

We conducted a series of 4 mesocosms tests using translocated, field-colonized insect communities that were exposed to 5 metals (Cd, 2X; Co, 1X; Cu, 3X; Ni, 2X; and Zn, 3X). Colonizations were for ~40 days using trays of pre-washed gravel placed in the same riffle of the same Colorado river in late summer or early fall depending on flow conditions. The 30-day exposures used 19-L buckets fitted with recirculating pumps to maintain a riffle-like current, and the buckets were set in chilled water baths to maintain suitable temperatures. Dilution water was trucked from the colonization site to the laboratory, and flow-through dosing was maintained by peristaltic pumps with about 2 volume replacements per day. The natural periphyton-based food web was maintained through grow lights, and no supplemental feeding was provided. In each test, the taxa richness ranged from about 23 to 35 taxa, and about 5 to 8 taxa were common enough to calculate concentration-response effect concentrations (ECs) in the same manner as in classic single-species tests. In most cases, repeated EC20 values varied within a factor of 2 to 3, although in one instance, the variability was almost a factor of 20. When ECs for the different species were overlain on published species-sensitivity distributions (SSDs) compiled from existing data, the ECs from the mesocosm testing nearly spanned the complete SSDs, ranging from the most sensitive to the most resistant ends of the distribution. This diversity of results appears consistent with patterns observed in metals-contaminated field settings. For the few insect taxa that were closely related to species that have been tested in single-species full life-cycle (FLC) tests, the 30-day larval survival endpoint was similar in sensitivity to the published FLC results. This suggests that the mesocosm larval ECs could be incorporated directly into aquatic life criteria or risk assessment datasets, much as fish early life stage (ELS) tests have long been used in lieu of far rarer and more difficult FLCs.

WP003 Why conduct rapid toxicity tests with field collected organisms?

B.J. Kefford, University of Canberra / Institute for Applied Ecology

Rapid toxicity tests are designed to determine the approximate sensitivity of many field collected species from specific ecological communities of interest. They aim to determine the approximate sensitivity of a large sample of species (10’s to about 100) to some chemical, chemicals or effluent, rather than the conventional practice in toxicity testing of more accurately determining the sensitivity of a smaller number of species. Rapid does not refer to the duration of exposure to chemicals but rather to the time and other resources per species tested. Rapid toxicity testing involves exposing field collected organisms to a chemical or a mixture of chemicals in the laboratory. To date these tests have used freshwater invertebrates and diatoms and marine invertebrates but in principle the approach could be extended to any group of organisms. Data obtained from rapid testing has been put to several uses. Species sensitivity distributions (SSDs) have been constructed with rapid test data from large sample of species (10’s to about 100) that represent specific communities of interest. Rankings of taxa’s sensitivities to chemical stressors have been developed with data from rapid tests which have then been used to construct, or modify, biomonitoring indexes, e.g. the diatom based SPEAherbicides index. Such indexes useful to interpret patterns in community structure along pollution and other gradients in field and mesocosm studies. Data from rapid tests has also been used to determine the ability of toxicity tests to predict the concentrations of chemicals that taxa inhabit in the field. Data from rapid tests conducted from species collected from multiple sites with different pollution histories has also been used to investigate pollution induced community tolerance (PICT). In this presentation, I will discuss how to conduct rapid tests, why conduct these tests and options for incorporating data from these tests into field and mesocosm programs.

WP004 Multiple biomarker responses and toxicity pathway analysis in snails Bellamyia aeruginosa exposed to tributyltin and triphenyletin in sediment

Q. Li, Tongji University / College of Environmental Science and Technology

Two organotin compounds, tributyltin (TBT) and triphenyltin (TPT) have been widely used as fungicides in agricultural activities and as ingredients of anti fouling paints since the 1960s. Sediments function as a secondary and significant source of TBT and TPT in aquatic ecosystems and may impose serious effects on benthic organisms and human health. Bellamyia aeruginosa (synonym: Sinotaia aeruginosa; Gastropoda, Caenogastropoda, Viviparidae) is a freshwater gastropod that is quite common throughout Chinese freshwater ecosystems and has great importance for human consumption. They are closely associated with surface sediments where they burrow in the upper layer and ingest particulate matter searching for the nutritive matter belonging to the sediment. In this study, the sub-chronic toxicity of sediment-associated TBT or TPT to snails Bellamyia aeruginosa at environmentally relevant concentrations was investigated. Multiple endpoints at the biochemical (EROD, SOD, CAT, protein carbonyl content and lipid peroxidation) were examined. High-throughput transcriptomic approach was applied to explore the toxicity mechanism of sediment-associated organotin compounds. TBT or TPT in sediment could result in induction of antioxidant defense system and oxidative damage in the hepatopancreas of B. aeruginosa after 28-d exposure. A transcriptomic profile of B. aeruginosa exposed to TBT and TPT was reported for the first time. CYP genes and EROD activity are sensible and reliable biomarkers, which could be an alternative tool.
in assisting reliable assessment of toxicity of TBT or TPT in sediment. Comparative pathway analysis revealed the alteration of steroid hormone biosynthesis and retinol metabolism in *B. aeruginosa* after 90-day exposure to sediment-associated TBT at the concentration of 2000 ng/g dw, which might affect both reproduction and lipogenesis functions. The ubiquitin proteasome system and immune system might be the toxicity target in *B. aeruginosa* after exposure to sediment-associated TPT for 90 days. The results offered new mechanisms underlying the toxicity of sediment-associated TBT and TPT.

**WP005 Diversity in toxicity testing - why field collected organisms are essential to the development of higher tier prediction tools for chemical assessment**

S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; G. Carr, The Procter and Gamble Company / Data & Modeling Sciences

Use of field collected biota for ecotoxicological testing has been a tradition in environmental toxicology before and since the days of Dr. Ruth Patrick’s river biological assessment teams probing responses of different trophic levels to systems perturbed by effluents in the 1940’s. The limitation of standard rearing, culturing, endpoint development and interpretation of responses to chemicals by lab-cultured organism has long been recognized as a shortcoming in chemical management. This eventually led to the use of microcosm and mesocosm approaches to supplement direct toxicity test investigations at the population level and also further emphasized the use of field-collected biota to understand extrapolation phenomena. In addition to micro/mesocosm studies as higher tier tools, ecotoxicologists also rely heavily on Species Sensitivity Distributions or SSDs for effects assessment. The limited nature of “standard test organisms” means SSDs are almost always heavily populated by “non-standard” field-collected biota subjected to chemical exposures to develop the sensitivity profiles for the chemicals. We recently developed a broad assessment of SSDs to understand roles of sample size on SSD characteristics and ways to address utilization of application factors. Both acute and chronic SSDs were assessed for 19 compounds and 22 individual data sets. Twenty data sets meet the commonly accepted criterion of a minimum of 10 species being represented across a range of phyla. Standard taxa were represented in all SSDs, although 4 instances occurred where standard algae and daphnids were absent. “Standard taxa” comprised 30% of the taxa and ranged from 2.4% (chlorpyrifos) to 50% (the anionic surfactant, HSAS) of species employed in the SSDs. Standard taxa and were only amongst the top two most sensitive taxa in only 4 cases. These observations demonstrate the essentiality of using field collected and non-standard species in ecotoxicological investigations. They are necessary to understand trophic-level tolerance patterns and trends (for example, photosynthetic organisms as being highly sensitive as a group to the zwitterionic surfactant, amine oxide). If field collected biota were not included in these assessments, fundamental linkages between standard taxa and mesocosm studies would also be more problematic.

**WP006 Probing Application Factors for SSDs - New Tools to Establish Robustness of SSDs with Adequate Biodiversity Present**

S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; G. Carr, The Procter and Gamble Company / Data & Modeling Sciences

Application Factors (AF) are routinely applied in the extrapolation of laboratory aquatic toxicity data to ensure protectiveness from exposure to chemicals in the natural environment. The magnitude of the AF is both a scientific and policy decision; however, in any case should be rooted in scientific knowledge so as to not be arbitrary. Information rich chemicals are often subjected to Species Sensitivity Distribution (SSD) analysis, largely supplementing non-standard species with traditional ecotoxicity test species, to transparently describe certain aspects of assessment uncertainty. SSDs are normally subjected to much smaller AFs than screening information data sets. We describe here a new set of tools useful to assess the quality of SSDs. Twenty-two data sets and 19 chemicals representing agrochemicals, biocides, surfactants, metals, and common wastewater contaminants were compiled to demonstrate how the tools can be used. “Add-one-In” and “Leave-one-out” simulations were used to investigate SSD robustness and develop quantitative evidence for the use of AFs. Theoretical new toxicity data were identified for add-one-in based on the expected probabilities necessary to lower the HC5 (5th percentile Hazard Concentration) by a factor of 2, 3, 5 or 10. Simulations demonstrate the basis for AFs in the range of 1 to 5 for well-studied chemicals with high quality SSDs. Leave-one-out simulations identify that the most influential values in the SSD comes from the extremes of the sensitive and tolerant toxicity values. Mesocosm and field data consistently demonstrate HC5s are conservative further justifying the use of small AFs for high quality SSDs.

**Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring New And Novel Approaches**

**WP007 Identification of environmental causes of reproductive failure through high throughput chemical screening using yeast**

R. Kumar, A. Oke, J. Robinson, University of California, San Francisco / Department of Obstetrics Gynecology & Reproductive Sciences; P. Allard, Azimuth Consulting Group / Institute for Society and Genetics; T. Woodruff, University of California, San Francisco / Program on Reproductive Health and the Environment; J. Fung, University of California, San Francisco / OB/GYN

The success of in vivo high-throughput chemical screens both to identify carcinogens and to discover effective therapies against cancer is well known. In contrast, very little has been done to employ this strategy to understand the toxicity of chemicals to the reproductive process although the consequences can adversely affect reproduction in this generation and result in birth defects and developmental disabilities in the next. An impediment to identifying and understanding the role of environmental chemical exposure is the prolonged delay between toxicant exposure and the manifestation of reproductive perturbations: when a pregnant woman is exposed to a reproductive toxin, the effects may only be seen in her offspring or generation after. As a result, there is a paucity of information on reproductive toxicity. Evaluation of reproductive toxicity has been most commonly performed using standard whole-animal rodent tests, which are costly, time consuming (years), require a large number of animals, and are typically not sensitive enough to capture the effects on gametes (egg and sperm), especially at the early stages of development. Here we describe a high-throughput screen to rapidly test a broad range of chemicals by incorporating an in vivo system using *S. cerevisiae* (budding yeast) to better capture a chemical’s effect on gamete production, a biological process known as meiosis. Our initial experiments using this yeast-based assay show that known mammalian reproductive toxicants (e.g. bisphenol A, triflumizole, fenarimol) can be positively identified by this assay suggesting that this assay could be an important aid in setting regulatory guidelines for chemical exposure particularly in regards to pregnancy and exposure to young children.

**WP008 A systematic approach to evaluate and utilize Molecular Initiating Events (MIE) for chemical classification**

M. Sapounidou, Liverpool John Moores University / Pharmacy and Biomolecular Sciences; M. Cronin, J. Madden, Liverpool John Moores University; S. Gutseit, G. Hodges, Unilever Research / Safety and Environmental Assurance Centre; D. Ebbrell, J. Firman, Liverpool John Moores University / School of Pharmacy and Biomolecular Sciences; J. Roberts, B. Campos, Unilever / Safety and Environmental Assurance Centre SEAC

Mode of Action (MoA) determination is an important part of understanding toxicity to aquatic organisms in the context of risk assessment and as part of regulatory schemes to enable read-across, chemical categorisation
and prioritisation. With a lack of harmonisation of current chemical -fragment based approaches to be able to adequately classify the full commercial chemical space, coupled with a shift towards mechanistic based approaches, there is a need to better define classification approaches. The Adverse Outcome Pathway (AOP) concept has gained significant traction as a means to interpret apical toxicity endpoints mechanistically. An AOP is a systematic approach that links molecular and biochemical interactions to individual or population responses and thus provides an opportunity to base classification schemes around this framework. A first key component in AOPs is the Molecular Initiating Event (MIE), where both chemistry and biology are integral components. There is a recognised need to evaluate the confidence of all parts of the AOP notably the MIE, Key Events (KEs) and Key Event Relationships (KERs); whilst schemes are in place for KEs and KERs, they have not been applied to MIEs. The aim of this study was to develop a scheme for classifying chemicals in MIEs relevant to aquatic toxicity. Prior to collation of MIEs, a framework was established to evaluate the ‘quality’ of MIEs in terms of the underlying evidence. Information on structural qualities of the MIE target; the interaction; associated chemistry; taxonomic applicability; along with the sources and the type of data (e.g. in silico, in vivo, in vitro) corresponding to MIE/MIE target of interest were documented. This led to an extended list of identified MIE and MIE targets. The MIEs were organised in 3 classes based on the type of interaction. This facilitated the utilisation of the chemical domain of MIE/MIE targets as building units for the chemical space per class. The chemical structural criteria for class assignment along with transparency in taxonomic applicability, data source and quality, were coded in a KNIME workflow. This approach provides the user with an informed MIE prediction that can be potentially used in the application of the AOPs to better understand chemical classification and to predict toxicity across aquatic species.

WP009 An In Vitro Toolbox For Bioaccumulation
J. Heckelmann, E. Salinas, B. Birk, E. Fabian, C. Gomes, B. Hidding, B. van Ravenzwaay, BASF SE / Experimental Toxicology and Ecology; T. Braunbeck, University of Heidelberg / Centre for Organisational Studies

Bioaccumulation plays an important role in the risk assessment and environmental fate of chemical substances. The main source of information is obtained by vertebrate testing, although different in vitro methods can reduce the overall number of animals needed for bioaccumulation assessment. This project aims to establish an integrated in vitro toolbox to estimate bioaccumulation in fish in support of alternative methods to animal testing. The toolbox consists of two cell culture assays, a fish embryo BCF screening, and a PBTK (Physiologically Based Toxicokinetic) model. As gills represent the main uptake route for waterborne substances in fish, an in vitro barrier model with fish gill cells is utilized to determine the chemical uptake rate. This assay was characterized regarding, e.g., monolayer and tight junction formations and validated using chemicals with known in vivo bioaccumulation factors. Since the biotransformation of absorbed substances play an important role for their clearance and in turn for their bioaccumulation potential, the fish hepatocyte assay, according to the OECD TG 319A, is utilized as the second in vitro model in the toolbox. The third model for the toolbox, uses fish non-protected embryonic life stages (2010/63/EU) to establish lipid-corrected BCF values. The assay is performed at a reduced temperature to extend the embryonic life stage and allow sufficient time for uptake and elimination. Kinetic rate constants and bioconcentration factors of substances shall be determined in the fish embryo to compare the results with in vitro cell culture assays and known bioconcentration factors in adult fish. The fourth aspect of the toolbox incorporates the in vitro and fish embryo data well as data from other sources (e.g., physico-chemical properties) into a toxicokinetic model to elucidate the behavior of the substances in fish and predict bioaccumulation potential.

WP010 Non-lethal blood sampling from rainbow trout in the laboratory and in situ
S. Pollard, C.D. Tyson, Ontario Tech University / Faculty of Science; J. Guchardi, University of Ontario / Faculty of Science; J.C. Anderson, D. Simmons, Ontario Tech University / Faculty of Science

The use of humane methods in animal research is an internationally recognized priority, but few EEM programs use nonlethal methods with fish, and the ones that do are normally limited to behavior, morphology, and reproduction. Non-lethal blood sampling methods support the three R’s of humane experimental technique (Replacement, Reduction, and Refinement). Small tissue samples can be sampled from fish to measure exposure to contaminants; however, for understanding biological effects, tissue samples are often limited to only one type of physiological response. One of the advantages of blood, serum, and plasma is that these fluids contain protein, metabolites, and signaling information from all tissues and organs within the entire organism, which facilitates a systems-level understanding of whole organism health. Much to our surprise, we can find no published protocol or studies that outline procedures for effective and low-impact non-lethal blood sampling in fish. Thus, the goal of the present study was to determine the impacts and survival of larger bodied fish after sampling small volumes of blood. In our approach, we housed 80 rainbow trout (Oncorhynchus mykiss) purchased from a local hatchery in our flow-through aquatic facility (Ontario Tech U, Oshawa On). We then anesthetized using MS-222 and sampled 1 ul of blood per gram of mass from each fish. We tested three different post-blood sampling treatments on the puncture wound; application of a liquid bandage, a swab of betadine, a swab of the fishes own skin mucus, and then we compared these to fish where we performed no post-treatment (as a negative control). After blood sampling, fish were examined weekly for 5 weeks. Overall, we observed 90% survival among all treatments; the most effective approach was the negative control (100% survival), while the post-treatment with the largest impact on fish survival was the use of betadine (75% survival). Based upon these results, we repeated the blood sampling with no-post treatment using 20 rainbow trout (freshly purchased, not previously tested upon) in situ using suspended cages at a nearby freshwater lake, and monitored fish behavior and survival for 5 weeks post-sampling. In this presentation, we will present the detailed results of these combined studies and describe what we have determined to be the safest non-lethal blood sampling protocol.

WP011 Developmental Toxic Effects of Three Alternative Antifouling Biocide on non-target marine fish
J. Jung, Korea Institute of Ocean Science and Technology (KIOST) / Risk Assessment Research Center; Y. Choi, Korea Institute of Ocean Science and Technology / Risk Assessment Research Center; M. Kim, Korea Institute of Ocean Science and Technology / Risk Assessment Research Center; C. Hong, Theragen Etex Bio Institute Inc.; J. Kang, Korea Institute of Ocean Science and Technology / Risk Assessment Research Center

To compare the toxic effects of three alternative commercial biocides on pelagic nan-target fish embryos, we investigate the adverse effects of developmental malformation and transcriptome analysis using high-throughput sequencing (RNA-seq). Overall, three biocides produced a largely overlapping suite of developmental malformation including spinal curvature and tail fin defect. However, pericardial edema defects were shown specially in embryos exposed to Sea-nine 211(R). At 48 hours after exposure, frequency percentage of mortality was shown 100% of mortality in the exposure group of 100 µg/L for sea-nine 211(R). Those biocides may be ranked in the following order from highest malformation and mortalities; Sea-nine 211(R) > Irgarol 1051(R) > Diuron. In consistent with, the gene expression level relating to malformation including the heart formation was higher in embryonic flounder exposed to Sea-nine 211(R) than those of Irgarol 1051(R) and Diuron, but genes relating to fin malformation increased commonly in three biocides exposure groups. In the differential gene expression (DEG) profiles sensitive (fold change of genes with cutoff P< 0.05), genes associated with nervous system development and synaptic signaling have varied significantly in common
with three biocides exposure groups. Embryos exposed to Diuron were changed highly related to cellular protein localization, whereas, genes associated with immune system process were up-regulated significantly at embryos exposed to Irgarol 1051(R). Embryos exposed to Sea-nine 211(R) showed up-regulation in genes related to actin filament organization and embryonic morphogenesis. Gene expression profiles were also observed the different DEG network including muscle cell development, nervous system development and transmembrane transporter activity in embryos exposed to three different biocides. Overall, our study provides a better understanding of the overlapping and unique developmental toxic effects via RNA-seq analysis in embryonic flounder. The results could be suggested to construction of emerging biocide management guild line by determined the toxic effects on non-target marine organism.

Contaminant Mixtures in Food: How Did They Get There and Should We Be Concerned?

WP012 Patterns of mercury and metal and organic co-contaminants in marine fish and shellfish

C. Chen, Dartmouth College / Biological Sciences; J. Gui, Geisel School of Medicine at Dartmouth / Biomedical Data Science; K. Yuan, Geisel School of Medicine at Dartmouth College / Biomedical Data Science

Fish consumption advisories have been established throughout the US for freshwater and coastal ecosystems. Most of the fish consumption advisories in the US are for mercury (81%), but significant numbers of others have been established for other metals and organic contaminants including polychlorinated biphenyls (PCBs) and their congeners, chlordane, dichlorodiphenyltrichloroethane (DDT), and others. Although the advisories are contaminant specific, humans are exposed to multiple contaminants through fish consumption. Past studies have focused only on individual contaminants, in particular mercury, without relating those exposures to others such as organic contaminants. Using publicly datasets in which multiple contaminants were measured in individual fish and shellfish samples, we examined the relationships between different contaminants (metals and organics) from the US Environmental Protection Agency’s National Coastal Condition Assessment (NCA) and the Mussel Watch Program of the National Oceanic and Atmospheric Administration. Our analysis of the NCCA, and Mussel Watch datasets utilized the covariate-adjusted Gaussian graphic model (GGM), which models the probability of co-occurrence between any two contaminants using imputation by chained equations and partial correlation. The final models for each of the available datasets reflect the co-occurrence between inorganic and organic contaminants, conditional on all covariates, allowing us to determine whether the interaction between some of the inorganic and organic contaminants is defined by certain environmental factors. Results from the network analysis are also compared to correlation analyses using pairwise comparisons. We examine the co-occurrence of mercury and organic contaminants in fish and shellfish in order to begin to evaluate the risk of human exposure to multiple contaminants posed by eating seafood and understand the processes related to their co-occurrence in aquatic organisms.

WP013 Advancing a Framework for Environmental Risk Assessment and Food Traceability Models for Global Food Safety

E.C. Umego, M.O. Ezenwa, University of Nigeria / Food Science and Technology; O.C. Nduka, University of Nigeria, Nsukka / Food Science and Technology

Food safety has been a global issue, and has consequently been a recurrent epidemic in recent history despite the advancement in modern technology, equipment use and in the handling of foods and food products. Many advanced countries of the world have been so much challenged to this particular issue. Basically, no food is 100 percent free or safe from either microbiological toxin, chemical toxin and or both. But these sometimes occur in limiting amount that is tolerable and acceptable to be regarded as being ‘safe’. Nowadays, modern architectural systems has put in place some treatments such as the use of pesticides to control pests, veterinary drugs and other environmental and biotechnology techniques in order to increase crop yield and productivity to ensure food security and its advancement. Furthermore, food either processed or non-processed move from one location to the other, and there could be possible contamination along the chain. All these happen within the environment. Several methods has been applied in order to ensure the safety of foods which among them are the Hazard Analysis Critical Control Point (HACCP System) which is basically in the food processing industries to ensure safety. The HACCP system has long been seen to have limitations due to recent food revolutions. The food Traceability system has also been into application, but on the other hand has limitations also. It is therefore necessary to advance a framework between Environmental Risk Assessment (ERA) strategies to synergize with the food traceability models that will give more assurance to safety approach apart from the normal tracking systems. ERA has several interactions in regards to hazards, human population, and ecological resources. It describes human populations, ecological resources which are agents to measure the exposure potential that will define the uncertainties, adverse effects and associated risks. This will enable effective communication because of the human health risks and ERA. Nevertheless, it will also enable more advanced techniques into the findings to enhancing global food safety on a long-term based.

Life Stage-Specific and Multi-Generational Effects of Environmental Stressors in Fish

WP014 Effects of Low, Subchronic Exposure of Commercial 2,4-D Formulation on Early Life Stages of Native Wisconsin Game Fish Species

G. Dehnert, University of Wisconsin, Madison / Zoology; W.H. Karasov, University of Wisconsin, Madison / Forest and Wildlife Ecology; M. Wolman, University of Wisconsin, Madison / Integrative Biology

Aquatic herbicides are used worldwide to eradicate nuisance and invasive plants despite limited knowledge of their toxicity to non-target organisms. 2,4-Dichlorophenoxyacetic acid (2,4-D) is a common active ingredient in commercial herbicide formulations, which triggers plant cell death by mimicking the plant specific hormone auxin. Application practices with 2,4-D commercial herbicides typically coincide with yearly freshwater fish spawning periods, exposing fish to xenobiotics at their vulnerable larval stages. However, the physiological impacts of 2,4-D on larval fish remain poorly understood, and hence, whether it may alter larval performance, fish populations, and ecosystem dynamics. We conducted a series of experiments to determine the effects of low concentrations (0.05, 0.50 and 2.00 ppm 2,4-D) of commercial amine salt herbicide formulation DMA(R)4IVM on the development and survival of nine freshwater fish species at various life stages. We observed reduced survival in embryo assays for 4 out of 9 species tested, reduced survival in 30-day larval assay for 4 out of 6 species tested, and no reduced survival in a 90-day juvenile assay in the 2 species tested. Altogether, the results indicate that the use of 2,4-D herbicide DMA(R)4IVM for weed control in aquatic ecosystems at current recommended concentrations (< 2 ppm whole lake; < 4 ppm spot treatment) could reduce fitness and survival of freshwater game fish species.
WP015 Life-stage-specific endpoints for estrogen disruptor screening in the zebrafish embryo

L. Vergauwen, University of Antwerp / Zebrafishlab / Dept Veterinary Sciences & SPHERE Dept Biology; E.D. Michiels, J. Perz Stanacev, University of Antwerp / Zebrafishlab / Dept Veterinary Sciences; A. Van Nuijs, University of Antwerp / Toxicological Center; A. Covaci, University of Antwerp / Toxicological Center; S.J. Van Cruchten, University of Antwerp / Applied Veterinary Morphology / Dept Veterinary Sciences; D. Knapen, University of Antwerp / Zebrafishlab / Dept Veterinary Sciences

New and improved approaches are needed to meet evolving regulatory requirements to evaluate ecotoxicity of chemicals worldwide, while at the same time reducing the use of laboratory animals. In this context, the fish embryo offers particular advantages since in several geographic regions, it is not protected under laboratory animals legislations. Additionally, an OECD test guideline for the Fish Embryo Acute Toxicity (FET) test (TG 236) is already available and can be used as a basis to add relevant exposure methods and biological endpoints for specific purposes. The use of fish embryos instead of adult fish can be considered from different perspectives. Either the fish embryo is used as a model for adult fish and adult endpoints are somehow translated and applied in embryos, or embryo-specific endpoints are studied. In this study we used endocrine disruptor screening in the zebrafish embryo as a case study and we investigated the potential of adding life-stage-specific exposure methods and endpoints. The presence of the yolk in early embryos results in an additional exposure route, corresponding to maternal transfer in a real-life scenario. We explored the use of micro-injection into the yolk as a way to dose chemicals, including hydrophobic compounds, to developing embryos. Although time- and dose-dependent estrogen receptor activation profiles were highly similar, we found evidence that the dynamics of molecular processes differed between micro-injection and the traditional aquatic exposure method, causing disruptions of development at distinct life stages and leading to different adverse effects. Adding a typical endpoint for estrogen disruption, vitellogenin protein levels, that is generally used in later life stages, was possible but seemed to provide limited sensitivity in embryos compared to adults or juveniles. Development is tightly regulated by hormones and thus highly sensitive to endocrine disruption. Here we show that neuromast development is indeed very sensitive to estrogen disruption, comparable to endpoints used in adult fish. In conclusion, when using fish embryos as alternatives to adult fish in toxicity testing, one can either choose to apply endpoints that are well-accepted in later life stages, or one can try to find new, embryo-specific endpoints, which may be more relevant and additionally may increase sensitivity.

WP016 Developmental stage at time of exposure is critical for observing toxicity effects in embryos of Atlantic cod exposed to dispersed crude oil

B.P. de Jourdan, Huntsman Marine Science Centre / Environmental and Molecular Toxicology; R.J. Eldridge, A. McCarthy, L.E. Burridge, Huntsman Marine Science Centre

The Atlantic cod (Gadus morhua) embryo is planktonic and floats in the water column near the surface for 2-3 weeks before hatching. This increases the potential exposure of the embryos to the dissolved phase of spilled crude oil, as well as possible surface slicks. There is growing evidence that exposure to contaminants during transient window of sensitivity critical to development could impart imminent lethality. The objective of this study was to characterize sensitivity to exposure of physically and chemically dispersed water accommodated fractions (WAF and CEWAF) of crude oil, during the fertilization, cleavage, blastulation, gastrulation, somitogenesis, pre- and post-hatching periods in Atlantic cod. Test concentrations (8) followed a log based dilution WAF (100%, 10.01%, and 1.0%) CEWAF (31.6%, 3.17%, 0.32%) stock, a dilution water control (seawater), and a dispersant control (Corexit 9500 applied at the same rate as the greatest test CEWAF concentration, based on a volume/volume percentage). Each concentration was replicated 3 times. Exposures were carried out in 25-mL scintillation vials, with 20 mL of exposure media, then after 24 hours the surviving organisms were transferred to 250-mL flasks until hatch. The exposures and subsequent monitoring were conducted in an environmental chamber, where temperature was maintained at 5+/−2°C with lighting for the entire test duration on a photoperiod of 16-hrs light and 8-hrs dark. Monitoring vessels were assessed for mortality and hatching daily, with 80% solution renewals every other day. Endpoints included survival, time to death, time to hatch, and assessment of developmental abnormalities using a modified blue-sac disease (BSD) index. Exposures at the beginning of the embryonic period and during the hatching window proved to be the most sensitive stages, showing a decreased percent hatch and an increase in BSD presentation respectively. Exposures during the middle of embryogenesis did not have a significant impact on hatching success.

WP017 Effects of early life-stage exposure to the novel brominated flame retardant, 1,2,5,6-Tetrabromocyclooctane, on reproductive capacity of zebrafish

D. Van Essen, S. Wiseman, University of Lethbridge / Biology

Brominated flame retardants (BFRs) that are added to many consumer products often are detected in aquatic ecosystems where they have the potential to cause adverse effects on organisms, including fish. The novel BFR 1,2,5,6-Tetrabromocyclooctane (TBCO) has recently been introduced to replace the major use BRF, hexabromocyclododecane (HBCD), and thus its environmental concentration is expected to increase. Little is known about adverse effects of TBCO on aquatic organisms. Based on previous studies with Japanese medaka (Oryzias latipes) it has been suggested that exposure to TBCO during early stages of development might impair oocyte meiosis, which would result in decreased reproductive capacity at sexual maturity. However, definitive studies have not been performed to address this potential effect. The objectives of the current study were to characterize the acute toxicity of TBCO to early life-stages of zebrafish (Danio rerio), investigate the molecular and biochemical mechanisms of toxicity, and determine whether exposure during early-stages of development might impact reproduction. Zebrafish embryos were exposed to a low, medium, or high concentration of TBCO within 30 minutes of fertilization until hatch and endpoints were measured over a five-day exposure. Exposure to TBCO increased mortality in a concentration-dependent manner that correlated with decreased heart rate. Exposure to low, medium, and high concentration resulted in 31.0, 58.3, and 71.0 % mortality, respectively. In comparison with the mean heart rate of control embryos, exposure to low, medium, and high concentration decreased heart rate by 20.8, 45.3, and 64.4 beats per minute, respectively. TBCO also increased the incidence of spinal curvature and uninfated swim bladders in a concentration-dependent manner. Incidence of spinal curvature among larvae exposed to low, medium, and high concentration decreased heart rate by 10.2, 59.6, and 96.5 % respectively. Similarly, incidence of uninflated swim bladders was 11.5, 65.2, and 93.6 %. Based on the mRNA abundance of genes important for the response to oxidative stress, the observed effects were not due to this mechanism of toxicity. Fish exposed to TBCO as embryos are currently being reared to sexual maturity in freshwater to examine reproductive capacity, including molecular (genomic and epigenomic) and biochemical processes that regulate oogenesis and gonad development and function.

WP018 Developmental exposure to venlafaxine suppresses growth in zebrafish

W.A. Thompson, University of Calgary / Biology; M.M. Vijayan, University of Calgary / Biological Sciences

Venlafaxine is a selective serotonin and norepinephrine reuptake inhibitor commonly prescribed to treat depression, anxiety, and mood disorders in humans. Due to excessive usage, this compound is commonly found in aquatic ecosystems globally, appearing in concentrations ranging from ng/L to µg/L. However, the consequences following developmental exposure to venlafaxine on non-target organisms are only beginning to emerge. We have previously shown that venlafaxine affects brain development and behavior in early life stage zebrafish (Danio rerio), but no studies have tested whether this drug
impacts growth. This is particularly critical, as programming changes due to early developmental venlafaxine exposure may alter growth trajectories. Here we tested the hypothesis that venlafaxine deposition in the embryo disrupts the endocrine growth axis leading to the suppression of postnatal growth in zebrafish. We injected zebrafish embryos between the 1-4 cell stage with either vehicle, 1 or 10 ng of venlafaxine. We followed the growth trajectory of zebrafish up to 60 days post-fertilization (DPF). At 60 DPF, fish were sampled for liver, muscle, and brain tissue, and assessed for basal cortisol levels, hepatosomatic index, and growth- and feeding-related molecular markers. There was significant reduction in body mass at 45 and 60 DPF in juveniles raised from venlafaxine-treated embryos. To assess if feeding is perturbed by the drug, we recorded food consumed over a 30-minute period in size matched fish at 120 DPF. Venlafaxine (10 ng) deposition in embryos reduced feed acquisition in adults. Venlafaxine did not affect basal cortisol levels, but disrupted the transcript abundance of genes involved in growth, including IGF-1, IGF-2, and leptin 1a in the liver. Overall, developmental exposure to venlafaxine suppresses growth, and this may involve endocrine disruption of the growth and feeding axis in zebrafish.

WP019 The sulfate metabolite of 3,3’-Dichlorobiphenyl (PCB-11) impairs Cypla activity and increases hepatic neutral lipids in zebrafish larvae (Danio rerio)

M. Roy, University of Massachusetts, Amherst / Environmental Health Sciences; P.R. Duche, University of Massachusetts, Amherst; K.C. Hornbuckle, University of Iowa / Civil and Environmental Engineering; A.R. Timme-Laragy, University of Massachusetts / Environmental Health Sciences

3,3’-Dichlorobiphenyl (PCB-11) is a lower-chlorinated PCB congener that is a byproduct of diarylide pigment manufacturing, and both PCB-11 and its metabolites have been detected in human samples. Our previous research in zebrafish (Danio rerio) demonstrates that static exposures to 20 µM PCB-11 starting at 1 day post fertilization (dpf) can stunt liver growth, and in co-exposures with other aryl hydrocarbon receptor (Ahr) agonists, PCB-11 can inhibit Cypla function to either prevent or exacerbate cardiovascular and craniofacial malformations, depending on the co-exposure. In this study, we tested whether two prevalent PCB-11 metabolites, OH-PCB-11 and PCB-11-Sulfate drive these effects, as well as whether chronic single exposures to PCB-11 or the two metabolites result in increased hepatic neutral lipid accumulation. Wildtype AB embryos were statically exposed to 0.002-20 µM OH-PCB-11 or 0.2-20 µM PCB-11-Sulfate from 1-4 dpf using the live EROD bioassay to assess Cypla activity and morphological growth, and then co-exposed to these same concentrations with either of the Ahr agonists 5 nM 3,3’,4’,5-Pentachlorobiphenyl (PCB-126) or 100 µg/L Benz[a]pyrene (B[a]P). In a separate experiment, fish were also exposed daily to 0.2 µM of either PCB-11, OH-PCB-11, or PCB-11-Sulfate from 1-15 dpf and assessed for neutral lipid accumulation using Oil-Red-O staining. Our results show that 2 and 20 µM OH-PCB-11 was lethal, but fish exposed to 0.002-0.2 µM OH-PCB-11 and 0.2-20 µM PCB-11-Sulfate developed normally with low Cypla activity. In both co-exposure experiments, all co-exposure groups did not differ in morphological development as compared to their respective Ahr agonist control groups. However, 20 µM PCB-11-Sulfate significantly lowered Cypla activity for both PCB-126 and B[a]P, from 500% and 300% activity, respectively, to DMSO exposure group levels. In chronic exposure experiments, fish exposed to PCB-11-Sulfate had a significant 30% increase in lipid accumulation levels as compared to the DMSO exposure group. These findings indicate that an acute 20 µM concentration of PCB-11-Sulfate may affect Cypla activity in the presence of Ahr agonists, and that lower 0.2 µM chronic concentrations of PCB-11-Sulfate can increase hepatic neutral lipid accumulation in early development. Further studies to confirm Cypla activity via qPCR and to test chronic exposures in the presence of Ahr agonists would help better elucidate the effects of this environmental contaminant.

Behavioral Ecotoxicology in the Lab and Beyond: Incorporating Environmental Complexity and Relevance

WP020 Identification of Environmental Pollutants Impairing Escape Response in Fish Larvae by using the Vibrational Startle Response Assay

M.D. Faria, X. Wu, IDAEA-CSIC / Environmental Chemistry; E. Prats, CID-CSIC; D. Raldua, IDAEA-CSIC / Environmental Chemistry

Predation is one of the main sources of mortality of fish at all life stages, but particularly for fish larvae. Whereas escape response is a behavioral reflex promoting larval survival to predator’s strikes, unnecessary escape responses have a high energetic cost and increase the risk of predation. Therefore, habituation of this response to irrelevant stimuli results is also essential for larvae survival. In spite of the ecological relevance of this response, the potential effect of the different environmental pollutants present in surface water on fish escape response is largely unknown. Recently we developed and validated the Vibrational Startle Response Assay (VSRA), an automated in vivo assay for identifying chemicals impairing the escape response and its habituation in zebrafish larvae. Now, we have used this assay to screen a group of 25 environmental pollutants previously recognized as neurotoxic, at environmentally relevant concentrations. The results demonstrate that some of these compounds have a significant effect on the arousal an/or the habituation of the vibrational-evoked escape response. We are currently assessing the predictivity value of VSRA by analyzing if the identified positive hits show a significant decrease on the survival to dragonfly strikes, and some preliminary results will be shown.

WP022 Effect of two pesticides (chlorpyrifos and imidacloprid) on the avoidance behavior of earthworm (Eisenia fetida)

Pesticides are among the most widespread environmental contaminants. Chlorpyrifos (O,O-diethyl O-(3, 5, 6-trichloro-2-pyridyl) (CPF) is a broad-spectrum organophosphate insecticide characterized by a P-O-C linkage and it is toxic for aquatic and terrestrial organisms. Its mode of action is based on a rapid phosphorylation of acetylcholinesterase (ACHE), an important enzyme involved in the neurotransmission processes in organisms. Imidacloprid (1-(6-chloro-3-pyridylmethyl)-N-nitroimidazolidin-2-ylidineamine (IMI) is a systemic neonicotinoid insecticide used to control sucking insects in crops that impacts the nicotine acetylcholine receptors; recently it was restricted in Europe as responsible for harmful effects on bees. The earthworm Eisenia fetida was selected as test organism according to the OECD standard guidelines (OECD 2004); the organisms were bought from a vermicomposting company in the north of Italy and maintained at 20 ± 2°C before and during the test. Two section-chambers (210x110mm) were filled with 250 mg (dry weight basis) of soil substrate (OECD soil), prepared by mixing quartz sand, kaolin clay and sphagnum peat in the proportion 70: 20: 10%. The soil was then spiked with the pesticides and adult worms (300-600 mg, wet weight) with well-developed clitellum were randomly introduced into the soils. The organisms were exposed simultaneously to the soil samples spiked with the pesticide and to the control soil (without pesticides). After a test period of 48h, the position of the animals was determined. Five different concentrations of CPF and IMI (1, 5, 10, 20 and 50% of 14d-LC50) were tested in three replicates. Residual concentrations of pesticides were determined over time by GC/MS-MS for CPF and by LC/MS-MS for IMI, respectively. At the end of the exposition, for each replicate the net response (NR, expressed as percentage) on worm behavior was calculated as follows: NR = ((C -T)/10) x 100 where: C = sum of earthworm behavior observed in the control soil, T = sum of earthworm behavior observed.
in the treated soil; 10 = total number of earthworms per each replicate. Earthworms play an important role in agricultural soils, maintaining and improving soil structure and fertility. The avoidance behavior test resulted as an important screening tool in soil eco-toxicology, because it is a low-cost method, with very simple test design, and can provide an early warning signal for environmental protection.

WP023 Effects of Fluoxetine and Predation Risk Span Generations in a Freshwater Snail
L.E. Beaty, Pennsylvania State University, Erie / Biology; N. Colvin, Pennsylvania State University, Erie; A.M. Simpson, Penn State, Erie / The Behrend College / Biology

Appropriate anti-predator responses are critical for prey species; these responses to predation risk are governed in part by serotonergic signaling. Wastewater effluent commonly contains compounds that can influence the action of serotonin. Fluoxetine (FLX), the active ingredient of Prozac(R), is a selective serotonin reuptake inhibitor, which may affect serotonergic signaling in freshwater animals and thus alter their responses to predation risk. The objective of this study was to determine how predation risk and FLX interact to influence the phenotype of Physid snails across two generations. We applied six treatments with three levels of FLX (0 µg/L, 0.1 µg/L, and 1.0 µg/L) and two levels of predation risk (presence/absence of crayfish cue) to F1 snails and quantified the behavior, morphology, and reproduction of F2 snails. We found that both FLX and predation risk experienced by F1 snails influenced the behavioral responses of F2 snails to perceived predation risk. Given that FLX is ubiquitous in wastewater effluent, future studies should examine the influence of FLX on trophic interactions to obtain a clearer picture of the potential ecosystem effects of this pharmaceutical.

WP024 2,4-Dichlorophenoxyacetic acid containing herbicide impairs essential visually guided behaviors of larval fish
G. Dehnert, University of Wisconsin, Madison / Zoology; W.H. Karasov, University of Wisconsin, Madison / Forest and Wildlife Ecology; M. Wolman, University of Wisconsin, Madison / Integrative Biology

Aquatic herbicides are used worldwide to eradicate nuisance and invasive plants despite limited knowledge of their toxicity to non-target organisms. 2,4-Dichlorophenoxyacetic acid (2,4-D) is a common active ingredient in commercial herbicide formulations, which triggers plant cell death by mimicking the plant-specific hormone auxin. Application practices of 2,4-D commercial herbicides typically coincide with yearly freshwater fish spawning periods. This practice exposes fish to xenobiotics at their vulnerable larval stages. The full impacts of 2,4-D on larval fish remains poorly understood, and hence, whether it may alter larval survival, larval behavior, fish populations, and ecosystem dynamics. In the present study, we exposed embryonic and larval zebrafish (Danio rerio) to the active ingredient 2,4-D (pure 2,4-D) or a 2,4-D containing commercial herbicide DMA4(R)IVM (DMA4) and evaluated morphology, survival, behavior, and nervous system function. At 2,4-D concentrations producing no overt morphological defects during embryonic or early larval stages, we observed reduced survival throughout a 21-day larval assay (4-8 ppm DMA4 and 0.75-4 ppm pure 2,4-D). Notably, prey capture, a behavior essential to survival, was reduced in 2,4-D-exposed larval zebrafish (4-8 ppm DMA4 and 0.75-4 ppm pure 2,4-D) and yellow perch (Perca flavescens) (4-20 ppm DMA4). In zebrafish, 8 ppm DMA4 exposure reduced prey capture when exposure was restricted to the period of visual system development. Consistent with these results, larval zebrafish exposed to 8 ppm DMA4 showed reduced neural activity within the optic tectum following prey exposure. Together, our results suggest that 2,4-D alters the development and function of neural circuits underlying vision of larval fish, and thereby reduces visually guided behaviors required for survival.

WP025 Effect of Elevated Embryonic Incubation Temperature on the Temperature Preference of Juvenile Lake Whitefish (Coregonus clupeaformis)
A. Harman, B. Aggarwal, M. Fuizen, McMaster University / Biology; D. Boreham, Northern Ontario School of Medicine / Medical Sciences; C. Somers, R. Manzon, University of Regina / Biology; J.Y. Wilson, McMaster University / Department of Biology

Lake whitefish (Coregonus clupeaformis) is an economically, and ecologically important species that has a wide distribution across Canada and Northern USA. Lake whitefish (LWF) spawn in shallow coastal areas in early winter, subjecting embryos to temperature fluctuations caused by thermal effluent discharged by coastal power stations. Previous research shows that LWF embryos incubated at 8°C experience increased mortality and altered metabolic/heart rate. They also display an “early hatch phenotype” exhibiting less developed body features, which may affect fitness during early development. Using a Loligo(R) shuttle box system, this study compares temperature preference (median occupied temperature) of juvenile LWF post-hatch, by exposing them to a range of temperatures and recording the behavioral response. Behavioral tests were optimized for a two-hour acclimation period (static) followed by two hours of data collection (dynamic). The temperature preference of LWF juveniles incubated at elevated temperatures (5°C, 8°C) will be compared to those incubated at the control temperature (2°C). Elevated temperature treatments are predicted to modify the temperature preference of juvenile LWF. The effect of body size, as a confounding variable, is being examined. The results of this study will be used to help inform management decisions on thermal effluent discharged into Lake Huron.

WP026 Developmental exposure to environmentally-relevant concentrations of four pesticides induces hypo- or hyperactivity in Delta Smelt larvae
P. Mundy, University of California, Davis / Anatomy, Physiology & Cell Biology / School of Veterinary Medicine; M. Carte, University of Namur / Zoology; K.E. Huff Hartz, University of Wisconsin, Madison / Zoology; M.C. Somers, R. Manzon, University of Regina / Biology

Behavioral tests can be a powerful tool for screening the neurotoxicity of compounds. Here we describe the development of a high-throughput system to evaluate contaminant impacts on the critically sensitive early-life stages of Delta Smelt (Hypomesus transpacificus), an endangered teleost species native to the California San Francisco Bay Delta (SFBD), USA. Leveraging the natural behavior of larval Delta Smelt, whereby they increase movement in bright light and decrease movement in the dark, we developed a test using a cycle of light and dark periods in a closed chamber, using light switching as a reliable stimulus to test hyper- or hypoactivity. Larval behavior was tracked using EthoVision software for total movement in each period. We used this test to evaluate the effect of four commonly used pesticides (bifenthrin, permethrin, fipronil, and chlorpyrifos) at environmentally-relevant concentrations, varying 100-fold in concentration. At 96 hours of exposure, all concentrations of bifenthrin caused hyperactivity during the light cycles in larval smelt compared to control. The highest concentration of permethrin caused hyperactivity in the light period at 48 and 72 h of exposure, and hyperactivity in the light period of 96 h of exposure. All concentrations of permethrin caused hyperactivity at 96 h of exposure in the dark periods. The highest concentration of chlorpyrifos caused hypoactivity in the dark periods at 48, 72, and 96 h, and hyperactivity in the light periods at 96 h of exposure. At 48 and 72 h of exposure, the highest concentration of fipronil caused hyperactivity in the light periods. These results indicate that this behavioral test is highly sensitive in determining the impact of
environments of high to varying crude oil concentrations prior to being tested for exploration, transportation, and disposal. Effects on predation, for example, can occur at much lower concentrations than mortality but also have the potential to alter the health of individuals and to impact inter-species interactions. The goal of this research was to better understand the role that neonicotinoids play in predator-prey interactions and how these might compare to results from published toxicity studies. For this research, we used the neonicotinoid pesticide, imidacloprid, as it was the first compound in the class to be developed and is still widely used. We have found that endpoints such as immobilization occur at concentrations that are not environmentally relevant, as a 48-hour acute D. magna acute immobilization test yielded an LC50 of 70.8 mg/L. Clearly, the use of D. magna may not be sufficient to inform toxicity values because of their relative tolerance. D. magna, however, may be an ideal candidate for a prey species in an essay to evaluate impacts of imidacloprid on predatory behavior. As an example, Odenate larvae will be used to develop an assay to determine the effects of environmentally relevant imidacloprid concentrations on predator efficiency. The LC50 from D. magna will be used to inform further experimentation with Odenate larva, a potentially more sensitive species. The ultimate goal of this research is to better understand the potential ecological effects of neonicotinoid pollution as a result of behavior alteration in sensitive predators.

WP028 Evaluating the behavioral sensitivity of two common larval fish models to changes in salinity
K.R. Scarlett, Baylor University / Environmental Science; B. Steele, Baylor University / Biomedical Studies; B.W. Brooks, Baylor University / Department of Environmental Science

Increased salinization of inland waters due to anthropogenic activity can lead to a wide variety of crucial ecological and economic environmental concerns. Elevated salinity can alter essential osmoregulatory mechanisms, physiological functions and species interactions in aquatic ecosystems. Herein, behavioral responses have been employed to examine environmental stress due to unique integrations of these effects among the physiology and ecology of an organism with the surrounding environment. Because changes in salinity gradients can alter environmental conditions, it is important to also understand how salinization may influence interactions in aquatic ecosystems. Using two common fish models, fathead minnow and zebrafish, we investigated changes in swimming activity during interchanging photoperiods with the exposure of different sodium chloride (NaCl) concentrations. Treatment levels examined were derived from the calculation of LC50 values for both species (60% LC50, 40% LC50, 20% LC50, 10% LC50, 5% LC50). Standardized (OECD FET, EPA WET) experimental guidelines were used for experiments with fathead minnow and zebrafish. Each organism was exposed for 96 hrs. to NaCl, before photomotor and locomotor responses were observed using a behavioral analysis software (ViewPoints). Following previously reported methods from our laboratory, behavioral observations occurred for 50 min., including 10 min. of acclimation, two 10 min. dark periods, and two 10 min. light periods. Zebrafish displayed more pronounced photomotor responses to changing photoperiods and more consistent statistically significant (p< 0.01, p< 0.05, and p< 0.1) behavioral changes at the highest salinity (60% LC50 or 5.786 g/L), though these responses depended on speed thresholds. Fathead minnows swimming behaviors were significantly affected primarily in the freezing and cruising speed thresholds; however, these responses were only significant (p< 0.01, p< 0.05, and p< 0.1) at the highest salinity treatment level (60% LC50 or 5.646 g/L). These results suggest that behavioral responses of fathead minnows are less sensitive to NaCl than zebrafish. Such information can be useful in understanding how changes in salinity gradients can alter locomotor behavior in combination with chemical and nonchemical stressors.

WP029 Addressing social complexity: Does a pharmaceutical pollutant affect dominance hierarchies in brown trout?
E. McCallum, Swedish University of Agricultural Sciences SLU; T. Brodin, Swedish University of Agricultural Sciences (SLU) / Department of Wildlife, Fish and Environmental Studies

Psychiatric pharmaceuticals (e.g., antidepressants, anxiolytics) in the environment have been gaining research attention because of their potential to modulate the behaviour and physiology of aquatic wildlife in a manner that may be detrimental for their fitness. The majority of studies to date have measured the behavioural and physiological effects of pharmaceutical compounds on individuals in isolated trials. Yet, animals often live with multiple conspecifics and take part in a variety of social interactions each day. To better understand how pharmaceutical contaminants affect animals in a more complex and realistic social setting, we exposed groups of four brown trout (Salmo trutta) to three treatments of a anxiolytic pharmaceutical commonly detected in municipal wastewater (oxazepam, benzodiazepine: 0 µg/L control, 1.5 µg/L low, or 30 µg/L high). We recorded aggressive interactions and the formation and stability of dominance hierarchies in these groups across five days. We expected exposed fish to be less aggressive and for dominance hierarchies to be less stable over time when compared to controls. Following behavioural trials, we sampled and analyzed plasma cortisol to determine if any exposure-related changes in aggressive behaviours were associated with reduced cortisol levels. Upscaling research to address the social complexity that animals experience in the wild is important for understanding the effects of pollutants in ecologically realistic scenarios.

WP030 Effects of crude oil exposure on teleost personality behaviors
A. Khursigara, University of Texas, Austin / Marine Science Institute; A. Esbaugh, University of Texas / Department of Marine Science

As a major aquatic environmental toxicant of concern, the impacts of crude oil exposure on marine fishes have been highly studied. However, much of this work has focused on oil-induced cardiotoxicity and the subsequent downstream impacts this may produce. Recent work suggests that neurological function is also impaired and may be just as sensitive as these cardiotoxic endpoints. Transcriptomics data from exposed larval fish showed that pathways related to neurological and cognitive function were severely disrupted, which was accompanied by a significant reduction in brain size. While there have been a few studies that have shown that acute oil exposures can reduce sociability and increase aggression in fish, there still remains a large gap in our understanding of the scope and significance of these alterations in behavior. The aim of this study was to not only investigate the potential impacts that oil exposure can have on individual personality traits, but the effect it may have on behavioral syndromes. Using the model species Danio rerio, fish were acutely exposed to varying crude oil concentrations prior to being tested for exploration,
activity, boldness, and sociability. Preliminary evidence suggests that oil exposure promotes a proactive archetype that coincides with reduced anti-predator behavior.

**WP031 Effects of the antihistamine fexofenadine on behavior and life-history of damselfly larvae is dependent on food availability**

T. Brodin, Swedish University of Agricultural Sciences (SLU) / Department of Wildlife, Fish and Environmental Studies; J. Fick, Umeå University / Department of Chemistry

Insects are the most abundant and diverse group on earth and a pivotal part of aquatic ecosystems. Recent reports show dramatic large-scale declines in insects and one factor suggested to explain this is pollution. Aquatic insects have been shown to bioconcentrate pharmaceuticals and also be affected by them behaviourally. Here I present new data on how behaviour and life-history of damselfly larvae is affected by the anti-histamine fexofenadine, and how this effects are affected by food availability. Larvae grew and developed faster without fexofenadine, but only under restricted food availability. This finding has implications for risk-assessments based on endpoints connected to life-history.

**WP032 Environmental nontargeted metabolomics of fish brains and other organs - can we scale from the lab to streams?**

K. Grubicova, R. Grabic, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters / South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocones; M.S. Santos, University of South Bohemia in Ceske Budejovice; G. Fedorova, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters / South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocones; P. Horky, O. Slavik, Czech University of Life Sciences Prague / Faculty of Agrobiology, Food and Natural Resources / Department of Zoology and Fisheries; B.W. Brooks, Baylor University / Department of Environmental Science; T. Randak, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters / South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocones

Behavioral alterations caused by presence of psychoactive compounds (e.g., pharmaceuticals, illicit drugs, pesticides, metabolites) in aquatic systems represent an emerging ecological issue that is not adequately assessed during regulatory risk assessments. Though there are number of laboratory studies providing evidence of diverse effects and potential adverse outcomes, upscaling subchronic laboratory experiments with single compounds (or simple mixture) to streams and other receiving systems in the field is challenging. We carried out a six month experiment with visible implant elastomer tagged wild brown trout restocked from a reference portion of a wadeable stream to a polluted reach. A WWTP effluent discharge, which contributed to 30% contribution to instream flow, affected part of the stream that is separated from upstream reference conditions in a downstream location with barriers to fish migration. We obtained useful information on concentration and bioaccumulation of psychoactive compounds across different exposure times and seasons, but this experiment design did not allow any evaluation of fish behavior. However, we have behavioral responses from laboratory studies with the same or similar species. We then employed LC-HRMS analysis to examine tissues from all laboratory and field specimens from exposures and controls. Sertraline was confirmed to highly bioaccumulate in brain tissues, and correlated with behavioral responses, unlike other substances accumulating in fish brains to a lower extent. However, nontargeted metabolomics of brain extracts showed significant changes among all groups (1, 3 and 6 months of exposure, and corresponding controls) in wild fish. When differences among controls in different seasons (postspawning, low activity and startup - 1, 3 and 6 months) were considered, we observed even more significant differences with exposed fish. Because it is difficult to separate markers of effect from compounds that were specifically observed to appreciably bioaccumulate, we applied specific markers obtained from laboratory studies of methamphetamine, citalopram, to examine whether similar responses exist under natural conditions. Such tissue specific metabolomics approaches appear promising for interpreting contaminant exposures during laboratory experiments and field observations. The study was financially supported by Czech Science Foundation (No. 16-06498S), the Ministry of Education, Youth and Sports of the Czech Republic - projects „CENAKVA“ (LM2018099), „CENAKVA Center Development“ (No. CZ.1.05/2.1.00/19.0380).

**WP033 The psychoactive pollutant fluoxetine compromises anti-predator behaviour in fish**

J.M. Martin, M. Saaristo, M.G. Bertram, Monash University / Biological Sciences; P.J. Lewis, RMIT University / School of Science; T.L. Coggan, RMIT University; B. Clarke, University of Melbourne / School of Chemistry; B.B. Wong, Monash University / School of Biological Sciences

Pharmaceuticals are increasingly being detected in aquatic ecosystems worldwide. Particularly concerning are pharmaceutical pollutants that can adversely impact exposed wildlife, even at extremely low concentrations. One such contaminant is the widely prescribed antidepressant fluoxetine, which can disrupt neurotransmission and behavioural pathways in wildlife. Despite this, relatively limited research has addressed the behavioural impacts of fluoxetine at ecologically realistic exposure concentrations. Here, we show that 28-day fluoxetine exposure at two ecologically relevant dosages done representing low surface water concentrations and another representing high effluent flow concentrations darters antipredator behaviour in Eastern mosquitofish (Gambusia holbrooki). We found that fluoxetine exposure at the lower dosage resulted in increased activity levels irrespective of the presence or absence of a predatory dragonfly nymph (Hemianax papuensis). Additionally, irrespective of exposure concentration, fluoxetine-exposed fish entered the predator ‘strike zone’ more rapidly. In a separate experiment, fluoxetine exposure reduced mosquitofish freezing behaviour common antipredator strategy following a simulated predator strike, although, in females, this reduction in behaviour was seen only at the lower dosage. Together, our findings suggest that fluoxetine can cause both non-monotonic and sex-dependent shifts in behaviour. Further, they demonstrate that exposure to fluoxetine at environmentally realistic concentrations can alter antipredator behaviour, with important repercussions for organismal fitness.

**WP034 Bisphenol S impairs learning behavior in adult female zebrafish by interfering with the ERK/CREB/BDNF pathway**

M. Naderi, A. Salahinejad, A. Attaran, D.P. Chivers, S. Niyogi, University of Saskatchewan / Biology

Bisphenol S (BPS) is a chemical that is widely used in numerous consumer products including polycarbonate plastics, epoxy resins, and thermal receipt papers as a replacement for bisphenol A, which is a well-known xenoestrogen. Growing evidence shows that BPS can interfere with several neuroendocrine systems in animals. In this study, we investigated the effects of chronic exposure to environmentally relevant concentrations of BPS on learning and memory in adult female zebrafish. To determine the mechanisms underlying BPS neurotoxicity, we focused on the ERK/CREB/BDNF pathway, which is associated with the neurotrophic/neuroprotective effect of estrogens on the central nervous system. Adult female zebrafish were exposed to either vehicle (DMSO), estradiol (1ug/l), or BPS (1, 15 and 30 μg/l) for 120 days. Fish memory was assessed in the object recognition task and object placement task. To this end, fish were exposed to two identical objects for 15 min. After a 24 h delay (retention interval), subjects were allowed to explore an object identified from a reference portion of a wadeable stream to a polluted reach. A WWTP effluent discharge, which contributed to 30% contribution to instream flow, affected part of the stream that is separated from upstream reference conditions in a downstream location with barriers to fish migration. We obtained useful information on concentration and bioaccumulation of psychoactive compounds across different exposure times and seasons, but this experiment design did not allow any evaluation of fish behavior. However, we have behavioral responses from laboratory studies with the same or similar species. We then employed LC-HRMS analysis to examine tissues from all laboratory and field specimens from exposures and controls. Sertraline was confirmed to highly bioaccumulate in brain tissues, and correlated with behavioral responses, unlike other substances accumulating in fish brains to a lower extent. However, nontargeted metabolomics of brain extracts showed significant changes among all groups (1, 3 and 6 months of exposure, and corresponding controls) in wild fish. When differences among controls in different seasons (postspawning, low activity and startup - 1, 3 and 6 months) were considered, we observed even more significant differences with exposed fish. Because it is difficult to separate markers of effect from compounds that were specifically observed to appreciably bioaccumulate, we applied specific markers obtained from laboratory studies of methamphetamine, citalopram, to examine whether similar responses exist under natural conditions. Such tissue specific metabolomics approaches appear promising for interpreting contaminant exposures during laboratory experiments and field observations. The study was financially supported by Czech Science Foundation (No. 16-06498S), the Ministry of Education, Youth and Sports of the Czech Republic - projects „CENAKVA“ (LM2018099), „CENAKVA Center Development“ (No. CZ.1.05/2.1.00/19.0380).
significantly less time exploring the novel/moved object compared with the control group, indicating an impaired memory in fish. This was associated with a reduction in phosphorylation of ERK and CREB proteins and downregulation of the BDNF gene in the brain. Taken together, our results suggest that BPS affects fish memory in a dose-dependent manner and its effects are mediated through the ERK/CREB/BDNF pathway.

WP035 Perfluorooalkyl substances in Bluegill (Lepomis macrochirus) and its relationship to liver histology and swimming performance
C. Coy, P.A. Moore, Bowling Green State University / Department of Biological Sciences; R. Belanger, University of Detroit, Mercy / Department of Biology; T. Newcomb, Michigan Department of Natural Resources

Per- and poly-fluorinated alkyl substances (PFAS) can be found in many household, industrial, and personal care products, including furniture, aqueous fire-fighting foam, and sunscreen. PFAS entered the environment through wastewater treatment plant effluent, leaching of fire-fighting foam into groundwater at application sites, and landfill leachate. Many recent studies have shown PFAS in surface waters and aquatic organisms around the world. PFAS levels are higher near contamination sources, such as Wurtsmith Air Force Base in Oscoda, Michigan, USA. Unexpectedly, PFAS levels have not biomagnified in Clark’s Marsh near Wurtsmith Air Force Base. Bluegill (Lepomis macrochirus) in Clark’s Marsh have higher PFAS levels than their predators, however, the reasons and effects of these high levels are unknown. To investigate these effects, Bluegill were sampled in Clark’s Marsh, Van Etten Lake, Lower Au Sable River, and Crooked Lake (Emmet County). Bluegill were individually tested for critical swimming speed, liver PFAS concentrations, and liver histology. The data collected was analyzed spatially and quantitatively to determine differences between PFAS effects at different sites and with different levels of PFAS. We hypothesize that higher PFAS levels will relate to higher amounts of vacuoles in liver tissue and a slower critical swimming speed. This research will help to determine how PFAS affects fish physiologically and behaviorally in environmentally relevant concentrations. Ultimately, this information will investigate how PFAS effects fish within an individual and potentially, an entire population.

WP036 Fish living near two wastewater treatment plants have unaltered behaviour and thermal tolerance but show changes in organ and tissue traits
S. Balshing, McMaster University / Department of Psychology, Neuroscience & Behaviour; K. Nikel, University of Waterloo / Biology; E.S. McCallum, Swedish University of Agricultural Sciences (SLU) / Department of Psychology Neuroscience Behaviour; H. Mehdi, S.N. Du, G. Scott, McMaster University / Department of Biology

Municipal wastewater treatment plants (WWTPs) are a significant source of anthropogenic pollutants and can pose a serious environmental stressor on aquatic ecosystems. In this study, we examined whether living close to WWTPs disrupted behaviour, thermal tolerance; b>c< b>and gross morphology in two native freshwater fishes: bluegill (Lepomis macrochirus) and green sunfish (Lepomis cyanellus), and one invasive species, the round goby (Neogobius melanostomus). There were appreciable differences in behavior across species: green sunfish were the most active and exploratory and bluegill spent more time under shelter. However, there were no behavioural differences within any of the three species between the fish collected from contaminated sites downstream of the WWTPs compared to fish collected from less impacted reference sites. Upper thermal tolerance (critical thermal maximum, CTmax) also differed among species (green sunfish > bluegill > round goby), but CTmax was similar between fish from highly contaminated and fish from cleaner reference sites. Fish caught near WWTPs had larger body and liver masses, and higher haemocrit compared to fish caught from the reference sites. Our results suggest that fish in the wild have some capacity to cope with any disruptive effects of exposure to WWTP effluent on the underlying physiological determinants of behaviour or thermal tolerance.

Poster Only: Application of Metabolomics in Effect and Exposure Assessment of Environmental Stressors

WP037 Metabolomic Analysis of Neonates and Adult Daphnia magna Exposed to Acetaminophen
E. Lari, University of Toronto / Biological Sciences; T. Jeong, University of Toronto, Scarborough / Department of Physical and Environmental Science; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences

As the pharmaceutical industry expands and the human population and longevity increases, more drugs are used and processed each day. Inevitably, these pharmaceuticals find their way into wastewater through human excretion and improper disposal. Thus, pharmaceuticals have been recently recognized as contaminants of emerging concern in aquatic environments. We investigated the impacts of acetaminophen - an over the counter drug that is frequently detected in wastewa - effluents and freshwater ecosystems - on the metabolic profile of neonate (less than 24-h-old) and adult (14-days-old) Daphnia magna. The study also investigates differences in Daphnia life stage on the sub-lethal toxicity of contaminants. Neonate and adult daphnids were exposed to 1, 5, or 10% of median effective concentration (EC50) of acetaminophen for 48 h. Following the exposure to sub-lethal concentrations, the metabolic profile of daphnids was investigated using targeted liquid chromatography-tandem mass spectrometry (LC-MS/MS) which measures 51 metabolites in D. magna. The result showed that acetaminophen changes the metabolome of both adult and neonate D. magna. However, the metabolic response of the two life stages differed. These observations at the molecular level might result in different manifestations at the organismal level. The results of the present study emphasize the importance of investigating the adverse impacts of environmental stressors, such as sub-lethal concentrations of acetaminophen, on different life stages of the receiving organisms.

WP038 1H NMR metabolomics applied to investigate metabolic changes from sub-lethal toxicity of disinfection by-products to Daphnia magna
L. Labine, University of Toronto / Department of Chemistry; A.J. Simpson, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences

Daphnia magna is a keystone species often used in environmental metabolomic studies to assess the impacts of anthropogenic stressors in aquatic environments. Disinfection by-products such as haloacetic acids (HAAs) are routinely discharged into freshwater ecosystems. Using D. magna, a 48-hour sub-lethal exposure to dichloroacetic acid (DCAA), trichloroacetic acid (TCAA), dibromoacetic acid (DBAA) and a mixture of equitoxicity of all three HAAs at varying sub-lethal concentrations, we investigated changes in the D. magna metabolic profile using 1H nuclear magnetic resonance (NMR) spectroscopy and multivariate statistics. Principal component analysis (PCA) showed statistically significant changes to the metabolome when D. magna was exposed to DCAA and to the HAA mixture. PCA scores plots of TCAA and DBAA resulted in a shift of the metabolome relative to the control but these were not significantly significant due to the large variation in D. magna responses. Quantification of metabolites found significant changes in proline, alanine and lactate. While other metabolite changes may not have been found to be significant, all of the 18 evaluated metabolites differed from the control. Pathway analysis showed that the chlorinated analogues (DCAA and TCAA) significantly disrupt the alanine, asparagine and glutamate metabolism pathways. Disruptions in this pathway could also alter other linked pathways such as the glycolysis and the citric acid cycle. For example, glutamate increases the rate of pyruvate transformation to alanine and is consistent with the observed changes in
alanine with exposure. Sub-lethal exposure to the mixture demonstrates an increase in metabolic changes which could suggest the presence of additive or synergistic interactions between the contaminants within the class. Sub-lethal exposure to HAAs alters the metabolism of D. magna and highlights the sensitivity of NMR-based metabolomics for detecting subtle perturbations to aquatic dwelling organisms.

WP039 Metabolic profiling of Daphnia magna sub-lethal exposure to phthalates using liquid chromatography tandem with mass spectrometry

E.A. Oliveira Pereira, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences

Phthalates are commonly used and added to plastics for flexibility, durability, and/or longevity. Due to their wide use in plastic products and the fact that they are not chemically bound to the plastic polymer, phthalates have been detected in a variety of aquatic and terrestrial ecosystems. *Daphnia magna* is a keystone freshwater organism, positioned at an intermediate level in many aquatic food chains, and is frequently used in ecotoxicological studies as a sentinel species for the toxicity assessment of pollutants. In this study, the *D. magna* metabolome is investigated to assess the sub-lethal toxicity of three phthalates (dimethyl phthalate, diethyl phthalate, and dibutyl phthalate). In a 48-h acute preliminary test, *D. magna* was exposed to a fraction of the concentration reported in the literature as EC50 (concentration that induces a response to a toxicant in half of the population) for the three phthalates. All organisms survived at the sub-lethal concentrations pertaining to 50%, 25%, 10%, and 5% of the respective EC50 values. *D. magna* was then exposed to the same concentrations of the three phthalates in a 48-h acute investigation. Targeted metabolite analysis by liquid chromatography tandem with mass spectrometry (LC-MS/MS) was used to quantify 51 metabolites that are linked to various biochemical pathways. Amino acids, nucleosides, nucleotides, neurotransmitters, and energy-related metabolites are among the 51 metabolites. Principal component analysis (PCA) was used to evaluate variations within the dataset for the different exposures relative to the control group. Metabolite changes were used in pathway analysis to ascertain which metabolic pathways were perturbed with sub-lethal exposure to dimethyl phthalate, diethyl phthalate, and dibutyl phthalate. This study highlights the sensitivity of metabolic profiling for measuring toxic responses to sub-lethal exposure. Given the ubiquity of phthalates in the environment, this information can provide a basic framework for potential ecosystem-level changes based on *Daphnia* health. Metabolomic profiling may also be used in ecosystem monitoring programs and provide insight into the overall environmental health.

WP040 Fenoxycarb Exposures Differentiate Metabolic Regulation at a Specific Reproduction Stage and Pairwise Metabolite Co-regulations in *Daphnia magna*

T. Jeong, University of Toronto, Scarborough / Department of Physical and Environmental Science; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences

*Daphnia magna* is a widely studied organism and is considered a model organism for metabolomic studies. The consistent asexual reproduction cycle is an attribute of *D. magna* and may result in metabolic variation of the species. However, to date, the reproduction stage information has not been considered in the design and data analysis of a comparative exposure study. This study examined if the consideration of reproduction stage provides an advantage to investigate comparative metabolic regulation in *D. magna*. Fenoxycarb was chosen as a model toxicant and *D. magna* was exposed to fenoxycarb for 1 and 12 days at the sub-lethal concentration 50 ng/L, which resulted in decreased neonate reproduction. 54 metabolites were quantified using liquid chromatography with tandem mass spectrometry and the measured metabolite concentrations were compared between the exposed and control groups. Two-way analysis of variance (ANOVA) results revealed that no metabolite concentrations were significantly differentiated by the fenoxycarb exposures. Otherwise, the time pattern comparison based on ANOVA-simultaneous component analysis showed a reversed time pattern of metabolite concentration regulation in the fenoxycarb exposures compared to the control. The reversed regulation pattern was only observed during reproduction stage 3, the last reproduction stage, but not during the other stages. Additionally, Pearson correlation analysis provided another aspect of fenoxycarb toxicity to *D. magna* that the pairwise correlations between metabolites are weaker in the fenoxycarb exposures compared to the control. Consequently, this study demonstrates the advantage of using reproduction stage information in *Daphnia* metabolomic studies and provides a new finding on the weakened co-regulation of pairwise metabolites with the fenoxycarb exposures.

WP041 Bacteria-endophyte enhanced phytotreatment of petroleum hydrocarbon-contaminated soil by *Nicotiana tabacum*

J.O. Anyasi, University of South Africa / Environmental Sciences

Pseudomonas parafulva is a bacterial strain isolated from an oil refinery discharge and capable of transforming various petroleum hydrocarbons. In order to evaluate the influence of a polycyclic hydrocarbon transforming ability of the bacterial strain on the phytoremediation of petroleum aromatic hydrocarbon (PAH), P. parafulvas Ros-1 was inoculated into tobacco plant. The tobacco plants were grown for 16 weeks with or without pyrene, chrysene, and perylene (500 mg/kg soil in each 1L pot) in non-sterile peat medium. Evidences were gained that P. parafulvas Ros-1 was present in high concentration in tobacco root tissues (3.1-8.9 _ 103 CFU g^-1_), while the strain was not detected in stem, leaves and rhizosphere. When tobacco was planted in uncontaminated medium, the phytotoxicity resulted in negative effects on the parameters tested which included biomass index, leaves and stem dry weight. However, there was stale effects on the plant. On the other hand, plants inoculated with the strain Ros-1 were much tolerant towards the phytotoxic effects of PAHs, in terms of root dry weight. Although the presence of plants acted as the main effective treatment for PAH dissipation (72-89%), the inoculum with Ros-1 strain lead to the highest PAH removal (up to 91%). In the present study, an environmental isolate with proper metabolic features was demonstrated to be possibly suitable as a plant endophyte for improving endophyte-assisted phytotreatment of petroleum hydrocarbon contaminated soil.

WP042 Fluorine incorporation into cellular lipids during growth of *Pseudomonas sp.* strain 273 with fluorinated alkanes

Y. Xie, University of Tennessee, Knoxville / Civil and Environmental Engineering; G. Chen, University of Tennessee, Knoxville; A. May, University of Tennessee; E. Tague, Thermo Fisher; S. Campagna, F. Loeffler, University of Tennessee, Knoxville

Fluorinated chemicals are prevalent environmental contaminants, in particular per- and polyfluoroalkyl substances (PFASs). PFASs are recalcitrant and many have been implicated in disease, thus representing a substantial human health concern. The backbone of PFASs is both hydrophobic and lipophobic while the terminal head group is hydrophilic. Due to these unique properties PFASs interact with various biomolecules, including phospholipids. Not surprisingly, PFASs were found to partition into membranes and impact membrane function in human, animal and bacterial cells. Recalcitrance of PFASs is often explained by the remarkable strength of the carbon-fluorine bond; however, microbial enzymes exist that break carbon-fluorine bonds at neutral pH and room temperature. This study explores the metabolism of fluorinated alkanes by *Pseudomonas sp.* strain 273. This soil isolate utilizes 1-fluorodecanes and 1,10-difluorodecanes, as well as linear straight chain C5-C16 alkanes as growth substrates under oxic conditions. During growth with these fluorinated alkanes as the sole source of carbon and energy, mineralization occurred and the majority of fluorine in the growth substrates was recovered as inorganic fluoride, indicating enzymatic cleavage of carbon-fluorine bond. Strain 273 did not grow with monofluoroacetate.
as the sole substrate; however, monofluoroacetate was co-metabolized in the presence of decane as a primary substrate. Ultra-performance liquid chromatography (UPLC)-mass spectrometry (MS) based fatty acid analysis of extracts from strain 273 cells metabolizing 1,10-difluoredecane identified degradation intermediates (e.g., β-oxidation intermediates), including fluoroctanoate. Also detected were monofluorinated fatty acids with extended chain length, such as C18:1. Untargeted lipidomic analysis applied to strain 273 cells grown with 1,10-difluoredecane revealed that up to 91% of phosphatidylethanolamine and 87% phosphatidylglycerol contained fluoride. No fluorinated lipids were detected in strain 273 cells grown with decane in the presence of fluoride. Pseudomonas sp. strain 273 has the unique ability to defluorinate and mineralize α, ω-fluorinated alkanes and also to assimilate organofluorine into glycerophospholipids as constituents of the cellular membrane. The discovery of covalent incorporation of fluoride into fatty acids and cellular membrane structures has implications for human health and the fate of fluorinated chemicals in environmental systems.

WP043 Methamphetamine and brown trout (Salmo trutta fario): bioaccumulation and metabolome effects at environmentally relevant and higher exposure levels

M.S. Santos, University of South Bohemia in Ceske Budejovice; K. Grabicova, R. Grubic, C. Steinbach, A. Vojis Stanova, T. Randak, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters / South Bohemian Research Center of Aquaculture and Biodiversity of Hydrogenes

Methamphetamine (METH) is a strong psychostimulant detected in water from nanograms to low micrograms per liter, due to inadequate removal in sewage treatment plants. Previous research demonstrated that psychostimulants can impact non-targeted organisms because of their evolutionary conserved drug targets; however, little is known about impacts of illegal substances on aquatic life. This study aimed to examine effects of METH and its metabolite amphetamine (AMPH) after exposure to environmental (1 µg L⁻¹) and higher levels (50 µg L⁻¹) of METH for 35 days, following a 4 day depuration phase, using brown trout (Salmo trutta fario) as a model. Parent compound (METH) and its biologically active metabolite (AMPH) was analyzed in plasma, muscle, brain, kidney and liver. Tissue specific bioaccumulation levels followed the order kidney > liver > brain > muscle > plasma. Although a low bioaccumulation factor was observed (0.13 to 80), plasma concentrations of both substances was close to the therapeutic level in humans, suggesting potential adverse effects and highlight the necessity for additional studies. The metabolite (AMPH) was analyzed in plasma, muscle, brain, kidney and liver. Ventilation rate was significantly increased in the high exposure compared to controls and a lower environmentally relevant level of 1 µg L⁻¹. Results of nontargeted metabolomics for both groups showed changes in the pattern of biomarkers related to fat metabolism across the two groups, the aPOP (e.g. per- and poly-fluoroalkyl substances, PFAS) significantly correlated with aFAs and select downstream oxylipin metabolites. More advanced location-specific analyses on the bears and insights into the altered biological mechanisms and toxicology is underway.

WP044 Lipid Metabolomic Profiling in Polar Bears: Do Environmental Contaminants affect the Biomolecular Response of the Lipid Metabolome?

A. Rand, Carleton University / Chemistry; A.D. Morris, Northern Contaminants Program / CIRNAC; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M. Dyck, Government Of Nunavut / Nunavut Department of the Environment

WP045 Changes in Metabolomic Profiles of Drilling Platform Mussels

H. Butler, SGS AXYS Analytical Services, Ltd. / Metabolomics; B. Chandramoulis, SGS AXYS Analytical Services, Ltd.

Drilling platforms produce discharges containing complex mixtures of potentially harmful chemicals that can vary depending on factors such as the processing chemicals employed, local geochemistry and the specific composition of the oil and/or gas. This complexity contributes to the challenge of evaluating the potential impacts of platform discharges on the immediate environment. Metabolomics, a tool for measuring concentrations of large numbers of endogenous metabolites, provides a method for examining and monitoring the wellbeing of local populations and can potentially identify early changes in critical biological systems, acting as early warning indicators. This study looks at metabolite changes observed in wild mussel populations collected from platform pillars at varying distances and depths from the discharge pipes on 3 distinct drilling platforms. Mussels were collected from pillars representing 14 distinct locations covering all drilling platforms and 2 collection depths (0.5m and 12m). A targeted metabolomics approach was used to measure the concentrations of 222 metabolites including amino acids, biogenic amines, lipids, fatty acids, hexose and metabolites associated with energy pathways. Multivariate statistical analyses were performed on the resulting metabolomics data to identify metabolites whose concentration levels increase or decrease between specific sites on each platform. Approximately 85% of the 222 metabolites could be detected in samples for each platform. Samples collected from Platform A showed significant distance-dependent differences in mussels collected at 0.5m below the surface but this was not the case for those collected at 12m below the surface suggesting that, for this platform, differences are weaker at larger depths. Fewer differences were seen for mussels collected from Platform 2 though a small number of lipids were identified as differing between the pillars at both collection depths. Analysis of mussels collected from Platform 3 showed metabolite differences that were both distance and depth specific. In all cases, the metabolites with statistically significantly concentration changes are being associated with functional biological information which allow us to identify associated pathways and potential biological impacts. This study illustrates the power of metabolomics as a strategy in environmental toxicology and serves as a template for future analyses.
Copper oxide (CuO) nanoparticles (NPs) and microparticles (MPs) are widely used in various industrial and consumer products and potentially pose risks to environmental organisms. Both particles' toxicity mode on organisms has mostly been attributed to oxidative stress and membrane perturbation in the literature. To further examine this toxicity mode, we employed a global metabolomics approach to investigate the changes of both polar and nonpolar metabolites in microalgae Chlorella vulgaris after exposure to CuO NPs and MPs (1 and 10 mg/l) and copper ions (0.08 and 0.8 mg/l). After 5-day exposure, a total of 75 differentiated metabolites were identified. The metabolic alterations caused by CuO NPs exposure were similar to those of CuO MPs and Cu ions, including accumulation of chlorophyll intermediates, membrane lipids remodelling (decrease of phosphatidylethanolamines and phosphatidylincholines, as well as increase of phosphatidic acids, phosphatidylglycerols, monoacylglycerols, diacylglycerols, digalactosylmonoacylglycerols, diacylglycerols, lysophospholipids, and fatty acids), perturbation of glutathione metabolism, and accumulation of osmoregulants. The only difference between metabolic responses to particles and ions was the accumulation of fatty acids peroxidation products at 1 mg/l CuO NPs and MPs. These results confirm the predominant role of dissolved Cu ions on the toxicity of CuO NPs and MPs, and reveal novel insights on how environmental photosynthetic organisms reprogram their metabolism to cope with oxidative stress and membrane damage induced by Cu ions, CuO NPs and MPs exposure.

The Fathead Minnow Reference Genome Assembly and Annotation: Overview and Utility for Sequencing-Based Technologies

WP047 Characterizing molecular toxicity pathways associated with 17β-Trenbolone exposure in adult fathead minnows to predict adverse apical outcomes

U. Fuchlyo, K.B. Steeves, S.M. Frugal Bandaralage, A.J. Alcaraz, University of Saskatchewan / Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; A.J. Masse, University of Saskatchewan / Toxicology; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

17β-trenbolone is a biologically active metabolite of trenbolone acetate, an anabolic steroid used as a growth promoter in the beef cattle industry. 17β-trenbolone is found to be stable in cattle excreta and has been an anabolic steroid used as a growth promoter in the beef cattle industry. 17β-trenbolone is a strong androgen receptor agonist and has been shown to cause masculinization of female fish where females, morphologically and chemically, exhibit male characteristics (i.e. dorsal pad and dorsal nuptial tubercle formation, as well as decreased vitellogenin and estrogen). While many studies have reported morphological and biochemical effects of 17β-trenbolone in fish, there are fewer studies focused on the underlying molecular pathways that contribute to these apical outcomes. To this end, this exposure was conducted to look at molecular response patterns in fathead minnows (Pimephales promelas) exposed to 17β-trenbolone and use these to characterize the toxicity pathways associated with exposure. Sexually mature fathead minnows were exposed to 17β-trenbolone for 21 d. After 4 d fish were subsampled for omics endpoints (i.e. transcriptomics, proteomics, and metabolomics). After 21 d the remaining fish were sampled for apical endpoints (i.e. histopathology, plasma steroid concentrations, as well as dorsal pad and dorsal nuptial tubercle formation in females). Fecondity was monitored throughout the exposure. Toxicity pathways will be characterized by analyzing the 4-d omics data and linking those to the 21 d apical endpoints. It is anticipated that this research will help identify molecular toxicity pathways for 17β-trenbolone in adult fathead minnows that could be used to predict adverse apical outcomes of exposure. This study is part of the EcoFoxChip project (www.ecotoxchip.ca).

WP048 Comparing microarrays to RNA-seq for transcriptomic analysis of whole Fathead Minnow larvae

M.S. Kostich, D.C. Bencic, R. Flick, US Environmental Protection Agency / ORD/NERL/EMMD; J. Martinson, US Environmental Protection Agency / ORD; W. Huang, G. Toth, A. Biales, US Environmental Protection Agency / ORD/NERL/EMMD

RNA-seq is displacing microarrays for mRNA expression analysis, due to the declining costs of sequencing, and published studies reporting better performance for RNA-seq. However, most empirical comparisons lack a gold standard, and those experiments that do have a gold standard often evaluate synthetic samples whose representativeness of real-world experiments is unclear. Furthermore, RNA-seq performance is expected to be a function of sample complexity and sequencing depth. For complex samples, deeper sequencing depth is expected to be required to quantitate expression of rare transcripts. We are interested in using mRNA measurements in whole Fathead Minnow (FHM; Pimephales promelas) larvae for detecting aquatic toxicant exposures. Whole larvae represent a wide variety of cell types, some of which constitute a very small percentage of the total sample. The applicability of other RNA-seq performance studies to this system are unclear. To compare RNA-seq to microarrays, we exposed 2d post-hatch FHM larvae to bifenthrin or negative control water for 48h, split the RNA from each larva, evaluating one sample half using a microarray and the other half using RNA-seq with a targeted sequencing depth of 30 million 100 base pair (bp) reads per sample. About 35 larvae were exposed to each condition. Reads were resampled at depths ranging from 2-30M reads per sample and lengths ranging from 25 bp to 100 bp. Larvae were resampled at depths ranging from 10 larvae per condition to 30 larvae per condition. Resampled reads were mapped to FHM gene models. Sets of normalized read counts per gene and microarray spot intensities were reduced to the most informative features using a linear model, and the reduced feature set was used to develop classifiers using randomForest. Ten-fold cross-validation was used to estimate performance (Brier scores). Our results showed excellent results for microarrays and RNA-seq across a range of read lengths, read depths, feature selection stringency, all of which had much smaller effects on performance than the number of samples per treatment. Near optimal RNA-seq results, comparable to microarray performance were achieved with 8 million mapped 35-mer reads per sample. Quality trimming of reads and read-mapping software had only minor effects. Our results suggest the primary advantage of RNA-seq stems from cost per sample, rather than from the quality of the measurement data.

WP049 Development of Exposure Classifiers using the Fathead minnow, including Evaluation of an Alternative Lower Cost, RNA-seq Library Preparation Method

J. Martinson, US Environmental Protection Agency / ORD; D.C. Bencic, R. Flick, M. Kostich, W. Huang, D.L. Lattier, A. Biales, US Environmental Protection Agency / ORD/NERL/EMMD

Transcriptome-wide screening of organisms exposed to different stressors has become common in the ecotoxicology literature, with RNA-seq becoming the preferred tool for mRNA expression analysis. Though costs continue to decrease such studies remain fairly expensive, resulting in underpowered experiments with limited numbers of conditions examined. Traditional short-read RNA-seq sequences across entire transcripts. Resulting sequences are mapped to a set of reference genes and the number reads mapping to genes is counted. Most researchers are concerned with comparing counts of reads mapping to a gene in one condition relative to another to determine whether the gene is being up or down regulated. This only requires that there is enough sequencing depth
so reads can be mapped/counted accurately so counts-per-gene can be compared. Sequencing the entire transcript results in wasted resources as accurate mapping can be achieved by mapping to a relatively small region of a given gene. This directly effects cost since the level of multiplexing is reduced to reach sufficient depth to get stable count values. PolyA-seq targets a limited region of the transcript, theoretically reducing the number of sequences required to achieve adequate per-gene sequencing depth. As costs are directly dependent on the level of multiplexing, polyA-seq should provide cost reductions by increasing the level of multiplexing possible. The aim of this work was to compare the performance of poly-A seq to traditional RNA-seq.Fathead minnows (FHM) were exposed for 48 h to copper (n=11), bifenthrin (n=11), or not exposed (n=10). Sequencing libraries were then prepared using traditional RNA-seq and polyA-seq kits. All other technical factors were kept identical. Following sequencing, reads were resampled at various depths (ranging from 2–20M reads per sample) and reads were mapped to FHM genes. Respective gene lists were compared at different per-sample sequencing depths to determine where they diverged. A functional comparison was also conducted by calculating the performance of gene-expression-based classifiers developed using randomForests in a ten-fold cross-validation at different sequencing depths. This presentation will highlight the utility of the FHM gene models in an RNA-seq expression study and present data comparing the performance of polyA-seq at different levels of multiplexing with results obtained using traditional RNA-seq and discuss these in terms of per-sample cost.

WP050 Differential Expression of Coding and Non-coding RNAs in Propranolol-exposed Fathead Minnow Larvae

G. Toth, D.C. Bencic, D.L. Lattier, W. Huang, M. Kostich, A. Biales, US Environmental Protection Agency / ORD/NERL/EMMD

Propranolol, a beta-blocker used for high blood pressure, is one of several pharmaceuticals which have been found in freshwater aquatic resources. 48 h post-hatch FHM larvae were exposed to propranolol (@ 100 µg/l - 5 mg/l) for 48 h. Lexogen Small RNA-Seq Library preparations were done, followed by Hi-Seq RNA-seq analysis. miRNA analyses were done using the mirDeep* program while piRNA analyses were conducted using the Pano and piRNN programs. Differential expression of the smRNAs was analyzed using edgeR. These results will be presented in the overall context of developing and characterizing exposure and effects biomarkers for propranolol.

WP051 Phylogenetic analysis of the Fathead Minnow genome

Phylogenetic analysis is an important component of the Fathead Minnow (FHM; Pimephales promelas) genome annotation process. It can be used to identify evolutionary relationships between FHM genes and genes from other species. Furthermore, genome-wide phylogenetic analysis allows more accurate reconstruction of species trees and estimation of divergence times between taxa than can be done with single gene analysis. Model species gene annotations often include consistently and accurately assigned descriptive gene names. These names can be used to infer functions and categorize genes into gene sets, which are valuable for interpreting changes in gene activity and sequence polymorphisms observed in functional studies. Resolving relationships between FHM and model species genes can be used to transfer model species gene annotations to genes predicted in FHM. FHM genes can be related to similar genes in other species as either analogs (convergent evolution), orthologs (direct one-to-one descent) or paralogs (descent with intermediate within species gene duplications). The nature of the relationships must be accounted for to accurately transfer gene names across species. Phylogenetic analysis of FHM genes together with genes from 17 model species allowed us to put descriptive gene names on over 20,000 of our approximately 26,000 FHM gene models. Analysis of FHM together with 19 fish and fish-like species identified over 1200 groups of one-to-one orthologs across all these species. Protein sequences for these genes were concatenated into one ‘super-gene’ for each species, which were then aligned with one another. Ambiguous parts of the alignment removed, and the remainder was used to construct maximum-likelihood phylograms. The phylograms were calibrated with fossil-based divergence time estimates, resulting in chronograms describing the evolutionary history of these species.
Fate and Effects of Chemicals from Stormwater Runoff

WP053 A Novel Pulsed Study Approach to Storm and Receiving Water Monitoring at the Scripps Institution of Oceanography in San Diego, CA

K. Buckley, C. Stransky, Wood Environment & Infrastructure Solutions, Inc. / Aquatic Sciences and Toxicology; M. Colvin, Naval Information Warfare Center, Pacific / Energy and Environmental Sustainability; G.H. Rosen, SPAWAR Systems Center, San Diego / Energy and Environmental Sustainability; R. Schottle, Wood Environment & Infrastructure Solutions / Aquatic Sciences; K. O’Connell, University of California, San Diego / Environmental Affairs; J. VanVoorhis, Wood Environment Infrastructure Solutions, Inc. / Toxicology

Current monitoring requirements for many ocean-front facilities under National Pollution Discharge Elimination System (NPDES) permits include standardized toxicity tests that use whole effluent guidelines. However, these protocols were originally developed for continuous point-source discharges and not episodic storm events. The University of California Scripps Institution of Oceanography (SIO) has monitored storm water discharges under an NPDES permit since 2005. Long-term monitoring at this site has demonstrated limited to no toxicity in receiving water samples in the laboratory or in situ during wet weather. To better understand impacts in the adjacent receiving waters, a pulsed study method to more realistically assess toxicological impacts related to storm water runoff into receiving waters. This novel method consists of a series of bioassays that alter the duration and concentration of storm water exposed to the test organisms. Whereas conventional laboratory tests expose purple urchin (Strongylocentrotus purpuratus) embryos to storm water continuously for a 72 to 96-hour period, a pulsed study performed during wet weather in 2018 included 6 and 26-hour exposure durations to undiluted stormwater after which embryos were transferred to clean filtered seawater. These time frames were chosen based on the 50th and 95th percentiles for storm events in San Diego. Results from the study indicated that duration of exposure did affect the outcome, with shorter exposures to storm water demonstrating less of an effect. To ensure protection and validate laboratory results, in situ tests are routinely performed concurrent to all compliance monitoring events providing a more representative measure of effects in this dynamic environment. These studies will assist with guidance to enhance prioritization of best management practices and future regulatory decisions that are both protective and appropriate for these unique episodic discharges.

K.C. Schieff, M. Beck, Southern California Coastal Water Research Project

Billions of dollars ($ US) will be spent in California on stormwater best management practices (BMPs) over the next 10-20 years attempting to treat wet weather runoff prior to discharge. Despite hundreds of structural BMP installations, no standardized effectiveness (e.g., influent-effluent) monitoring occurs to assess how well these treatment structures perform. The goal of this project was to compile the ad hoc BMP monitoring throughout California to assess effectiveness for concentration reductions. Four methods were evaluated for assessing effectiveness including percent reduction, effluent probability, linear regression, and quantile regression. Water quality data from 81 BMPs and 1,700 site-events (storm BMP combinations) were compiled spanning the period 1998-2018 for seven different flow-through BMPs such as bioretention, permeable pavement, or constructed wetlands. Of these, vegetated swales and media filters performed the best, having the largest concentration reductions for total and dissolved copper (50%), lead (71%), and zinc (78%). BMP removal for nitrate (14%) and phosphorus (36%) removal were less effective for these flow-thru BMPs. At times, some BMPs actually exported nutrients, typically because of leaching from bioretention media (i.e., mulch) or exported plant materials from vegetated swales. Quantile regression was the best performing statistical method for assessing effectiveness due to the fewest assumptions, least bias, and moderate precision compared to the other statistical methods. Based on quantile regression, the uncertainty associated with BMP effectiveness was quite large, with the 5th and 95th probabilities of achieving specified effluent concentrations ranging up to an order of magnitude. Based on the compile date the uncertainty was not due to differences in precipitation, but may be due to geography (underlying geology) and age of BMP (maintenance practices).

WP055 Bioretention soil media efficiency in reducing tire dust leachate toxicity to aquatic life

C. Duchey, Washington State University / Department of Evolutionary & Environmental Biology; J.D. Stark, Washington State University / Dept of Entomology; J. McIntyre, Washington State University

Road runoff contributes to the total pollutant budget of receiving waters. Besides combustion engine emissions, brake and tire wear are major contributors to traffic-related particulate matter. Tire particulates released into the environment per capita is estimated at 0.81 kg/year. Tire dust has a complex chemical composition and some of its components are water soluble. During rain events chemicals from tire dust can be leached into stormwater runoff. Coho salmon (Oncorhynchus kisutch) are acutely sensitive to chemicals that leach from tires. Previous assays showed that coho salmon are approximately 10-fold more sensitive to tire dust leachate than the crustacean Ceriodaphnia dubia (LC50 estimated at 0.1 g/L for coho salmon vs. 1.05 g/L for C. dubia). A laboratory study was conducted to assess whether bioretention soil media (BSM) could reduce or eliminate toxicity of tire dust leachate to juvenile coho salmon and to C. dubia. A tire dust mixture was created by grinding tread from nine different tires (new and used) from light duty vehicles. A 2 g/L tire dust leachate was produced using a closed recirculating system, allowing water to run through the tire dust mix for 24 h. The tire dust leachate was treated via infiltration through a BSM composed of 60% sand and 40% compost and was tested on juvenile coho salmon (24-h exposure) and on C. dubia (2-day and 8-day exposure).

WP056 Evolution of a NPDES Permit- Novel Implementation Strategies for Storm Water Compliance Monitoring at the Scripps Institution of Oceanography in San Diego, CA

C. Stransky, Wood Environment & Infrastructure Solutions, Inc. / Aquatic Sciences and Toxicology; R. Schottle. Wood Environment & Infrastructure Solutions / Aquatic Sciences; K. O’Connell, University of California, San Diego / Environmental Affairs

The University of California’s Scripps Institution of Oceanography (SIO) campus is situated adjacent to an Area of Special Biological Significance (ASBS) in southern California. In 2005, the University was issued a National Pollutant Discharge Elimination System (NPDES) permit, one of the early Ocean Plan exceptions granted to allow discharges to an ASBS, The Scripps ASBS is one of the 34 designated ASBS’ throughout the State of California. Seawater from SIO research facilities and a public aquarium, as well as storm water during wet weather, enters the ocean therefore requiring an NPDES permit to monitor discharges from the facility during both dry and wet weather. As the first marine institution in the State to receive an exception, the University has become a vanguard for development and implementation of innovative and more representative monitoring strategies under their permit. This presentation will highlight the key special studies conducted by the University to more accurately characterize possible impacts to the receiving waters of the ASBS. Results from these novel studies have helped to inform regulators to develop a definition of natural water quality for ASBS’ statewide. The key special studies and advisory committee findings to date include; Defining natural water quality; A site specific dilution model; Species sensitivity evaluations and implementation of the EPA Test of Significant Toxicity to establish compliance; Toxicity identification evaluation (TIE) studies for stormwater and the receiving water; Ongoing special studies including in situ “SEA-Ring” toxicity monitoring of receiving waters and pulsed studies to further examine storm water impacts under more representative exposure scenarios.
WP057 Longevity of bioretention depths for preventing acute toxicity from urban stormwater runoff

J. W. Maguire, Washington State University / School of the Environment; J. A. Davis, San Francisco Estuary Institute; N. L. Scholz, NOAA-NWFSC; J. K. McIntyre, Washington State University / School of the Environment

The migration of coho salmon every fall from the ocean to freshwater streams coincides with increasing rainfall in the Pacific Northwest. Much of this rainfall runs off of asphalt and other impervious surfaces found in urban areas, such as the Puget Sound Basin, and into the very streams where salmon spawn. Exposure to urban stormwater runoff, which contains a complex mixture of contaminants, can be acutely toxic to coho salmon. Previous studies have demonstrated the effectiveness of bioretention treatment systems in treating urban runoff and preventing acutely lethal and sublethal effects to aquatic organisms. Municipalities are especially motivated to incorporate bioretention treatment systems into existing infrastructure in order to comply with National Pollutant Discharge Elimination System (NPDES) permit requirements. NPDES permits are administered by the Washington Department of Ecology (Ecology) and require local governments to manage polluted stormwater in order to mitigate the effects of pollution and contamination on downstream waters. The current study aims to determine the effectiveness and longevity of bioretention soil media over time at various infiltration depths, including those shallower than 18 inches, the depth currently required by Ecology. Stormwater runoff is being collected from a busy, urban road site and applied to experimental columns, containing five different depths of bioretention soil media. Runoff is applied at an accelerated rate in order to simulate 10 water years over two calendar years. The chemical and biological effectiveness of the columns in treating urban stormwater runoff will be assessed using analytical chemistry and the health of two fish species: juvenile coho salmon and zebrasfish embryos. The study outcomes are expected to help inform stormwater managers, National Pollutant Discharge Elimination System (NPDES) permit coordinators, and others involved in stormwater management.

WP058 Low exposures of urban stormwater runoff are lethal to coho salmon

J. Prat, Washington State University / Payaup Research & Extension Center; J. D. Stark, Washington State University / Dept of Entomology; J. Davis, US Fish and Wildlife Service / Division of Environmental Assessment and Restoration; N. Scholz, NOAA / fisheries; J. K. McIntyre, Washington State University

Urban stormwater runoff contains a complex mixture of toxicants that is acutely lethal to coho salmon (Onchorhynchus kisutch). Although it is unknown what chemicals in the mixture are responsible for the toxicity, the land use most strongly related to rates of mortality in the field is roads -- particularly busy arterials. Juvenile and adult coho salmon experimentally exposed to 100% collected road runoff die within a few hours of exposure. In field studies, dead coho spawners are observed following rain events, but it is unknown how dilute are the chemicals causing the mortality, nor how quickly these mortalities occur after exposure to runoff. To better understand the lethality of road runoff to coho salmon, we experimentally exposed juvenile coho salmon to dilutions of road runoff collected from a busy arterial in Seattle, Washington, USA, varying the concentration and exposure duration. Two pilot tests indicated that concentrations above 25% caused 100% mortality within 24 h and that no mortalities occurred at any concentration beyond 24 h. Using runoff collected from a subsequent three storm events, the 24-h median lethal concentration (LC50) for each event was remarkably similar at 6-10% (95% C.I. = 5-12%). The NOEC (estimated from dose-response curves) ranged from 0.3-1.2%. Runoff from an additional storm event (24-h LC50 = 4%; 95% C.I. = 3-6%) was used to determine minimum exposure durations to cause mortality. Factorial exposures of 1, 2, 4, and 8 h were conducted for runoff concentrations of 5%, 11.2%, and 25% and survival monitored up to 24 h. Nearly all mortality occurred after fish were transferred to clean water. Mortality (24-h) occurred for exposures as brief as 1 h at 25%, 2 h at 11.2%, and 8 h at 5%. No mortality occurred following 1-h exposure to 11.2% and following 1, 2, and 4-h exposures to 5%. All other combinations of exposure time and concentration caused mortality for at least some individuals. Median lethal exposure times were approximately 22 h for 5% runoff, 5.5 h for 11.2% runoff, and 1.8 h for 25% runoff. By linking these results to observed rates of mortality in urban creeks, we can begin to estimate the amount of treatment required for runoff entering streams where coho salmon spawn.

WP059 Mapping Particle Deposition Patterns with GPS Drifting Particle Simulators in Pearl Harbor Hawaii

J. M. Guerrero, Space and Naval Warfare Systems Command / Energy & Environmental Sustainability Branch; B. Chadwick, Coastal Monitoring Associates / Environmental Sciences; L. Hsu, Naval Information Warfare Center (NIWC), Pacific; K. Markilie, Naval Facilities Engineering Command (NAVFAC), Hawaii; J. Radford, Zebra-Tech, Ltd.; A. Sybrandy, Pacific Gyre Inc.

Source assessment and control is a critical challenge for investments in sediment cleanup as well as in the prevention of future contaminated sediment liabilities. Stormwater sources are at the nexus of this challenge, spanning virtually every harbor, coastal and riverine site. Stormwater discharge assessment is connected to every aspect of regulatory compliance, including National Pollutant Discharge Elimination System (NPDES) permitting, Total Maximum Daily Load (TMDL) actions, Environmental Installation Restoration (E/IR) programs, and associated source control strategies. The ubiquitous and non-point source nature of these sources makes them difficult to characterize and control effectively. Regulatory pressure to reduce and cleanup adjacent water bodies is increasing. This poster presentation will demonstrate two tracking and monitoring technologies specifically modified by the US Navy, Naval Information Warfare Center (NIWC) Pacific, to assess the trajectories and deposition patterns of particles associated with stormwater and other discharges that impact sediment quality. The Drifting Particle Simulator (DPS) is a GPS drifter with position data telemetry, programmable depth control, and bottom detection, for measuring depositional footprints and sampling of source related particles. The DPS tracks water currents at depths of 1-30 meters, and accommodates a range of additional sensors. The Sediment Deposition (SeDep) Sensor is an adaptation of a standard USGS Load-Cell Scour Sensor modified to incorporate a highly sensitive differential pressure sensor. The SeDep senses small changes in sediment load and measures both scour and depositional variations such as infilling of gravel and cobbles with fine grained sediments. These technologies were deployed in Hawaii at the Pearl Harbor Naval Complex (PHNC). The demonstration focused on determining the depositional footprint of particles associated with a storm drain. The results showed that particles released could potentially deposit over a 1-1.5 km wide area to the north and south of the outfall under the influence of tidal currents and silt sized particle settling rates. Depositional rates suggest that movement and deposition into the footprint correlate to runoff events and ship driven scour and resuspension.

WP060 Specification of copper in bioretention soils receiving runoff from a copper roof

E. L. McGovern, D. R. Ownby, R. E. Casey, Towson University / Chemistry

Roofing materials can be a substantial source of copper (Cu) released into the environment. Previous studies have demonstrated that bioretention planter boxes can attenuate >90% of Cu in stormwater from sheet Cu roofing materials. Less is known about the fate of retained Cu in bioretention media that have received stormwater inputs over a long duration. This study evaluated the speciation of Cu retained in bioretention planter boxes that received runoff for 4.3 years. Nine soil cores were obtained from each of two replicate planter boxes. Cores ranged from 21-34.5 cm in depth and were divided into top, middle, and bottom soil sections and sieved (< 2 mm) prior to analysis. Nitric acid (7 M) extractable Cu was determined for each sample and selected samples were subjected to a modified Tessier sequential extraction analysis. Total Cu in the core sections ranged from 11-1043 mg Cu kg⁻¹ of dry soil. Copper concentrations were generally...
highest at the top of the planter box with Cu concentrations decreasing with depth. Cu concentrations were highest in closest proximity to the downspout (at the center of the box) and generally declined toward the periphery of the planter boxes. The total load of Cu retained in the media was 7 to 10 times greater in the top layer compared to the bottom layer. Sequential extraction analysis yielded similar results to the total extractable Cu values when all fractions were summed. Summed fractions represented approximately 70-110% of Cu recovered in the 7 M nitric acid extractions. Overall the highest Cu concentrations were in the organic fraction and the lowest were in the exchangeable fraction. Because copper found in the organic fraction is generally less bioavailable and less subject to leaching, these results suggest that Cu in aged bioretention material may be relatively stable. Because the majority of the Cu was found in the potentially less bioavailable fractions and the lower layers of the planter box had much lower Cu concentrations than the surface, these results suggest that the bioretention media in these planter boxes had substantial capacity for continued copper retention beyond the 4.3 year period that was evaluated.

**WP061 Acute toxicity of copper and zinc pulse exposure to Ceriodaphnia dubia**

T. Hoang, Loyola University, Chicago / Institute of Environment and Sustainability; J. Sanchez, K. O’Malley, Loyola University, Chicago / Institute of Environmental Sustainability; M. Colvin, G. Rosen, Naval Information Warfare Center, Pacific / Energy and Environmental Sustainability

The continuous traditional exposure method to assess the toxicity of pollutants to aquatic organisms is not always relevant, especially for pollutants coming from stormwater discharges and runoff. The present study characterized the acute toxicity of copper (Cu) and zinc (Zn) to Ceriodaphnia dubia using pulse exposure method. Less than 24 h old C. dubia were exposed to a Cu or Zn pulse of 6h, 12h, 26h, or 96h under standard laboratory conditions. These pulse durations were chosen based on analysis of frequency of rain in the U.S. over the past 20 years, and therefore would be relevant to runoff and stormwater exposure. Except for the 96h exposure, surviving organisms at the end of the shorter pulses were transferred to clean water and monitored for mortality to 96h post initiation of the exposure. Lethal median concentrations (LC50s) were determined based on mortality of the organisms both at the end of the pulse and the full 96 h test. In general, acute toxicity increased with increasing pulse duration in the short term. For example, the LC50 for the 6h pulse mortality decreased, following a power function, from 44.8 µg Cu/L to 23.5 µg Cu/L for 12h pulse and 96h pulse and 752 µg Zn/L to 158 µg Zn/L for 12h pulse and 96h pulse, respectively. Interestingly, the mortality continued to increase post metal exposure, after the organisms were transferred to clean water. The LC50s for the end pulse were approximately 1.5-2 times higher than those for the end of the 96 h test. These results indicate a latent effect of Cu and Zn to Ceriodaphnia dubia. Surviving Ceriodaphnia dubia from metal exposed treatments were visually smaller than those in the control. Reproduction was also lower in Cu and Zn treatments compared to the control. This study reveals that continuous exposure without post exposure assessment might underestimate the toxicity of pollutants. More research should be conducted to understand latent effects of pollutants to aquatic organisms.

**WP062 Daphnia magna Demonstrate Severe Toxicity to Stormwater Runoff**

L. Wedel, University of Cincinnati; L.M. Jackson, University of Cincinnati / Biology

First season rain events and snowmelt carry high levels of pollutants, where they are deposited directly from surrounding storm water sewer systems to nearby receiving waterways (Karlsson et al., 2010). Seasonal first flushes of storm water demonstrate high levels of pollutants such as heavy metals, organic compounds, and snow-melting agents. Standard acute toxicity tests were run on populations of the invertebrate, Daphnia magna, to demonstrate the toxicity of storm water runoff from major highways, creeks and rivers in Cincinnati, Ohio. First flush seasonal rainfall was collected in March 2019 from the uttermost downstream of the Mill Creek watershed; the Ohio river, where Mill Creek empties into it and diluted to 25%, 18%, 9%, and 3%. Mortality was 20% in Mill Creek site 25 and 15% in the Ohio River at 9% dilution. In dilutions as small as 3%, the water remained lethal to the D. magna between 25-30%. D. magna and other primary consumers support the entire ecological food chain of aquatic ecosystems. The health and vitality of all levels of the food chain are dependent on the survival of the D. magna and other invertebrates, and toxic storm water runoff is becoming malignant to the higher level consumers of the food chain.

**Fate and Effects of Metals: Mechanistic Knowledge of Metal Interactions With Aquatic Biota**

**WP063 Development of QICAR models to address the lack of toxicological data for technology-critical metals**

S. Le Faucheur, University of Pau and Pays de l’Adour / Département F.-A. Forel des sciences de l’Environnement et de Leau; C. Fortin, INRS - Centre Eau Terre Environnement; J. Mertens, EPMF; E.J. Van Genderen, International Zinc Association; A. Boulemant, RíoTinto; P. Campbell, University of Quebec / INRS Eau Terre Environnement

Over the last twenty years, industrial advances in diverse areas (e.g., computers, catalytic converters, wind turbines) have led to the increasing use of a wide range of ‘new’ elements, including metals that were previously poorly exploited. The potential impacts of many of these technology-critical metals (TCM) on aquatic biota remain to be elucidated. Quantitative structure-activity relationships (QSAR) have been developed for many years to fill a similar gap for new organic compounds. Here, a similar approach was used to develop Quantitative Ion Character Activity Relationships (QICARs) to relate intrinsic metal properties to their toxicity towards aquatic organisms. In total, 23 metal properties (e.g. molecular weight, density...) were tested as predictors of acute EC50 values for 12 data-rich metals (Ag, Cd, Cu...) for algae, daphnids and fish. Metal characteristics were examined for missing values as well as redundancy using principal components analysis. Simple and multiple linear regressions were developed using the toxicological data expressed as a function of the total metal concentrations and the free ion activities. In that latter case, linear free energy relationships were additionally used to estimate the binding constants of the TCM with HO-, CO32-, EDTA4- and Cl-. These values were lacking. Finally, the QICARs were tested by comparing the predicted EC50 values for the TCM with the few measured values that are available. Twelve out of the 15 ‘best’ QICAR models (adjusted r² > 0.6) used Xm2r as the predictor. Xm represents the metal electronegativity and r is the ionic metal radius; for a given metal ion, the composite Xm2r parameter, also known as the covalent index, is a measure of the importance of covalent interactions relative to ionic interactions. The effects of the TCM was well predicted using the total metal concentrations. However, the models based on the free ion activities systematically underestimated their EC50 values. This unexpected result might be due to the formation of neutral polyhydroxo-complexes in the exposure media leading to extremely low free TCM activities (< 10^{-15} M), a speculation that differs markedly from that of the data-rich metals used to construct the models. QICARs show potential as a screening tool to review toxicity data and flag ‘outliers’, which might need further scrutiny. The TCM fall into this latter category and require further testing to elucidate the role of polyhydroxo-complexes in metal toxicity.
WP066 Bioaccumulation and Subcellular Measurements of Trace Metals in Amphipods collected from the Yellowknife Area
J. Labrie, University of Quebec in Montreal / Biology; A. Rolland, Université du Québec à Montréal / Biological Sciences; M. Palmer, Gov. Northwest Territories / Cumulative Impact Monitoring Program; J. Chetelat, National Wildlife Research Centre Environment Canada; M. Amyot, University of Montreal / Biological Sciences; M. Rosabal, University of Quebec, Montreal / Département des Sciences Biologiques

Mining activities in the Yellowknife area have increased concentrations of various trace elements (mainly arsenic) in nearby aquatic ecosystems. As a consequence, these contaminants accumulated in aquatic organisms can provoke harmful effects for their survival. However, little attention has been paid to examine the toxicity potential of these metals for aquatic organisms, in particular, for invertebrates. We aim to evaluate the potential for toxicity of trace elements in amphipods considering bioaccumulation and subcellular measurements of these contaminants. Knowledge of subcellular metal partitioning, which reveals the subcellular targets (sensitive compartments) responsible for adverse effects including mitochondria, heat-denaturable proteins and microsomes is necessary to understand and predict metal toxicity. Furthermore, these measurements allow researchers to determine the metal-handling strategies used by aquatic organisms to cope with high metal concentrations. To perform these measurements, amphipods were collected from three lakes and five sites in Yellowknife Bay in 2015 and in 2017. To better estimate bioaccumulation measurements, depuration experiments (to remove gut contents), adsorption essays (to remove metals on the surface) and dissections (to estimate metals from the exoskeleton and the soft tissue) were conducted in parallel, and metal concentrations were determined by ICP-MS/MS for a suite of metals (arsenic, antimony, lead, cadmium, zinc, copper, selenium, lanthanide, cerium, yttrium). Our results showed significant spatial differences for As, Sh, Cd, and Pb (but not for Ce and La), which reflect the impact of mining activities on aquatic ecosystems sampled. For some elements studied, internalized metal burden was consistently higher (more than 40%) than that measured as adsorbed. Our results also showed that a 48-hour depuration step is needed for mostly all the trace elements analyzed. With regards to subcellular analysis, a customized protocol has been validated using enzymes specific to subcellular fractions. Next steps will be focused on the application of the subcellular metal partitioning approach, which allows us to discriminate between metals accumulated in the metal-sensitive compartment and in the detoxified-metal compartment. Such information should help the development of improved models for predicting metal toxicity, based on the biologically active pools that contribute to toxic responses and not on the total accumulated metal concentrations.

WP067 Developing whole sediment toxicity assays with early life stages of medaka fish for assessing heavy metal contaminated sediment
P. Chen, C. Lee, W. Li, G. Chen, National Taiwan University / Department of Agricultural Chemistry

The aquatic sediment is considered as a sink and source of heavy metals due to their non-biodegradable and high accumulative properties. These toxic metals can be released to the water column from sediment, thus enhancing exposure risk to the aquatic life. However, the method with...
WP068 Mitochondrial responses for exploring heterogeneous resolutions of contaminant bioavailability using cell-based in vitro assays

Z. Wang, Jiangxi University of Science and Technology

With the intensive developments induced by rapid industrialization and extensive urbanization, increasing amounts of anthropogenic contaminants have been discharged into aquatic environments. While using traditional methods based on the chemical analysis alone of extracted samples from environmental and biological matrices, it is difficult to accurately determine the bioavailability of contaminants and then reflect their cell-based effects as well as subsequent toxicity risks. Therefore, understanding the degrees of contamination and pollution characteristics regarding of entirely environmental matrix and biological samples in the selected study sites and successfully culturing the primary cells from critical tissues in aquatic organisms of ecological niche, the field exposure were performed to analyze the subcellular distributions and adverse effects of contaminants combined with cell-based in vitro assays and in situ tests. Further, the dynamic exchanges, translocation and mobilization of contaminants such as metals were then clarified among the “various particles, pore water and cells in exposed organisms” interfaces of matrix through measuring relevant dynamic parameters and resultant induced fluxes during experimental procedures. Moreover, coupled with chemical analysis to quantify the mitochondrial components (mitochondrial proteins, lipids, and nucleic acids, modulating mitochondrial membrane potential and ATP production et al.) within culture wells of primary cells and molecular approaches to assess the expression of responsive genes in field exposure, the mechanisms of associated toxicity were elaborated and the interactive relationships were then obtained between chemical bioavailability and in situ stress. Simultaneously, the assays of cell-based evaluation and monitoring were established considering the consistency of framework as protocols among cell culture, field tests and exposure effects. Overall, the adverse outcomes acquired in this study support full-scale considerations of environmental prevention and retrieval and thus provide robust tool to scientifically extrapolate the environmental quality guidelines, further improving accuracy and ecological relevance towards future pollution monitoring as powerful tools and more comprehensive risk assessments in complex scenarios. (The author acknowledge financial support by Grant No. 21777156/B070403 from National Nature Science Foundation of China.)

WP069 The effects of waterborne chromate (Cr6+) on protein abundance patterns in Lake trout (Salvelinus namaycush) and White sucker (Catostomus commersonii)

N. Tannouri, D. Simmons, Ontario Tech University / Faculty of Science; J.P. Sherry, T. Neheli, J. Miller, Environment and Climate Change Canada / Water Science & Technology Directorate; D.G. Potrier, Ontario Ministry of the Environment, Conservation, and Parks; T. Watson-Leung, Ministry of the Environment, Conservation and Parks / Aquatic Toxicology Unit; R. Chong-Kit, Ontario Ministry of the Environment, Conservation, and Parks / Laboratory Services Branch; S. Maedler, V. Furdui, Ontario Ministry of the Environment, Conservation, and Parks; E.J. Reiner, Ontario Ministry of the Environment, Conservation and Parks; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences

In anticipation of the development of the Ring of Fire in Northern Ontario for the mining of Chromium, we assessed the effects of Cr6+ on the plasma proteome of Lake trout and White sucker - two species’ which are native to that region. Juvenile Lake trout were exposed in the laboratory to waterborne Cr6+ (0, 0.2 ppb and 3 ppm). Exposures lasted for 21-days in flow-through conditions, with the exception of the highest (3 ppm) treatment because we had observed mortalities after 7-days in our pilot study. Plasma proteins were analyzed using a reverse phase liquid-chromatography tandem quadrupole time-of-flight mass spectrometry system with data-dependent full scan acquisition, and peptide spectral files were subsequently sequenced and matched to proteins using bioinformatics software. Results from liver transcriptome analyses from these same fish indicate there was significant differential gene expression in both the 0.2 ppb and 3 ppm treatments. There were also significant changes in the concentration of some plasma metabolites. Plasma protein abundance will be compared to these results to detect where there is an agreement between the datasets and we will discuss how changes in gene expression caused by exposure to Cr6+ could result in higher level biological effects, and be used for monitoring fish health in Ring of Fire mining activities.

WP070 Copper binding to a rainbow trout gill cell line: determination of biotic ligand model parameters

S. Klieweg, Wilfrid Laurier University / Department of Chemistry and Biochemistry; S. DeWitte-Orr, Wilfrid Laurier University / Department of Biology; S.D. Smith, Wilfrid Laurier University / Department of Chemistry and Biochemistry

Copper is a potentially toxic element in aquatic environments that is also an essential nutrient, aiding in the growth and development of all aerobic organisms. In small quantities, copper acts as a micronutrient, playing a large role in many enzymatic reactions but at increased concentrations, copper is a potential aquatic pollutant causing metal toxicity. The biotic ligand model (BLM) is a tool that is used for metals risk assessment and helps to establish protective water criteria, guidelines and risk assessment. Previously, the BLM has been used to model metal complexation directly at the biotic ligand (e.g., gill) for both whole organisms and primary gill cells but has not yet been used to model metal complexation directly for gill cells from a continuous cell culture. For this study, the cupric ion selective electrode was used to directly characterize copper binding to a rainbow trout gill cell line, RTgill-W1. Prior to titration cell viability curves and EC50 values were generated using the RTgill-W1 cell line to determine what concentrations of copper (II) sulfate induces cell toxicity using two fluorescence indicator dyes, Alamar Blue and CFDA-AM. These tests confirmed the titratable range for the cells in order to maintain viability. For titration, RTgill-W1 cells were seeded into cell culture inserts and copper titrations performed at non-toxic concentrations. Preliminary results suggest that the interaction of copper with cell derived from a continuous cell line is much weaker than interactions with cells from primary culture. These results will determine the potential use of RTgill-W1 as an alternative to whole organism and primary cell testing; thus, potentially providing an alternative to animal testing. Additionally, this study will provide insights into cupric ion transport in a rainbow trout gill continuous cell line.
Fate, Effects, Mitigation and Monitoring of Oil and Oilfield Wastewater Spills in Freshwater Ecosystems

WP071 Inland oil spill planning: Baseline fish health for pallid sturgeon in the Upper Missouri River Basin and bull trout in the Flathead River, Montana

Enhanced oil and gas production in North America have led to large volumes of product transport in pipelines, railcars, and tanker trucks. Formations such as Three Forks and Bakken within the Williston Basin of Montana and North Dakota have produced more than 1 million barrels of oil per day. Along with the enhanced transport comes greater risks of spills within transportation corridors which often follow riverine habitat for fish species important for recreation, commerce, and conservation. Risk characterization identified potential threats from oil spills to populations of two threatened or endangered species, pallid sturgeon (Scaphirhinchys albus) in the Upper Missouri River Basin and bull trout (Salvelinus confluentus) in Montana. The objective of this study was to develop baseline fish health information on these species or appropriate surrogate species in critical habitats with elevated risks of oil spills. Shovelnose sturgeon (Scaphirhinchys platyrynchus) were collected in three locations near the confluence of the Missouri and Yellowstone Rivers and cutthroat trout (Oncorhynchus clarki lewisi) and mountain whitefish (Prosopium williamsonii) were collected from critical bull trout habitat along the Middle Fork of the Flathead River. Fish health metrics evaluated included gene expression/enzyme induction in various tissues, differential changes in white blood cells, polycyclic aromatic hydrocarbon bile metabolites, histological changes in gills, metabolic oxidative stress, immune dysfunction, and disruption of endocrine signaling pathways. Baseline values are presented as well as comparisons of these metrics in fish from oil spill investigations. These data are critical to accurate evaluation of injury to fish populations in post-spill monitoring and assessments.

WP072 Zooplankton metabarcoding to assess the ecological impact of remediation efforts after diluted bitumen spills: A mesocosm study

P. Ankley, Y. Xie, University of Saskatchewan / Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; M. Perry, University of Manitoba / Department of Environment and Geogrophy; S.N. Higgins, M. Paterson, V. Palace, IISD-Experimental Lakes Area

The Freshwater Oil Spill Remediation Study (FOReSt) is a collaborative project to determine the efficacy of minimally invasive methods for removing diluted bitumen (dilbit) from freshwater shorelines. In 2019, pre-weathered dilbit was applied to shoreline enclosures (5 x 15m) deployed in two areas with physically different underlying substrate types (organic/peat and rock/cobble). Dilbit was applied at a dosing level of 1:10000 (oil:water) and, after 72h, was removed using sorbent pads and low pressure shoreline rinsing. Two secondary remediation techniques were then employed: nutrient addition for enhanced Natural Recovery (eMNR), or COREXIT EC9580A(TM) shoreline cleaner. Adult fathead minnows (Pimephales promelas) were deployed into each enclosure (n = 12) for an exposure period of 80 days. Dermal mucus was sampled from every individual prior to deployment, and upon recapture at the end of the exposure period. F$_2$-isoprostanes were quantified in the mucus using high performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS) to compare levels of lipid peroxidation related to oxidative in exposed FHM relative to those in control enclosures. Levels of F$_2$-isoprostanes were also compared to biomarkers of polycyclic aromatic hydrocarbon (PAH) exposure, namely...
Potential environmental impacts of oil spills are a concern for the Canadian public and the oil industry. Optimizing methods to treat residual oil that remains after an oil spill cleanup and to assess the potential impacts of residual oil in impacted freshwater systems are both high priorities. In 2018, the International Institute for Sustainable Development-Experimental Lakes Area (IISD-ELA) began a collaborative program to examine the efficacy of minimally invasive remediation methods for residual bitumen and conventional heavy crude oil in the freshwater shoreline environments. In 2018, model oil spills in contained shoreline environments (15X2.5m) were used to examine the efficiency of immediate oil recovery and then to compare degradation of residual oil via Monitored Natural Recovery (MNR). Results from the 2018 pilot study were used to design a larger study being performed in 2019 that focuses on comparing the efficacy of oil removal using nutrient additions, a shoreline cleaner and engineered floating wetlands relative to MNR. As part of these studies the effects of residual diluted bitumen on juvenile fathead minnow development and deformity rates were evaluated. Because exposure to UV radiation can potentiate the toxicity of certain compounds in residual oil by up to 100-fold, we conducted a paired test exposing juvenile fathead minnows to water from enclosures treated with model spills of diluted bitumen with and without UV radiation.

WP076 Assessing the efficacy of minimally invasive remediation techniques for oil spills on freshwater shorelines using bile metabolites in fish

J. Dearnley, University of Manitoba / Chemistry; V. Palace, IISD-Experimental Lakes Area; P. Bulloch, University of Manitoba / Chemistry; L. Timlick, University of Manitoba / Department of Environment and Geography; D.M. Pamparin, IRIS; L.E. Peters, University of Manitoba / Fisheries and Oceans / Department of Environment and Geography; M.L. Hanson, University of Manitoba / Department of Environment and Geography; G.T. Tomy, University of Manitoba / Department of Chemistry

The boreal shield is Canada’s largest terrestrial ecozone covering more than 1.8 million km² and containing more than 22% of the country’s freshwater resources. While numerous crude oil pipelines and rail transportation routes cross the boreal zone, additional information is required to establish the most effective remediation methods for oil spills in lakes within this region. The Freshwater Oil Spill Remediation Study (FOReSt), conducted at the IISD-Experimental Lakes Area in Northwestern Ontario, Canada is using controlled model spills of diluted bitumen in mesocosms deployed in physically different shoreline environments of a boreal lake. Enhanced monitored natural recovery (eMNR) and a shoreline cleaner were applied as remediation techniques to residual oil remaining after traditional cleanup was performed. In terms of chronic toxicity, polycyclic aromatic compounds (PACs) represent the most toxicologically relevant compounds in crude oil. Biliary PAC metabolite concentrations are well established as a biomarker of short-term exposure to PACs. In this study, biliary metabolites were quantified in fathead minnows (Pimephales promelas) living within the mesocosms and used as a metric to evaluate the efficacy of the different remediation techniques studied. Concentrations were determined using liquid chromatography-mass spectrometry. Results from this study will inform spill responders regarding the best remedial methods to use on shorelines affected by oil spills in the future.

WP077 Tracking the fate and biodegradation of oil-derived carbon in simulated oil spills in lake limnocorals

J. Rodriguez Gil, L. Cundall, University of Ottawa / Department of Biology; M.L. Hanson, University of Manitoba / Department of Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada / Emergencies Science & Technology; D.M. Orihel, Queen’s University / Department of Biology / School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; J.M. Ahad, Natural Resources Canada / Geological Survey of Canada; J.M. Blais, University of Ottawa / Biology

Commercialization of land-locked crude oil reserves, such as the Athabasca Oil Sands, involves terrestrial transportation of the extracted crude, increasing the potential for a spill in freshwater systems. While many coastal and marine systems are known to host active microbial communities able to degrade oil-derived hydrocarbons, there is limited research into the potential for microbial communities in freshwater systems to make use of these carbon sources and contribute to natural attenuation after a spill. The BOREAL project set out to assess the fate and effects of diluted bitumen spilled into a boreal lake via a large-scale, in-lake study where nine 10-m diameter limnocorals were treated with varying amounts of diluted bitumen. Within the greater BOREAL project, this study aimed to track the movement of oil-derived carbon through the experimental systems and determine the carbon sources used by the active microbial communities. Because of its geological age, bitumen contains no detectable radiocarbon (Δ14C = -1000‰), whereas the 14C content of recently fixed organic matter reflects that of modern atmospheric CO2. As a result, radiocarbon can be used to track incorporation of petrogenic carbon in the environment. Water samples were collected from the high (~1,600 oil:water, v:v), medium (1/5,700), and low (1/6,600) treatment limnocorals, as well as the control, on day -4 before oil application and 8 times up to day 70 post application. Radiocarbon isotopes (Δ14C) were determined in the dissolved and particulate organic carbon as well as dissolved inorganic carbon fractions. Δ14C values averaged ~410% in the DOC and POC fractions of the highest oil/water treatment on day 70 indicated significant oil contribution to the carbon in these pools. Petrogenic contributions were less apparent in the DIC (Δ14C ~ -10‰). Radiocarbon contents of the total organic fraction were also measured in surface sediment samples collected on days -4 and 78. Phospholipid fatty acids (PLFAs) in the same surface sediments were also extracted and quantified. No treatment-dependent differences in PLFA composition, a surrogate for the active microbial community composition, were observed. Compound-specific Δ14C values were determined on six individual or grouped PLFA fractions and were used to assess the degree to which oil-derived carbon was being used and incorporated by different elements of the active microbial community in the surface sediments of the limnocorals.

WP078 Wild-sourced fathead minnow embryos exposed to Cold Lake Blend diluted bitumen spilled at the IISD-Experimental Lakes Area

L. Lara-Jacobo, Autonomous University of Baja California, Tijuana / Chemistry; L. Timlick, University of Manitoba / Department of Environment and Geography; L. Baillon, Institut National de la Recherche Scientifique (INRS) / Centre Eau Terre Environnement; J.L. Rodriguez-Gil, J.M. Blais, University of Ottawa / Biology; M.L. Hanson, University of Manitoba / Department of Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada / Emergencies Science & Technology; D.M. Orihel, Queen’s University / Department of Biology / School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; V.S. Langlois, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement

The physical effects of oil in marine environments have been well studied, but there is a critical lack of information regarding the impacts of oil spilled undergoing natural weathering in freshwater lakes. The
specific aim of this project was to study the potential effects of Cold Lake Blend (CLB) diluted bitumen spilled into a Northwestern Ontario boreal shield lake in wild living fish embryos. For this, three subsequent experiments were conducted in one of the IISD-ELAs (Lake 260) in early, mid, and end of July 2018. Fertilized embryos of wild fathead minnow (Pimephales promelas) were exposed to water drawn from 9 large limnocorals, which encompassed 2 controls and 7 CLB dilbit concentrations. Each FHM exposures lasted 7 days. At exposure completion, mortality rate, malformation occurrence, and/or hatch time were recorded. Preliminary data suggest that at the tested concentrations, the spilled dilbit does not alter fish embryo survivorship, but is likely inducing malformations for the exposed animals. Chemical analysis is ongoing. Future work include 1) a recovery exposure to be performed in summer 2019 to assess fish embryonic recovery and 2) a throughput transcriptional investigation of all time-points, including targeted real-time RT-PCR analysis of a series of genes related to xenobiotic detoxification and oxidative stress (e.g., cyp1a, ahr, gst, gsr, and p53). This research is part of the large NSERC-SPG research effort where the results will help to understand the direct and indirect repercussions of a dilbit spill in freshwater ecosystems.

WP079 Limnocorral study to examine impacts of diluted bitumen on wild small-bodied freshwater fish at IISD-Experimental Lakes Area, northwestern Ontario
L. Timlick, University of Manitoba / Department of Environment and Geography; J. Séguin, J.M. Blais, University of Ottawa / Biology; M.L. Hanson, University of Manitoba / Department of Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada / Emergencies Science & Technology; V.S. Langlois, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; D.M. Orihel, Queen’s University / Department of Biology/School of Environmental Studies; J.L. Rodriguez-Gil, University of Ottawa / Department of Biology; V. Palace, IISD-Experimental Lakes Area

The Boreal lake Oil Release Experiment by Additions to Limnocorals (BOREAL) project began in 2018 at the IISD-Experimental Lakes Area (Ontario, Canada) to study the fate, behaviour, and potential toxicological impacts of diluted bitumen (dilbit) in fresh water. Model spills were contained within seven 10 m diameter, littoral limnocorals (~2 m deep) and dilutions ranged from 1:100,000 to 1:1,000 dilbit:water. These values were chosen to represent a regression of real-world spills equivalent to the 50th and 99th centiles in North America over the last two decades. Two additional limnocorals untreated with dilbit and fish caught from the open lake serve as references. Adult male and female finescale dace (Phoxinus neogaeus) were released in the limnocorals 21 days after oil addition, while incidental juvenile fathead minnows (Pimephales promelas) were present in the enclosure from oil addition onwards. Here we report the effects of chronic exposure (~21 days) on reproductive health of adult fish, development of juveniles, and physiological and molecular responses in both stages. Assessed metrics of reproductive health and metabolism include calculation of male and female gonadal somatic indices, egg diameter, histological development of gonads in both sexes, and condition factor. Gills were scored for deformities and hepatocyte volume indexes were examined as well as mRNA upregulation of Cyp1a. Results indicate that in the lower exposures (~1:10000) there are no significant effects on the health of adult or juvenile small-bodied fish, but in the higher exposures (~3:10000) there is a significant increase in mortality.

WP080 Use of Petroleum “Biomarkers” to Isolate Chemical Behaviours of Diluted Bitumen in a Freshwater Boreal Lake
B. Hollebone, Z. Yang, K. Shah, R. Faragher, Environment and Climate Change Canada; M.L. Hanson, University of Manitoba / Environment and Geography; D.M. Orihel, Queen’s University / Department of Biology / School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; J.M. Blais, University of Ottawa / Biology

Recent reports from the Royal Society of Canada (RSC) and the United States National Academy of Sciences (NAS) have highlighted the difficulties in modelling the behaviour of heavy oils, including dilutted bitumen. Of particular concern are the behaviours and mass balances for evaporation, dissolution, photolytic degradation and degradation. However, experimentally, it is challenging to find chemical markers in crude oils that are affected primarily by single types of behaviour, to estimate the rate of these behaviours and so determine mass balances for the oil spilled. The recalcitrant hydrocarbon fossils found in abundance in bitumen may offer unique solutions. The C14 to C16 diesel-range alkylated adamantanes are good candidates for following evaporation; they will not readily photodegrade, are not significantly water soluble, and are not favoured as food-sources by oil degrading organisms. Similarly, the aromatic steranes are insoluble in water, too massive to readily evaporate, and not biodegraded, however their aromatic chromophores can be chemically degraded by photolysis. Using a dataset from oils exposed for 80 days in a boreal lake at the International Institute for Sustainable Development-Experimental Lakes Area, we examine the hypotheses that these petroleum “biomarkers” are suitable for the task of quantifying evaporative and photodegradation changes in diluted bitumen, in response to the data gaps identified by the RSC and the NAS.

WP081 Petroleum hydrocarbons in the water column and sediments following experimental additions of diluted bitumen to freshwater limnocorals
S.S. Stoyanovich, J.L. Rodriguez-Gil, University of Ottawa / Department of Biology; M.L. Hanson, University of Manitoba / Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada; D.M. Orihel, Queen’s University / Department of Biology / School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; K. Shah, Z. Yang, Environment and Climate Change Canada; J.M. Blais, University of Ottawa / Biology

The BOREAL (Boreal-lake Oil Release Experiment by Additions to Limnocorals) project involved adding diluted bitumen (dilbit) to a series of nine limnocorals installed in a freshwater lake to examine the fate, behaviour and effects of hydrocarbons in a boreal lake. A regression design was utilized, comprised of 2 controls (one near field and one far field) and 7 treatments that received dilbit volumes ranging from 1.5 to 179.8 L of dilbit, resulting in oil/water ratios ranging between 1:1000 to 1:10000. This presentation will focus on assessing the partitioning behaviour of dilbit’s chemical constituents; including n-Alkanes, mono/poly cyclic aromatic hydrocarbons (BTEX and PACs) and petroleum biomarkers, between the dilbit slick, water column and sediments. Briefly, total BTEX concentrations measured in the water over the first four days of the study showed rapid increases in water column concentrations, reaching maximum concentrations by day 1, ranging from 1.83 to 107 mg/L across all treatment levels. Total PAC (TPAC) concentrations in the water column reached their maximum (ranging from 729 to 2466 ng/L) across all treatments by day 15. Following this increase, concentrations in the water column then began to deplete, coinciding with a subsequent increase in sediment TPAC concentrations. At the end of the experiment, sediment TPAC concentrations ranged from 49 to 188 ng/g dry weight, while sediments in direct contact with sunken dilbit had TPAC concentrations ranging from 1800 to 5600 ng/g dry weight. Petroleum hydrocarbon contamination of both the water column and the sediments followed a dose-dependent relationship, with higher levels of contamination observed in the higher dilbit treatments. These results are important for our understanding of dilbit’s behaviour in the environment across a wide range of possible spill sizes and the potential impacts it can have on important environmental media such as the water column, the sediments and the surrounding biota. It is our hope that our findings will help inform evidence-based management strategies for the transport of dilbit in Canada.
WP082 Toxicokinetics of Polycyclic Aromatic Compounds and Metals in Giant Floater Mussels (Pyganodon grandis) Exposed to a Simulated Diluted Bitumen Spill

J.Y. Seguin, University of Ottawa / Biology; J.J. Mason, Queen’s University; M.L. Hanson, University of Manitoba / Environment and Geography; B.P. Hollebone, Environment and Climate Change Canada; D.M. Orihel, Queen’s University / Department of Biology / School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; J.L. Rodriguez-Gil, J.M. Blais, University of Ottawa / Biology

Canadian bitumen is mainly transported via pipeline, train, and trucks, all posing a risk as they can lead to the accidental release of diluted bitumen (dilbit) into the aquatic environment. In the summer of 2018, a collaborative large-scale field experiment was conducted at the IISD - Experimental Lakes Area to assess the impacts of a dilbit spill in a freshwater ecosystem. The research objectives of the Boreal lake Oil Release Experiment by Additions to Limnocorals (BOREAL) project are to understand the fate, behaviour, and potential toxic effects of dilbit in a Boreal lake ecosystem to inform evidence-based management strategies for the transport of dilbit in Canada. A range of controlled dilbit spills were conducted in seven 10 m diameter limnocorals (~100,000 L of water) resulting in environmentally realistic dilbit:water dilutions ranging from 1:66,071 to 1:588, representative of the upper half of the distribution of oil spill sizes occurred in North America in the last decade. Additionally, two limnocorals, not treated with dilbit, were studied as controls. Here we identify the bioaccumulating compounds associated with naturally weathered dilbit in giant floater mussels (Pyganodon grandis), and determine the rates at which they are accumulated and excreted. More specifically, the bioaccumulation and toxicokinetic parameters of polycyclic aromatic compounds (PACs) and various metals were evaluated. When environmental [Na\(^+\), K\(^+\), Ca\(^{2+}\), Cl\(^-\), and HCO\(_3^-\)] in freshwater systems are critical for physiological functions. However, elevated concentrations of chloride ions from road salts eventually make their way into waterways. Previously, Daphnia have been used as test organisms to generalize the toxicity of Cl\(^-\) from road salt to zooplankton species, and these experiments have played a crucial role in our understanding of the environmental effects of increased salinity. Although Daphnia are vital to the functioning of freshwater ecosystems, many lakes with elevated Cl\(^-\) concentrations are shallow and therefore are not ideally suited to these pelagic species. Consequently, two dominant littoral Cladocera species (Eubosmina longispina and Chydorus Brevilabris) were selected as test organisms for this study because results from sediment core analysis suggest that they are particularly Cl\(^-\) sensitive (E. longispina) and Cl\(^-\) tolerant (C. brevilabris). 21-day renewal bioassay experiments were conducted with eight different Cl\(^-\) treatments, ranging from 0.4 mg/L to 1200 mg/L using a softwater medium. This softwater medium more closely reflects actual conditions in Precambrian shield lakes in the region. Our results add to the growing body of work examining whether the current Canadian Water Quality Guideline (CWQG) for chloride concentrations in lakes is sufficient for the protection of aquatic life in low-nutrient sites typical of the Precambrian Shield.

WP084 Assessing the impact of chloride from road salt on the survival and reproduction of two littoral Cladocera species (E. longispina and C. brevilabris)

R. Valleeau, M. Celis-Salgado, Queen’s University / Biology; A. Paterson, Ontario Ministry of the Environment, Conservation and Parks / Dorset Environmental Science Centre; J.P. Smol, Queen’s University / Department of Biology

Road salt is commonly used as a deicing agent for winter road maintenance. Of the several compounds that can be used for this purpose, sodium chloride (NaCl) is the most commonly used in Canada. NaCl is highly water-soluble and, because of their conservative nature, almost all chloride ions from road salts eventually make their way into waterways. Previously, Daphnia have been used as test organisms to generalize the toxicity of Cl\(^-\) from road salt to zooplankton species, and these experiments have played a crucial role in our understanding of the environmental effects of increased salinity. Although Daphnia are vital to the functioning of freshwater ecosystems, many lakes with elevated Cl\(^-\) concentrations are shallow and therefore are not ideally suited to these pelagic species. Consequently, two dominant littoral Cladocera species (Eubosmina longispina and Chydorus Brevilabris) were selected as test organisms for this study because results from sediment core analysis suggest that they are particularly Cl\(^-\) sensitive (E. longispina) and Cl\(^-\) tolerant (C. brevilabris). 21-day renewal bioassay experiments were conducted with eight different Cl\(^-\) treatments, ranging from 0.4 mg/L to 1200 mg/L using a softwater medium. This softwater medium more closely reflects actual conditions in Precambrian shield lakes in the region. Our results add to the growing body of work examining whether the current Canadian Water Quality Guideline (CWQG) for chloride concentrations in lakes is sufficient for the protection of aquatic life in low-nutrient sites typical of the Precambrian Shield.

WP085 Major Ion Toxicity Studies in Daphnia magna: Hemolymph Ion Concentration and Transepithelial Potential Endpoints

C. Morris, McMaster University / Biology; M. Sakarya, G. Singh, McMaster University; M.J. O’Donnell, McMaster University / Department of Biology

Cladocera are powerful osmoregulators and thrive in a wide range of aquatic ecosystems. Fluorocarbon concentrations within these environments cause disturbance to the hydromineral homeostasis of freshwater species. Major ions (Na\(^+\), K\(^+\), Ca\(^{2+}\), Cl\(^-\) and HCO\(_3^-\)) in freshwater systems are critical for physiological functions. However, elevated concentrations of these ions cause osmoregulatory stress in freshwater animals that live in hypo-osmotic habitats. Many anthropogenic activities (e.g. mining, de-icing with road salt, irrigation) have been identified as sources of major ion runoff into freshwater habitats. Daphnia magna, a cladoceran toxicology model, is adapted for active ion uptake and reduction of passive ion loss in freshwater to maintain its osmotic balance. Using ion-selective microelectrode techniques, hemolymph ion concentrations were evaluated. When environmental [Na\(^+\)] or [K\(^+\)] are gradually elevated, the animals exhibit a sustained elevation in the hemolymph levels of the same ion. This corresponds with previously published LC50 values, indicating that hemolymph ion levels may be used to help predict toxicity. Interestingly, the rise in hemolymph [K\(^+\)] was mitigated by exposure to ambient Na\(^+\). Conversely, the rise in hemolymph [Na\(^+\)] was mitigated by exposure to ambient Ca\(^{2+}\). Lastly, transepithelial potential (TEP) (another measurable parameter that could be used to predict toxicity) baseline was characterized. Alterations in TEP took place following exposure to elevated ambient levels of major ions. These data advance our understanding of whether hemolymph ions and TEP could be used to build a model to predict major ion toxicity in environmental context.

WP083 Acute toxicity of NaCl based road salts to aquatic macroinvertebrates

H.R. Wilson, Alma College / Environmental Studies; A.D. Harwood, Alma College / Environmental Studies / Biology

In Michigan alone, salt application on state highways ranges from 343,000-760,000 metric tons per year. About half of these salts enter freshwater ecosystem. The research objectives of the Working Towards Solutions – Experimental Lakes Area to assess the impacts of a dilbit spill in a freshwater ecosystem. Normalization for chloride ion had no effect on these relationships; therefore, the toxicity of road salts used in this study can be predicted based on chloride ion concentrations. Although LC50 values found in this study were greater than environmental concentrations reported by existing literature, more research is needed to evaluate chronic or sublethal effects of road salts on freshwater macroinvertebrates.

FWater Freshwater Salinization: Causes, Effects and Working Towards Solutions

WP083 Acute toxicity of NaCl based road salts to aquatic macroinvertebrates

H.R. Wilson, Alma College / Environmental Studies; A.D. Harwood, Alma College / Environmental Studies / Biology

In Michigan alone, salt application on state highways ranges from 343,000-760,000 metric tons per year. About half of these salts enter freshwater ecosystem. The research objectives of the Working Towards Solutions – Experimental Lakes Area to assess the impacts of a dilbit spill in a freshwater ecosystem. WP086 The Relative Toxicity of Road Salt Alternatives to Early Life Stage Freshwater Mussels

L.H. Nguyen, C. Zhang, University of Houston, Clear Lake / Environmental Science

With the increasing use of glyphosate- and glufosinate-based herbicides in agricultural and non-agricultural sectors, the need for routine monitoring is warranted to protect environmental and public health exposures. Currently, the consensus on whether or not glyphosate is cancerous is contentious and controversial, and there is no effective method, such as direct injection ion chromatography coupled with a single quadrupole mass spectrometry (IC-MS), that can be used for the routine analysis of glyphosate, glufosinate, aminomethyl phosphonic acid (AMPA), and 3-methyl phosphonyl propionic acid (MPPA) concentrations in water. A novel direct injection IC-MS method with pre-concentration was developed to analyze these compounds in surface/drinking water and wastewater samples. The pre-concentration (anion exchange column) technique allowed for lower detection limits without the labor-intensive and time-consuming step of derivatization. The calculated method detection limit (MDL) for glyphosate, AMPA, glufosinate, and MPPA were 0.352, 0.174, 0.509, and 0.324 µg/L, respectively. The method shows an excellent linear range (0 - 50 µg/L) and good recoveries (41% - 125%) except for MPPA. Representative water samples across the U.S. were collected for determination of all four compounds (n = 14, 4, and 6 for drinking water, surface water, and wastewater, respectively). Glyphosate, AMPA, glufosinate, and MPPA were found to have a detection frequency of 7, 13, 100, and 100%, respectively. The range of concentration for glyphosate, AMPA, glufosinate, and MPPA were MDL - 20.9, MDL - 40.6, 14.8 - 176.6 and 2.3 - 26.11 µg/L. The IC-MS method coupled with an online pre-concentration SPE column can serve as a better and cost-effective alternative over existing methods to accurately analyze glyphosate, glufosinate, AMPA, and MPPA at their environmentally relevant concentrations. Although the sensitivity of this online SPE IC-MS method still needs to be refined in reference to LC-MS/MS at the sub-ng/L or ng/L level, we were able to demonstrate that glyphosate, glufosinate and their degradation products can be frequently detected in the environmental water at their ug/L level. Our results implied negligible adverse human health effects based on the existing maximum contaminant level (MCL) in drinking water (700 µg/L) and reference dose (2 mg/kg-d) for glyphosate, but the health risks of the other three compounds remain unknown because of the lack of current regulatory thresholds.

WP088 Glyphosate: General researches and toxicology - a scientometric review

N. Ghia, Federal University of Technology - Paraná Campus Dois Vizinhos (UTFPR-DV) / Biology and Ecology; N.R. Zuanazzi, Federal University of Technology - Paraná / Postgraduate Program in Agroecosystems; E. de Oliveira, Federal University of Technology - Paraná Campus Dois Vizinhos (UTFPR-DV)

Glyphosate (GLY) is a broad-spectrum organophosphate herbicide. It is currently the most used herbicide globally. The International Agency for Research on Cancer (IARC) has recently (2016) classified GLY as a Group 2A, i.e., ‘probably carcinogenic to humans’. With the enormous input of scientific information daily, it is difficult to follow and analyze all the global publications. In this sense, the scientometrics analysis is a super new tendency that help to evaluate quantitatively the scientific and technological activity in diverse fields. For this reason, the aim of this research was to perform a scientometric review with all the publications about GLY, specially focusing in the researches categorized as ‘toxicology’. The data were retrieved from the Web of Science database (WoS) (http://apps.webofknowledge.com). The searched keyword was TS (Topic Search) = Glyphosate. It was found 10,509 results, among 1975 and 2019. After the refinement we selected 10,069 records. The data were analyzed using WoS tools and CiteSpace, to evaluate and visualize co-citation networks. With all the refined records about GLY, the H-index was 124, with an average of 16.62 citation per item. It means that this dataset had 124 papers with at least 124 citations each. The leader country was USA, with the highest citation count (3621) and centrality (c=0.34). The 2nd ranked was Brazil with 970 citations, but 9th in centrality (c=0.08), followed by Canada (740) and China (620). Germany was the 2nd in centrality (0.22), followed by Australia (c=0.12), and Poland (c=0.1). China, France and Germany were set in Cluster #0, whilst USA, Australia and Argentina were in Cluster #1; and Brazil, Canada and Spain were in #2. About the WoS categories, the top ranked item was AGRICULTURE, with 4426 citation counts, followed by AGRONOMY, with 3191. The 3rd was PLANT SCIENCES (3177), followed by ENVIRONMENTAL SCIENCES & ECOLOGY (1694), ENVIRONMENTAL SCIENCES (1458), CHEMISTRY (1173) and TOXICOLOGY (789). On other hand, the top ranked item by centrality was TOXICOLOGY, with centrality of 0.30, followed by ENGINEERING (0.28), CHEMISTRY (0.23), BIOCHEMISTRY & MOLECULAR BIOLOGY (0.21), and AGRICULTURE (0.18). The centrality reflects the influence of an area or countries whilst the frequency main the visibility. Thus, we can see that not always the category with greater visibility has greater scientific influence. In this sense, by this metric, TOXICOLOGY is the important research area in GLY researches.
WP089 Preliminary assessment of the potential impacts of neonicotinoids on wild fish health in Ontario streams

G. Tetreault, J. Miller, Environment and Climate Change Canada / Water Science & Technology Directorate; E.A. Gilroy, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.J. Bartlett, Environment and Climate Change Canada / Water Science and Technology Directorate

Pesticides are designed to be toxic and can cause detrimental effects not only to the species that they are intended to control but also to non-target organisms. Previous studies have documented the occurrence and distribution of neonicotinoid insecticides in surface waters in over 90% of Ontario streams sampled. There is concern about their potential to cause changes in higher levels of biological organization such as fish health. This study investigates fish health and fish populations and community structure in two small watersheds in southern Ontario (Canada): Sturgeon Creek, which is in close proximity to agricultural activity and where neonicotinoids have been routinely measured, and Cedar Creek, which is removed from agricultural activity. The ability of Pumpkinseed sunfish (Lepomis gibbosus) to respond to contaminants (e.g. oxidative stress, acetylcholinesterase [AChE]) and whole organism endpoints (e.g. weights, lengths, organ weights, visual anomalies) were analyzed and compared between collection sites. At the time of fish collections, surface water grab samples from Sturgeon Creek had measurable levels of imidacloprid and acetamiprid. Fish in Sturgeon Creek were larger and had greater hepatosomatic indices than those collected at the reference site. Analysis of AChE and oxidative stress indicators are on-going. The results generated from this research will be provided to Health Canada’s Pesticide Management Regulatory Agency (PMRA) for consideration when conducting risk assessments, special reviews, and re-evaluations, and when developing water quality guidelines for these compounds.

WP090 Assessing Daphnia magna population-level response to the differential toxicity of chlorpyrifos and chlorpyrifos-oxon at the watershed scale

S. Krail-Maggio, P. Janney, J.J. Jenkins, Oregon State University / Environmental and Molecular Toxicology

Pacific Northwest freshwater resources are key elements in the life history and ecology of Pacific salmon and steelhead (Onchorhynchus sp.). In addition to overfishing, critical habitat degradation and loss has been identified as contributing to population decline, resulting in 28 evolutionary significant units listed as threatened or endangered under the Endangered Species Act. Characterizing risks to Pacific salmonids and their food web related to pesticide exposure requires complex spatial and temporal information on life history and ecology, as well as pesticide use patterns and environmental fate. Probabilistic methods can be used to characterize realistic pesticide use practices while ecotoxicological models can simulate pesticide transport from the application sites to freshwater resources utilized by Pacific salmonids and their food web allowing for spatial and temporal estimation of exposure of aquatic receptors. Daphnia magna was chosen as a sensitive indicator of receptor response to freshwater toxicant exposure, allowing modeling results to be cautiously extrapolated to other populations of aquatic receptors higher on the species sensitivity distribution. For this study, a probabilistic approach was used to characterize use practices of the organophosphate insecticide chlorpyrifos in the Zollner Creek watershed, Willamette Valley, Oregon between 2010 and 2011. The Soil and Water Assessment Tool (SWAT) was used to simulate the fate and transport of chlorpyrifos and chlorpyrifos-oxon, a degradation product of toxicological concern, and estimate daily aqueous exposure concentrations. In aquatic life, chlorpyrifos is metabolized to chlorpyrifos-oxon, which is thought to be the primary neurotoxic agent. To investigate the impact of chlorpyrifos use practices on aquatic resources in the Zollner Creek watershed, we utilized daily model estimates of chlorpyrifos and chlorpyrifos-oxon concentrations and a Tier 1 population model, parameterized with acute and chronic bioassay data, to evaluate the combined effect of chlorpyrifos and chlorpyrifos-oxon on D. magna population dynamics over a 2-year period.

WP091 Potential aquatic toxicity of pesticide mixtures in Canadian Prairie wetlands

E. Malaj, K. Liber, University of Saskatchewan / Toxicology Center; C.A. Morrissey, University of Saskatchewan / Department of Biology

WP092 Current-Use Pesticides in New Zealand Streams: Comparing Results from Grab Samples and Three Types of Passive Samplers

K.J. Hageman, Utah State University / Chemistry & Biochemistry; C. Aebig, University of Otago / Department of Chemistry; C.S. Wong, Southern California Coastal Water Research Project Authority / Chemistry; K. Luang, University of Winnipeg / Richardson College for the Environment; S. Kaserzon, T. Reeks, The University of Queensland / Queensland Alliance for Environmental Health Sciences; M. Greenwood, National Institute of Water and Atmospheric Research; C.D. Matthaei, S. Macaulay, University of Otago / Department of Zoology

New Zealand uses more than a ton of pesticides each year; many of these are mobile, relatively persistent, and can make their way into waterways. While considerable effort goes into monitoring nutrients in agricultural streams and programs exist to monitor pesticides in groundwater, very little is known about pesticide detection frequencies, concentrations, or their potential impacts in New Zealand streams. We used the Polar Organic Chemical Integrative Sampler (POCIS) approach and grab sampling to survey pesticide concentrations in 36 agricultural streams in Waikato, Canterbury, Otago and Southland during a period of stable stream flows in austral summer 2017/18. We explored a new approach for utilizing site-specific POCIS sampling rates. We also tested two novel passive samplers designed to reduce the effects of hydrodynamic conditions on sampling rates: the Organic-Diffusive Gradients in Thin Films (o-DGT) aquatic passive sampler and micro-porous polyethylene (MPT) tubes filled with Strata-X sorbent. Multiple pesticides were found at most sites; two or more were detected at 78% of sites, three or more at 69% of sites, and four or more at 39% of sites. Chlorpyrifos concentrations were generally the highest, with a maximum concentration of 180 ng/L being measured. Concentrations of the other pesticides were generally below 20 ng/L. Mean concentrations of individual pesticides were uncorrelated with in-stream nutrient concentrations. Most pesticides were frequently detected in POCIS due to its higher sampling rate and the relatively low concentrations of most pesticides. In contrast, chlorpyrifos was most frequently detected in grab samples. Chlorpyrifos concentrations at two sites were above the 21-day chronic No Observable Effect Concentration (NOEC) values for fish and another two sites had concentrations greater than 50% of the NOEC. Otherwise, concentrations were well-below NOEC values, but close the New Zealand Environmental Exposure Limits in several cases.
WP093 Ecological Risk Assessment of pesticides from freshwater ecosystems in Pampas region of Argentina: Legacy and current use compounds contribution

E. Iturburu, IIMYC CONICET UNMDP; G. Calderon, FAUD, UNMDP. CONICET / Instituto del Hábitat y del Ambiente (IHAM); M. Amé, National University of Córdoba-CONICET / CIBICI-Fac. Cs. Químicas; M. Menone, Universidad Nacional Mar del Plata / Lab de Ecotoxicologia

Agricultural production in Pampas region is one of the most important economic activities in Argentina. However, the possible environmental effects related to the growth of this activity in the last years have not been studied enough. Particularly, the effects of pesticides mixtures are a topic of great concern both for society and regulatory authorities worldwide, given the possible additive and synergistic relationships between these chemicals and their possible effects on aquatic biota. Based on a concentration addition model, this study developed an Ecological Risk Assessment (ERA) of pesticides from freshwater ecosystems in Pampas region. For this purpose, reported pesticides concentrations available in public bibliography and a Risk Quotients (RQs) approach were used. A cumulative risk map was established to display RQs for current use pesticides (CUPs) and legacy chemicals. The ΣRQs were calculated for 66 sites, using available reported measured environmental concentrations (MECs) and predicted no effect concentrations (PNECs) of pesticides. While RQ for only CUPs resulted in a high and very high risk (ΣRQ>1) for 29 % of the sites, when legacy pesticides were incorporated this percentage reached the 41 % of the sites, increasing significantly the absolute values of ΣRQ. Herbicides like glyphosate and atrazine contributed considerably to the ΣRQCUPs while organochlorines were the major contributors for ΣRQs when legacy pesticides were incorporated. Moreover, some active ingredients (acetochlor, carbendazim and fenitrothion) which are approved for their use in Argentina but banned in EU showed high contribution to ΣRQCUPs. The present study is the first attempt to develop an ERA in surface water of the Pampas regions of Argentina and it provides a starting point for a more comprehensive pesticides monitoring and a further risk assessment program.

WP094 California’s Stream Pollution Trends (SPoT) Program: Ten years of monitoring sediment toxicity and contaminants

K. Siegler, B.M. Phillips, J. Voorhees, University of California, Davis / Environmental Toxicology; L.B. McCalla, S. Zamudio, University of California, Davis / Marine Pollution Studies Laboratory at Granite Canyon / Environmental Toxicology; K. Faulkenberry, University of California, Davis / Aquatic Toxicology; R.S. Tjeerdema, University of California, Davis / Environmental Toxicology

California’s Stream Pollution Trends (SPoT) Program assesses long-term trends of contaminant concentrations and toxicity in watersheds throughout the state. As part of the State Water Resources Control Board’s Surface Water Ambient Monitoring Program, sites at the base of 90 watersheds have been monitored annually for sediment toxicity and a suite of current-use and legacy pesticides, industrial organic chemicals, and trace metals since 2008. Toxicity is assessed with the amphipod Hyalella azteca, and more recently with the midge Chironomus dutilus as well. Monitoring results are related to land use within each watershed. Toxicity and contaminant concentrations, particularly pesticides, tend to increase with increasing urban land use. The addition of C. dutilus testing at urban sites has identified toxicity at sites that were not toxic to H. azteca, indicating the importance of testing with multiple species of varying sensitivity. SPoT’s network of sites is used to support California’s integrated report and support other agencies, and data from SPoT sites support a number of collaborations from urban stormwater programs to specific trend monitoring. In addition to regulatory uses, SPoT data are used to investigate the efficacy of the Department of Pesticide Regulation’s 2012 pyrethroid pesticide label changes, and the effectiveness of recent brake pad regulations. SPoT is the first statewide program to evaluate trends of the current-use pesticide fipronil and the algal toxin microcystin in sediments, both of which were detected in many regions. As part of California’s Open Data Initiative, an interactive data portal was developed to allow broad public access to SPoT data. Data from all aspects of SPoT will be presented to summarize the first decade of this statewide monitoring program.

WP095 Monitoring and Risk Assessment of Chlorfenapyr Residue

Y. Cho, J. Kim, Gyeongnam Department of Environmental Toxicology and Chemistry; J. An, Gyeongnam Department of Environmental Toxicology and Chemistry / Environmental Toxicology Research Group; J. Song, Korea Institute of Toxicology, KIT; Y. Kim, S. Jeong, J. Jung, Gyeongnam Department of Environmental Toxicology and Chemistry; J. Seo, Korea Institute of Toxicology

This study was conducted to monitor the residue of Chlorfenapyr in Korean melon and to assess its risk for human health. This study was carried out on three different field trials and the pesticide was uniformly sprayed two times with intervals of 7 days onto the crop using a powder sprayer at ratio of approximately 2.0 L/10 m² (a.i. 5%). After last application, the crops were harvested at 0, 1, 3, 5, 7 and 14 days. The samples collected from the field trials were divided into two specimens of peel and pulp, and then each sample was analyzed using GC-MS/MS after a QuEChERS pretreatment method. Analytical method was validated prior to analysis of samples, showing method limit of quantitation (MLOQ) was 0.008 mg/kg and the recovery’s results with three spiking levels (MLOQ, 10 times of MLOQ, 50 times of MLOQ) ranged from about 70.0 to 115.0% and relative standard deviation (RSD) was less than 11.7% for all samples. Most residue of chlorfenapyr remained in peel part during the test period and about 10 to 20% of total residues were detected in pulp part. Based on the residue results of chlorfenapyr, a risk assessment was calculated using a percentage ADI depending on an ED1 value, resulting in less than 0.09 % and considered to be safe for human health.

WP096 Temporal Patterns of Pesticide Residues in Four Major River Basins in Korea

C. Kim, K. Son, H. Lee, E. Lee, National Institute of Agricultural Sciences / Department of Agro-food Safety & Crop Protection

To evaluate residues of environmental concerned pesticides which mainly include pesticides used for rice cultivation, total ninety four sampling sites were selected through main streams and branch streams of four major river basins. And the water samples at these sites were collected four times per year, April, May-June, July-August, and September-October or November-December in 2012 and 2014. Besides, the water samples at sites of Keum, Mangyang and Dongjin rivers belong to the Keum river basin were regularly collected with a month interval, especially biweekly from May to August in 2013. Of the pesticides monitored, fenoxanil, hexaconazole, isoprothiolane, iprobenfos and thiофenate-methyl fungicides were mainly detected in rice season. While other fungicides including diniconazole, procymidone, fenarimol, muriarim and boscalid, were detected with low frequencies and their average residue levels in positive samples were also fairly low. Of the insecticides monitored, some organophosphorus, cadusafos, diazinon, fenithiofan, fenitrothion, phenthoate and prophos, two carbamates, carbofuran and fenobucarb, and endosulfan were detected with low frequencies and low residue levels. Of the herbicides monitored, nine pesticides which include alachlor, butachlor, dimethametryn, dithiopyr, ethalfluralin, metolachlor, oxadiazon, simetryn and thiobencarb were detected with frequencies of 1-48% and in their residue level of 0.01-1.9 μg/L. Detection frequencies and residue levels of insecticides and herbicides were the highest in waters sampled in May and June. Almost pesticides detected were for the rice plants and their residue levels were very low to compare with standard values.

WP097 Estimating Regulatory Surface Water Pesticide Thresholds from Effect Databases

L.L. Petchick, S. Bub, S. Stehle, J. Wolfram, R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences

Regulatory threshold levels (RTL) represent robust benchmarks for assessing aquatic risks of pesticides in surface waters. However, RTL
are currently only available for a few substances as a result of extensive literature searches reviewing regulatory documents. Thus, we developed a model that estimates large numbers of RTL using publicly available ecotoxicological effect databases. The model applies validity criteria used in USEPA review guidelines and is validated against manually retrieved RTL. Estimated RTL (N=779) are made publicly available and kept up-to-date via continuous synchronization of effect databases. The provided dataset enables large-scale risk characterizations and can be used for informed decision making for various stakeholders. Especially regions without established pesticide regulation may benefit from this dataset by using it as a baseline information for pesticide risk assessment and for the identification of priority substances.

WP098 Persistent pesticides: Effects of Endosulfan on gene expression and enzymatic activity of the aquatic invertebrate Chironomus riparius

A.M. González, National Distance Education University / Mathematical Physics and Fluids; M. Novo, Complutense University of Madrid / Biodiversity, Ecology and Evolution Department; J. Martínez-Guztirte, National Distance Education University / Física Matemática y de Fluidos

Endosulfan is an organochlorine pesticide widely used against pests and mites for the last five decades around the world. Commercialized as a mixture of α and β isomers (7:3), α has a longer half-life about 157 days. It has been banned in many countries, but due to their chemical properties, such as semi-volatility and relative persistence, it is a ubiquitous contaminant present in air, soils and water reservoirs. It was the most used pesticide in the United States for a wide number of crop types, including cotton, cereals, fruit trees. Besides, it is an extremely toxic and harmful compound to beneficial non-target invertebrates, aquatic life, and even humans by the consumption, because it biomagnifies in the food chain. Chironomus riparius, as a basal organism in the food chain, is ideal to evaluate the effects of endosulfan in water bodies. In this work we have exposed fourth instar larvae at 0.1, 1 and µg/L, environmentally relevant concentrations, for 24 hours, looking for a deeper analysis of the effects of these acaricide at sub lethal concentrations for C. riparius. The aim was to understand the changes on the organism at gene expression level by Real time PCR using an array designed with 42 genes related to endocrine system, detoxification response, immune system, DNA repair, apoptosis and stress response as well as the enzymatic activity of Glutathion-S-transferase (GST), Phenoloxidase (PO) and Acetylcholinesterase (AChE). All evaluated routes have been altered by endosulfan exposure, significant differences were found on Met, EcR, InR, E93, Dis, Cyp9f2, GSTδ3, GST β, MRPl, Proph, Def, ATM, PARP, hsp70, hsp40, and hsp24 mRNA levels, showing a strong effect despite the low concentrations used. According to the enzymes at the concentrations tested, no differences were observed, showing less neurotoxic effect (AChE) on Chironomus comparing to the previous results in other invertebrates and for PO and GST activity activation, a longer exposure may be necessary. These results reflect the damage suffered in organisms despite the absence of lethality, showing the importance of this exposure over the next generations. The new risk assessment strategies should contemplate a combination between physiological parameters and damages at the molecular level in order to obtain a comprehensive evaluation of the toxicants in the environment. Funded by: Ministerio Economía y Competitividad CICYT (SPAIN), CMT RTI2018-094598-B-I00

WP099 Occurrence of organochlorine pesticides and current use pesticides in the atmosphere and fecal from primates in protected areas

S. Wang, Indiana University, Bloomington / School of Public and Environmental Affairs; T. Steineche, Indiana University / Department of Anthropology; K. Romanak, Indiana University / Department of Anthropology; M. Wasserman, Indiana University / Department of Anthropology; M. Venier, Indiana University / SPEA

The prevalence and environmental adverse effects of organochlorine pesticides (OCPs) and current use pesticides (CUPs) are a well-known problem. Since environmental threats occur across boundaries, protected areas are vulnerable despite their conservation status. Sharing a close evolutionary history with humans, nonhuman primates meet crucial criteria for serving as informative sentinels. While biomonitoring can be a challenge in wildlife, fecal sampling can provide information regarding internal exposure with minimal disturbance to threatened populations. Therefore, we examined the occurrence of OCPs and CUPs in the atmosphere and in fecal samples from primates in Costa Rica and Uganda. Our goal was to identify how regional differences and protected status influenced potential exposure to organic pollutants in protected areas. Air samples were collected using passive air samplers (PAS) with polyurethane foam (PUF) disks. PAS were deployed for ~3 months in Kibale, Uganda, and two biological field stations in Costa Rica, La Selva (LS) Biological Station and Las Cruces (LC) Biological Station. Fecal samples from primates were also collected in Kibale and Costa Rica. Samples were analyzed for OCPs and CUPs using gas and liquid chromatography mass spectrometry. In air, the most abundant OCPs were alpha-endosulfan and alpha-chlordane in Costa Rica and hexachlorobenzene (HCB) in Uganda, and the most abundant CUP was chlorpyrifos for both countries. Significantly higher concentrations for CUPs were observed around LS, while LC had a higher concentration of OCPs. Land use analysis indicated that LS had a higher fraction of agriculture than LC (33% vs. 14%), suggesting higher CUPs concentration at LS was related to pesticide intensive crops, while higher OCPs concentration at LC may be attributed to the area’s long agricultural history characterized by small-scale subsistence farming or long-range transport. In fecal samples, the most abundant OCPs were alpha-HCH, beta-HCH, and HCB in both Uganda and Costa Rica and the most abundant CUP was chlorpyrifos. This is the first to report the occurrence of OCPs and CUPs in feces of primates. The levels of target chemicals measured in primate’s feces together with negative health effects associated with some of these chemicals are a concern for primates living in these areas.

WP100 Organochlorine Pesticide Residues in Locally Cultivated Allium fistulosum, Spinacia oleracea, Lactuca sativa L. in Lagos, Nigeria

L.O. Ezugba, University of Lagos / Cell Biology and Genetics; E.O. Dada, University of Lagos / Cell Biology and Genetics / Environmental Biology Unit

Concerns are mounting over the health risks associated with the use of pesticides, especially organochlorines, to control crop pests in developing countries. In this study, some vegetables (Allium fistulosum, Spinacia oleracea and Lactuca sativa L.) and soil samples from three farms (Idi-Araba, Tejuosho and Alapere) in Lagos, Nigeria, were evaluated for organochlorine pesticide residues, using gas chromatography-mass spectrometry (GC-MS). The hazard index of consuming these vegetables was also calculated. Eighteen organochlorines were detected in the vegetable and soil samples at varying concentrations. In Idi-Araba farm, α-BHC occurred in highest concentration of 0.06±0.07 mg/kg in the shoot of L. sativa, Endosulfan I occurred in highest concentration of 0.29±0.26 mg/kg in A. fistulosum, while both P, P-DDE and L-Cyathrin occurred in highest concentrations of 0.08±0.03 mg/kg and 0.08±0.08 mg/kg respectively in the shoot of S. olerace. In Tejuosho farm, L-Cyathyrin, PF-38, and Chlorothalonil occurred in highest concentrations of 0.50±0.71 mg/kg, 0.13±0.07 mg/kg, and 0.03±0.01 mg/kg in the shoots of L. sativa, A. fistulosum, and S. olerace respectively. In Alapere farm, Endosulfan I occurred in highest concentration of 0.33±0.02 mg/kg in the shoot of L. sativa. Aldrin occurred in highest concentration of 0.02±0.01 mg/kg in the shoot of A. fistulosum, while L-Cyathyrin occurred in highest concentration of 0.04±0.05 mg/kg in the shoot of S. olerace. The concentrations of these organochlorine residues were higher than the Maximum Residual Limit (MRL) prescribed by the European Union (EU) Commission. Furthermore, Hepatoclar, Aldrin, and Endosulfan I was highly bioaccumulated and translolated by all the sampled vegetables. The Hazard Index (HI) calculated for A. fistulosum and S. olerace from Idi-Araba farm, and L. sativa from Tejuosho farm exceeded 1 (HI>1). This implies that the consumption of these vegetables exposes the consumers.
to potential health risk. Therefore, governmental protection agencies at all levels in Nigeria are advised to embark on awareness campaign, and institute monitoring programmes aimed at discouraging farmers from using organochlorine pesticides.

**WP101 Assessment of organochlorine pesticide residues in water and some selected fish species of Oli River, Nigeria**  
O. Idowu, Teesside University / School of Health and Social Care; A. Adeleye, Nigerian Institutes of Oceanography and Marine Research

The risk of Organochlorine pesticides in the protected areas is increasing due to the various agricultural activities ongoing around some national parks. The aim of this study was to determine the concentration of the spectrum of Organochlorine Pesticide in water samples from Oli River passing through Kainji Lake National Park and discharging into River Niger to assess the potential toxicity within the ecosystem. The physicochemical parameters of water sample were measured and analyzed by gas chromatography. Six fish species were sampled twice including Tigerfish (Hydrocyrus forskalii), Tilapia (Tilapia zilli), catfish mormyrid (Mormyrus delicious), Silver catfish (Chrysichthys nigrodigitatus), Nile perch (Lates niloticus). Homogenised samples were extracted by Soxhlet extraction and cleaned-up with florisil adsorbent and characterized for organochlorine content using Gas Chromatography (GC) equipped with Electron Detector (ECD). Substances such as α-BHC, δ-BHC, Heptachlor, aChlordane, Endosulphan I, Endosulphan sulphate, pp-DDT, and methoxychlor show higher concentration between 0.0356-0.113 ppm while the others of the OCP spectrum detected show lower concentration between 0.0152-0.0286 ppm. However, Endrin showed the lowest concentration with 0.09%. The highest concentration with 15.72% (α-BHC) followed by Endosulphan II (6.77%) and pp-DDT (6.44%) was found in Oli River. In all the cases, the levels of OCPs were a little high when compared to the FEPA limit of < 0.01 ppm. The mean concentrations of OCPs were higher than European Community allowable limit of 0.1ug/L for individual OCP. Ten OCPs were detected from the samples analyzed which include, α-BHC, β-BHC, Lindane, chlorothalonil, d-BHC Heptachlor, Aldrin, Heptachlor-epoxide (B), Dieldrin Endrin, Endosulphan 11, P”P”-DDT, Endosulphan Sulfate, P”P”-DDT, Lambda-Cyhalothrin, permethrin. α – BHC has the highest concentration in the fish species with a concentration of 3.853 mg/kg in fish Heterbranchus bidrosalis and the lowest organochlorine contaminant was P”P”-DDT which ranges from 0.056-0.0212 mg/kg in Mormyrus delicious. The Organochlorine concentration value of all the fish species was above the limit of Maximum Residue Limit (MRLs) and Dietary Intake (ADI) and these levels could harm the wildlife in the river. There is a need for enforcement of legislation on the use of insecticides by the farmers especially in surrounding of protected areas.

**WP102 Effects of Organophosphate Aquaculture Pesticide Azamethiphos on American Lobster (Homarus americanus) Larvae (Stage I, II, III)**  
B. P. de Jourdan, Huntsman Marine Science Centre / Environmental and Molecular Toxicology; L.E. Burridge, A. McCarthy, Huntsman Marine Science Centre; M. Sarrette, University of Moncton; D. Daoud, Homarus, Inc.

Both the American Lobster fishery and salmon aquaculture are important to the economy of Atlantic Canada. Where these industries operate in close proximity, research is needed to better understand any interactions and their possible effects. Lobster larvae, like other crustaceans, are known to be more susceptible to contaminants than adults. Laboratory exposures have revealed various pesticide effects on lobster larval survival, behaviour, development, and immunity. Salmoan(R) WP50 is a fully registered pesticide formulation used as a bath treatment to control sea lice (Lepeophtheirus salmonis or Caligus elongatus) in farmed Atlantic salmon (Salmo salar) in Atlantic Canada. The Salmoan(R) WP50 formulation is a wettable powder having 49.8% by weight of the organophosphate azamethiphos. This study explored the effects of Salmoan(R) WP50 on the survival and development of planktonic early life stages of American lobsters, Homarus americanus. Individual lobsters of Stages I, II, and III, were exposed for 3 hours to a water-borne concentration of Salmoan(R) WP50 at six nominal target concentrations; 0, 0.5, 1.6, 5, 16, and 50 µg azamethiphos/L (n = 30 individuals per treatment), which are reflective of concentrations observed following application and dispersion. Treatment-related effects were observed, with higher concentrations causing increased mortality and decreased moulting success. Significant effects on immobilization were observed after 3 hours of exposure to concentrations as low as 2.8 µg L⁻¹ azamethiphos. Acetylcholinesterase (AChE) response proved consistent across stages in terms of acting as a biomarker for exposure. Decreasing AChE activity was significantly correlated with increased immobilization and mortality, and activities below 1.1 (2.4, standard error), 1.2 (7.3, standard error), and 22.9 (7.4, standard error) nmol/min mg for Stage I, II, and III respectively, may indicate significant immobilization and predict future mortality of those stages. The temporal and geographical overlap of larval lobster life stages and the use of Salmoan(R) WP50 is important to consider when assessing potential risk.

**WP103 Effects of pesticides on aquatic and soil non-target organisms on different levels of biological organization - a project introduction**  
C. Lackmann, RWTH Aachen University, Institute for Environmental Research; M. Velki, Josip Juraj Strossmayer University in Osijek, Department of Biology / Ecosystem Analysis; H. Hollert, RWTH Aachen University / Institute for Environmental Research / Dept. of Ecosystem Analysis; T. Seiler, RWTH Aachen University / Ecosystem Analysis; M.T. Schmitz, RWTH Aachen University / Biologie V Institute for Environmental Research, RWTH Aachen University

During the last years a vast decline in species diversity has been observed not only in Germany but worldwide. This decrease is often linked to the usage of pesticides. A lack of biodiversity can have adverse effects not only on food chains and whole ecosystems but indirectly also ecosystem services. As pesticides eventually reach various environmental compartments, they present a problem for both soil and aquatic ecosystems. The current regulations only include standardized toxicity testing of the active substances, so important data is missing on the different modes of action and possibly varying toxicity of commercial formulations. To assess the possible impacts on the environment it is therefore helpful to extend the available data for pesticides already in use. To this end, it is also necessary to improve existing and develop new methods for assessing the effects of these substances on different levels of biological organization. Methods for the investigation of effects and toxicity mechanisms however often require high numbers of laboratory animals. A thorough investigation of pesticide effects using improved methods should therefore try to keep the number of used laboratory animals as low as possible. The application of early warning signals (biomarkers) can be of an advantage. However, they do not always conclude possible effects on whole populations. Consequently, a comprehensive test battery should investigate different levels of biological organization. This project will try to further develop a multi-species and multi-biomarker strategy to investigate the effects of the herbicides dimethenamid-P and prosulfocarb as well as the insecticides thiacloprid and esfenvalerate. Besides conventional enzymatic endpoints novel non-invasive, fluorescence-based assays will be applied. Both soil (Eisenia fetida) and aquatic model organisms (Daphnia magna) will be used for the experiments in this study, including study of behavioral changes as a sensitive, low-dose effect. This project is funded by the Deutsche Bundesstiftung Umwelt DBU (German Federal Environmental Foundation).

**WP104 The effect of Triphenyltin on zebrafish larvae as a non-target organism model**  
A. Arenzon, F. Saez, Federal University of Rio Grande do Sul / Center of Ecology / Ecotoxicology Lab; L. Hainzenreder Bauer, Federal University of Rio Grande do Sul

Triphenyltin (TPhT [(C₆H₅)₃Sn-X]) has been widely used in many countries as an agricultural fungicide for the control of fungus diseases and
bliet on several crops. Also, this compound has also been worldwide used as molluscicides to control snails in rice crops. Unfortunately, this procedure on a large scale is dangerous considering its environmental effects such as the toxicity to non-target organisms. The toxic effects of this compound to aquatic life have been reported; however, when fish are considered, those results were obtained based on toxicity tests conducted with more resistant stages like juveniles or adults. Based on that, acute lethal fish toxicity tests were carried out using Danio rerioembryos and larvae as the test-organisms. Embryos were exposed from 90 minutes post-fertilization to 96 hours post-fertilization. Acute toxicity test using the larval stage was conducted for 48h using zebrafish between 6 and 14 days old. The commercial product Mertin 400, a suspension containing 400 g/L 1 TPhT hydroxide was used and experiments are still being carried out in order to achieve a statistic robust analysis. The present study highlights the necessity of using the most sensitive developmental stage when considering standard methods to evaluate the effects of substances representing non-target species.

WP105 Assessing interspecific variation in earthworm pesticide toxicokinetics

A. Robinson, Centre for Ecology & Hydrology; S. Short, Cardiff University; E. Lahive, Centre for Ecology & Hydrology (NERC); P. Kille, Cardiff University; D. Spurgeon, Centre for Ecology & Hydrology

Widespread interspecific variation is seen in the sensitivity of soil invertebrates to chemical pollutants (e.g. pesticides). Since chemical risk assessments are performed on the basis of tests in a small number of reference species there is a danger of significantly underestimating the effect a toxicant may have in the environment. Differences in toxicity may be caused either by toxicokinetic (TK) or toxicodynamic (TD) factors. By combining TK and TD parameters a robust predictive tool may be developed to identify chemicals or organisms that pose particular risks. In this study we assess the sensitivity of 5 earthworm species to different organic toxicants of increasingly complex modes of action. Sensitivity was measured using toxicity tests carried out over 4 weeks at 7 concentrations of fluoranthene, chlorpyrifos, cypermethrin and imidacloprid, measuring both survival and reproduction (cocoon production rate). For chemicals showing the greatest inter-species variation in sensitivity, the TK parameters (uptake rate K₁ and elimination rate K₂) were calculated by exposing individuals to 14C labelled chemicals and analysed using a liquid scintillation counter. Tissue specific concentrations differed significantly between species, even when overall body levels were similar. Differences in TD parameters were addressed by assessing target receptor diversity and expression levels for key tissues. Important differences in tissue specific expression and ligand specificity were observed which may drive variation in sensitivity. In particular, non-target binding effects were found to greatly influence susceptibility to insecticides. Overall, greater ranges in sensitivity were found for chemicals that have a specific biological target than for toxicants that have a non-specific mode of action, such as non-polar narcosis. This suggests significant potential for variation between species when the nature of the mechanism of action is complex, with the majority of effects being driven by differences in TD parameters rather than TK.

WP106 Effects of Cyprosulfamide, Mefenpyr diethyl and their Primary Herbicides on Survival, Growth and Reproduction of Daphnia Magna

O. Femi-Oloye, University of Saskatchewan / Toxicology Center / Veterinary and Biomedical Sciences; F.F. Oloye, Adekunle Ajasin University; J.K. Challis, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences

Safeners are becoming an important class of chemicals because they prevent or reduce injury caused by herbicides used to selectively remove weeds from crops. These safeners can find their way into aquatic environments, where they may cause adverse effects on aquatic species. This work examined the effects of cyprosulfamide and mefenpyr diethyl on the freshwater invertebrate Daphnia Magna, in both acute and chronic studies. The acute studies were designed using seven concentrations ranging from 0.01-100 mg/L. The results from the acute exposure (48 hrs) using cyprosulfamide and mefenpyr diethyl (separate exposures) showed no lethal effects at concentrations up to 100 mg/L, suggesting that these chemicals are unlikely to elicit acute effects in aquatic invertebrates at environmentally relevant concentrations. Chronic exposures for both chemicals at 1, 10 and 50mg/L over 21 days were conducted to assess growth and reproduction endpoints. Additional experiments are ongoing to test the mixture toxicity of cyprosulfamide and mefenpyr diethyl in combination with their primary herbicides (Isoxaflutole and fenoxaprop-p-ethyl respectively). This work represents an important preliminary assessment of the toxicity of herbicide safeners.

WP107 Fate, Mobility, and Behaviour of Five Herbicide Safeners in Aquatic, Sediment, and Soil Environments

J.K. Challis, University of Saskatchewan / Toxicology Centre; F.F. Oloye, Adekunle Ajasin University; O. Femi-Oloye, University of Saskatchewan / Toxicology Center / Veterinary and Biomedical Sciences; P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences

Herbicide safeners work against the injurious effects of many herbicides to protect the crop plant. Safeners are applied in large volumes in commercial formulations, however, their fate and behaviour in soil and aquatic environments are poorly understood. In this work, the direct and indirect photolytic behaviour of five safeners (cyprosulfamide, mefenpyr diethyl, dichlormid, benoxacor, furilazole) will be investigated under natural sunlight. Photolysis rate constants and quantum yields were determined and photodegradation products were identified using Orbitrap ultra-high-resolution mass spectrometry. Soil sorption experiments were conducted to estimate the distribution coefficient (Kd) and organic carbon normalized distribution coefficient (Koc). The data were fitted to Freundlich and Langmuir sorption isotherms. Several different soil properties were assessed including organic carbon content, cation exchange capacity, pH, and clay content. This work provides important physio-chemical properties of these safener chemicals that will be important to understand their fate and behaviour in the environment and facilitate appropriate exposure and risk assessment of these poorly understood chemicals.

WP108 Application of nanotechnology towards improving efficiency in application of fungicides

R. Owusu, M. Wiafe-Kwagyan, E. Dankyi, University of Ghana

Copper is one of the most widely used antifungal agents in organic farming worldwide. In cocoa farming in Ghana, copper-based fungicides are the predominant chemicals approved for the control of black pod disease, a devastating fungal disease caused by Phytophthora palmivora and Phytophthora megakarya. However, the excessive usage coupled with the non-biodegradable nature of copper is a major cause for environmental concern. This study explored the use of a simple, cost effective and green approach in synthesising and applying nano-copper as an improved alternative to conventional copper fungicides. The nanoparticles take advantage of their smaller sizes, increased surface area, and higher surface-to-volume ratio thereby improving activity, efficiency and toxicity to target pest. Copper nanoparticles were synthesized using extracts of diverse local plant materials with known fungal activity, to explore possible synergies. Synthesized nanoparticles were characterised using UV-Visiblespectroscopy, x-ray diffraction spectroscopy and scanning electron microscopy. Microbial studies showed a clear correlation between size and morphology on the one hand and antifungal activity under laboratory conditions. The findings show huge promise in the use of these materials towards improving the efficiency of fungicide application.
WP109 Modeling Vapor Drift Potential of Dicamba Herbicide
S. Das, University of Otago / Chemistry; K.J. Hageman, Utah State University / Chemistry & Biochemistry

Dicamba, (3, 6-dichloro-2-methoxybenzoic acid) is a synthetic systemic herbicide, widely used around the world because of its versatility in noxious and invasive weed control. It is considered only mildly to moderately toxic to mammals, pollinators, wildlife, and aquatic organisms; however, due to its tendency to volatilize, it can undergo vapor drift and deposit on non-target fields. This can cause injury to nearby sensitive plants, ultimately resulting in crop damage and yield loss. For instance, dicamba alone has damaged about 3.6 million acres of off-target crops in the United States in 2017 cropping season. While only a handful of field studies were conducted to chemically measure dicamba volatility, no quantitative prediction is available in the form of modeling to identify the factors that trigger the volatilization of dicamba. To better understand dicamba volatilization and vapor drift potential under field conditions, we have used a visual screening tool, developed by our research group to predict the volatilization and vapor drift potential of dicamba herbicide from an agricultural field. The screening tool uses the environmentally relevant partition coefficients and the mass-balance distribution of pesticides between soil, plant, air, and water to calculate 24-h cumulative volatilization losses. Different environmentally relevant conditions were analyzed to identify the conditions under which the greatest dicamba volatilization occurs. We have found that, at least ~20% of applied dicamba will volatilize within 24 hours of spraying if the ambient air temperature remains at 30 °C and more importantly, current recommended wind speed (1.3 - 4.5 m/s) for dicamba application can cause more than 10% cumulative dicamba loss within 24 hours of application, which suggest more careful investigation of wind speed effects to control dicamba volatilization and off-target injury. However, minor/no visible effect was observed with changing soil physicochemical properties. Measured losses of dicamba under field conditions were also compared with the modeled predictions. This modeling approach could be used to aid future decision-making regarding dicamba herbicide regulation and use in the agriculture sector.

What’s Next? Future Contamination Challenges for Water Resources and Identifying Novel Tools to Solve Them
WP111 The Future is Now: How Current Research on Contaminants of Emerging Concern Can Inform Management of Water Resources

Population growth, aquifer depletion, infrastructure failure, saltwater intrusion, floods, and drought: these are just a few of the environmental drivers which currently affect the quantity and quality of water available for human and ecosystem use. Such effects are projected to exacerbate future water crises. It is unlikely that the amount of potable water will be more than we currently have. What can we, as scientists and stewards of the future, do now to mitigate the impacts of these environmental conditions? This presentation is designed to be the introduction to the Wave session “What’s Next? Future Contamination Challenges for Water Resources and Identifying Novel Tools to Solve Them.” The goal of the session is to encourage a high-level interdisciplinary discussion. This presentation is an outgrowth of a paper commissioned by the American Geophysical Union for its Centennial collection on Grand Challenges in the Earth and Space Sciences. It will be tailored, based on the other submissions to the session, to set the groundwork for the discussion within the session.

WP112 Drugs of Abuse and Illicit Drugs: An Environmental Analytical Method for Detection and Quantitation

A critical North American public health issue is the opioid epidemic. Beyond the direct human impact, there is concern that widespread use of opioids, drugs of abuse, and other illicit drugs could adversely impact ecosystem health and increase secondary human exposure. These drugs and their metabolites can pass through wastewater treatment plants and enter surface waters. The psychoactive properties for some drugs are a concern for ecosystem health, with oxycodone and cocaine recently detected in mussels and shrimp, respectively. There is a need for analytical methods to understand and characterize the occurrence, distribution, and fate of these drugs in the environment. To this end, an ultra-high performance liquid chromatography mass spectrometry (UHPLC-MS) method was developed for pain management drugs, depressants, stimulants, and hallucinogens (including amphetamines, barbiturates, benzodiazepines, cannabinoids, and opioids) as well as some common metabolites of these drugs. The method was validated in surface water, wastewater effluent, and bed-sediment. This low part-per-billion to part-per-trillion detection method will provide further understanding about the variety, concentration, and potential exposure pathways of these drugs, and represents a valuable tool to assess risk to water quality, ecosystem health, and human exposure. In the future this method will be expanded to analyze for these drugs in biosolids and aquatic insects.
WP114 Development of a direct injection LC-MS/MS method for the detection of glyphosate and aminomethylphosphonic acid (AMPA) in Sri Lankan well water

J. Ulrich, Duke University / Civil and Environmental Engineering; N. Jayasundara, University of Maine / School of Marine Sciences; L. Ferguson, Duke University / Civil and Environmental Engineering

The global burden of disease due to unsafe drinking water is large and disproportionately impacts the developing world. In recent years, persistent water-borne diseases in these countries, potentially intensified by the presence of emerging contaminants, have become an increasing issue. Within Sri Lanka, rural areas have recently been experiencing an epidemic of chronic kidney disease of unknown etiology (CKDu) that appears to be linked to drinking wells with considerably hard water. It has been hypothesized that the pesticide glyphosate is a driver in kidney toxicity within this region due to the long half-life of glyphosate in hard water (~7-22 years) and its ability to form metal complexes with nephrotoxic metals in the environment. Due to the zwitterionic characteristic of the pesticide, typical analytical methods for the detection of pesticides are incompatible. Here we present a novel LC-MS/MS direct injection method for the detection of glyphosate and its main degradation product AMPA within groundwater and surface water. The method uses reversed-phase and weak anion-exchange mixed mode column chromatography to analyze both glyphosate and AMPA. Mixed-mode chromatography is successful in retaining glyphosate (and other negatively charged polar compounds) for enhanced identification and quantification using mass spectrometry, which overcomes the challenges of the zwitterionic characteristics of both glyphosate and AMPA. Detection is performed using a high-performance, ion-funnel equipped triple quadrupole mass spectrometer. Due to the high-performance of the mass spectrometer, we estimate our detection limits for glyphosate and AMPA to be between 1-3 ppb and our limits of quantitation to be between 5-10 ppb. This work is one of the first studies to utilize a direct injection LC-MS/MS method to analyze glyphosate and AMPA in water. In addition, the application of the method to analyze these important pesticides in drinking water sources within the developing world is novel. Our results will help to further understand the persistence and origins of CKDu in Sri Lanka while advancing toxicology research in this region of the developing world.

WP115 Risks Assessment of Typical Emerging Contaminants and their Byproducts during the Photochemical Transformation in Water

Y. Gao, Institute Environmental Health & Pollution Control; G. Li, Guangdong University of Technology / School of Environmental Science and Engineering; T-Au, Guangdong University of Technology / Institute of Environmental Health and Pollution Control

Emerging contaminants such as fragrance synthetic musks and bactericides have attracted attention worldwide recently, due to the widespread occurrence and potential toxicities. Given their extensive use, emerging contaminants have caused a widespread contamination in water environment. Especially they may photo-chemically transform into other products. Accordingly, the aquatic ecosystems and human health are exposed to an unknown cocktail of these pollutants as well as their degradation products. Therefore, it is of great concern to unmask the transformation mechanisms, kinetics, as well as the potential toxicity of these photochemical products. This study will focus on the two different categories of typical emerging contaminants, synthetic musks including poly cyclic musk (tonalide) and nitro musk (musk xylene) and bactericide parabens. The direct and indirect photo-chemical transformation processes were modeled using both experimental and high-accuracy molecular orbital theory calculations. Results show that the OH-indicated indirect photochemical transformation of musk xylene occur mainly via H-abstraction pathways from its methyl group, while tonalide and parabens mainly via both +OH-addition and H-abstraction pathways. Furthermore, in assessing eco-toxicity and human health of these products, several products were found to be more bioaccumulative and harmful to organisms. The obtained results will provide the helpful information for environmental protection and will help design further experimental studies.

WP116 USEPA CompTox Chemicals Dashboard as a web-based data resource to help identify contaminants in water

A.J. Williams, US Environmental Protection Agency / National Center for Computational Toxicology; J.R. Sobus, E.M. Ulrich, US Environmental Protection Agency / Office of Research and Development National Exposure Research Laboratory

Non-targeted screening, targeted screening and suspect screening, as well as “Known Unknowns” and “Unknown Unknowns” are now common terms in the field of water analysis. While mass spectrometry data processing can be highly automated, the identification of chemicals from the resulting extracted masses, formulae or fragmentation patterns utilizes reference spectral libraries or ranking of tentative candidate lists from large structure libraries. The USEPA CompTox Chemicals Dashboard provides access to data for ~875,000 substances, searchable by mass and formula and then ranked using associated meta-data. Cheminformatics approaches are also utilized to provide mapped relationships between individual substances and their “MS-Ready” (desalted, non-stereospecific) forms. This presentation will review how the freely available Dashboard application can be utilized to support structure identification using mass spectrometry and our efforts to enhance the application using computational spectral fragmentation and access to predicted data such as relative retention time index values and computed collision cross section values to support ion mobility spectrometry. This abstract does not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

WP117 Impact of extreme weather events on organic pollutant occurrence in surface waters: Hurricane Florence in North Carolina

L. Ferguson, A. Joyce, G.J. Getzinger, Duke University / Civil and Environmental Engineering

Hurricane Florence made landfall in North Carolina on September 14, 2018 and moved across the state until September 17, drenching the eastern half of NC with rain and causing massive flooding in the Cape Fear and Neuse river basins. Because of unprecedented inundation of agricultural, residential, and industrial areas with floodwaters and widespread failure of storm and sanitary sewer systems during the storm, it was deemed likely that the storm could lead to large-scale releases of organic pollutants into rivers and their associated floodwaters. We have addressed this concern by conducting water sampling along longitudinal transects in the Neuse, Trent, and Cape Fear rivers within Eastern NC during the height of flooding (9/19/18) and after subsidence of floodwaters (10/10/19) for analysis of a broad suite of organic pollutants. Water samples were analyzed using UHPLC with ultra-high resolution tandem mass spectrometry (Orbitrap Fusion Lumos, ThermoFisher Scientific) and non-targeted compound identification was conducted using a harmonized data processing workflow including mass spectral feature consolidation, aggregated spectral library searching, computational mass spectrometry-based structure annotation, occurrence/use metadata integration, and probability-based annotation validation. Results show evidence for point-sources of untreated wastewater in river samples collected downstream of several wastewater treatment plants that experienced failure or overflow conditions during the storm, as evidenced by elevated signals for sucralose and polyethoxylated surfactants. Signals for several polyfluorinated alkyl substances (PFAS) were elevated in the Cape Fear and Neuse rivers during storm conditions, suggesting the presence of specific sources for these compounds associated with storm flooding. Most conventional stormwater tracers and agrochemicals were observed at lower signal intensity in floodwater-impacted samples than samples from normal flow conditions in the rivers studied here, indicating significant dilution due to the large volumes of water associated with the Hurricane impacts. Overall, our
results show that floodwaters associated with extreme storm events have unique organic pollutant signatures, consistent with point- and diffuse sources of contaminants due to inundation.

**WP118 Unleash the Data: Integrating high resolution MS and bioassays to better identify the causes of toxicity to human and environmental health**

A theme of current environmental research is to develop tools that correlate and identify responses to toxicants in water resources, to the identity the causes, individually or in mixtures, of that observed toxicity. One important constraint is the limited number of chemicals that can be identified and quantified in environmental samples due to limitations in analytical techniques and unavailability of authentic standards needed to verify identities and concentrations of any toxicants. For organic contaminants, recent advances in high-resolution mass spectrometry have permitted identification of thousands of unique molecular entities in environmental samples, each of which may contribute to any toxicity measured for that sample. These nontarget screening or analysis (NTA) approaches have become singularly important techniques in environmental analytical chemistry. Data analysis tools that systematically and iteratively sort these molecular entities to standardized levels-of-confidence result in prioritized sets of known, suspect, or unknown contaminants that may contribute to observed toxicity. Parallel developments of in vitro and low complexity in vivo effects-based assays (bioassays), provide a similar non-targeted screening approach for organic contaminants in water samples. Bioassays measure cumulative toxicity responses from environmental mixture exposures. For both NTA and bioassays, interpretative sophistication is required to understand the effects of multiple contaminants or multiple toxic responses present in environmental samples. Integrating these two data-rich streams of chemical and biological information to extract meaningful knowledge (with tools such as iceber modeling, mass balance) is an area of focused research effort with the potential to yield significant advances in our understanding of the sources of aquatic toxicity that could have adverse effects upon human and ecosystem health. This presentation examines recent developments in NTA analysis and toxicity screening and the potential for integration of these data streams to advance our understanding of the sources of toxicity and to characterize that toxicity. We discuss the challenges to comprehensively assess the sources and mechanisms of toxicity in water, soil, tissue, and sediment and the implications these challenges pose for improving human and ecosystem health.

**The Impacts of High Resolution Mass Spectrometry on Analytical Chemistry**

**WP119 Accurate PAH Analysis using Gas Chromatography coupled to High Resolution Quadrupole Time-of-flight Mass Spectrometry (GC-QTOF-MS)**

_C. Yang, Environment and Climate Change Canada; C. Brown, Environment and Climate Change Canada / Pacific and Yukon Laboratory for Environmental Testing_

Polycyclic aromatic hydrocarbons (PAHs) and their alkyl-substituted homologues (APAHs) generally occur in crude oil and are widely found in environment. Their accurate identification and quantitation are critical to reliable toxicity assessment and damage evaluation of oil pollution to the environment. At present, identification and characterization of these petroleum compounds mainly rely on gas chromatography coupled to a single quadrupole mass spectrometer (GC-MS) in selected ion monitoring mode. Analyses using low resolution mass spectrometry (LRMS) can be severely interfered with by other co-eluted material even though with proper sample preparation and chromatographic separation, potentially resulting in misidentification and overestimation of target analytes. This is especially true when PAHs occur only in trace amounts or in chemically complex environmental samples, where their chemical fingerprints which are usually relied upon for the identification of target compounds have been significantly altered. Capillary gas chromatography coupled to a quadrupole time-of-flight mass spectrometer (GC-QTOF-MS) delivers faster full spectrum, acquiring higher resolution, and a more accurate mass measurement than a single quadrupole MS. QTOF-MS increases the detection selectivity by using exact monoisotopic mass, eliminating or reducing interferences both internally from petroleum content and sample matrix, and externally from the added quality control materials; thereby improving the confidence of identification and quantitation accuracy of analytes. This study compared GC-MS and GC-QTOF analyses of PAHs and their C1- to C4- alkylated homologues in a number of crude oils, refined products and petroleum-impacted environmental samples. Quantitation disparities were found for various PAHs analyzed by LRMS (unit mass +/- 0.5 u) and HRMS (exact monoisotopic mass +/- 10 ppm). Results of PAHs with high abundance in samples, particularly naphthalene and phenanthrene series, are generally very comparable by using the two different instruments, while significant difference was obtained for the analyses of pyrenes and polycyclic aromatic sulfur heterocycles (PASHs). For instance, the concentration of dibenzothiophene and benzo-naphthothiophenes determined in 20 samples by GC-QTOF are averagely 87.1 +/- 1.8% and 92.9 +/- 1.5 % of those by GC-MS, respectively.

**WP120 Analysis of Short Chain Chlorinated Paraffins (SCCPs) using negative chemical ionization (CI) and low energy EI by high-resolution GC/MS**

Short Chain Chlorinated Paraffins (SCCPs) are bioaccumulative and persistent in the environment and are commonly used as flame retardants in plastics and other materials, as well as in few other applications such as metal processing. Analysis of these compounds represents substantial challenge due to their self-interference as well as an interference with other components of complex industrial matrices. Thus, the analytical technique not only have to be sensitive but also very selective, this is where high-resolution MS can be very attractive, especially when combined with negative CI and low energy EI. Here, we demonstrate the performance of high-resolution GC/Q-TOF for SCCP analysis in complex SCCP mixtures. The pure congener standards as well as standard SCCP mixtures were analyzed using a high-resolution GC/Q-TOF system. The data were acquired in both negative CI (using methane as a reagent gas) as well as low energy EI. NCI fragmentation patterns of SCCPs were evaluated for comparison with established methods using pure congeners standards. When methane was used as a reagent gas, NCI spectra of SCCPs exhibited minor fragmentation. In most cases M- and (M-HCl)- were predominant ions with some contribution of (M-H)- and (M-CI)-. No significant fragmentation of the carbon backbone was observed. Low energy EI data indicated higher degree of fragmentation of the SCCPs as compared to negative CI. However, using this technique allowed to detect the SCCP species with low CI content (such as C10C4).

**WP121 Approaches to the Interrogation of Non-targeted Sample Data Acquired by High Resolution Accurate Mass (HRAM) mass spectrometry**

_A. Vien, J. E. Doig, University of Saskatchewan / Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; P. D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre_

Increasingly, High Resolution Accurate Mass (HRAM-MS) mass spectrometry is being used in the analysis of complex chemical mixtures. The ability of HRAM-MS to potentially resolve all compound masses even in the most complex mixtures suggests the possibility of using untargeted approaches to collect all chemical information from a sample and
then apply post hoc chemometric techniques to scrutinize samples for compounds of interest. This paper addresses the challenges in the development of chemometric approaches to perform data analysis on non-target mass spectra of water and sediment samples. Water samples and sediment TOC samples were diluted to 30% MeOH and 0.1% formic acid and were then analyzed by direct infusion into the ESI source of an Orbitrap mass spectrometer running at a nominal resolution of 240,000 at 200 m/z. Spectra were acquired at approximately 2 Hz and around 1000 spectra were averaged to provide a single mass spectrum for each sample. In water and sediment samples approximately 5,000-1,0000 individual ‘features’ can be identified in the mass range 80 - 1200 m/z with fewer than 5% of these peaks represented by overlapping peaks as determined from expected peak widths. We have investigated both ‘top down’ methods to identify all features and targeted interrogation of the mass spectra for various algal pigments and metabolites. Pigments such as aphanizophyll, zeaxanthin and echinenone were commonly detected in sediment core sections from a small lake while secondary metabolites such as microcystins and saxitoxin were comparatively rare. Together these approaches suggest the feasibility of collecting and screening water and sediment DOC samples for ‘chemical features’ and then archiving those data in silico for subsequent interrogation.

WP122 Are there any other non-classic PFASs binding to FABP?

D. Yang, University of Toronto / School of the Environment; J. Sun, H. Peng, University of Toronto / Department of Chemistry

Per- and polyfluoroalkyl substances (PFASs) are great concern due to their persistence, bioaccumulation and toxicities. Fatty acid bind protein (FABP) has been reported as one of the major factors to determine toxicokinetics of PFASs. But the potential role of FABP has been only characterized for several classic perfluorinated acids such as perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), while there are hundreds of PFASs and their precursor compounds reported in the environment by non-targeted analysis. In this study, we aim to determine the potential PFASs binding to FABP in a global level, by integrating biochemistry and non-targeted analysis methods. Firstly, human liver FABP protein was expressed and purified from E. coli, the binding affinities of 74 structural diverse PFASs with FABP was determined by competitive fluorescence method. A quantitative structure-activity relationship (QSAR) was established by integrating molecule descriptors and functional groups. Secondly, the potential PFASs binding to FABP from technical products containing hundreds of uncharacterized PFASs was investigated. The technical products were incubated with recombinant FABP protein, and then the PFASs bound to FABP were identified by Affinity Pull-down combined with untargeted analysis. The bound ligands were dissociated by methanol and analyzed by Q-Exactive High Resolution Mass Spectrometer. The global interaction spectrum between PFASs and FABP will provide an important basis to understand the bioaccumulation and toxicities of non-classic PFASs.

WP123 Are We Doing Non-Targeted Analysis Right? A Progress Report from the Benchmarking and Publications for Non-Targeted Analysis Working Group

E.M. Ulrich, US Environmental Protection Agency / Office of Research and Development / National Exposure Research Laboratory; B. Place, National Institute of Standards and Technology / Chemical Sciences Division

The broad availability of high-resolution mass spectrometers has made their use more common for environmental and other applications, particularly for suspect screening and non-targeted analysis (NTA). While fields like metabolomics have developed mature methodologies and quality control practices, NTA of the exposome is still experiencing a steep learning curve and growing pains. The current state of NTA has been described as “the wild west,” where each research group approaches the technique in their own way, with little overlap, consistency, or harmonization. The EPA’s Non-Targeted Analysis Collaborative Trial (ENTACT) used ten mixtures of 1,269 unique and known substances to look at the state of the science, provide insight into the chemical space coverage, and identify potential benchmark methods and approaches for NTA. Approximately 30 laboratories participated in ENTACT and each used their own methods and approaches not only to analyze the samples, but to interpret the results and their performance. Many ENTACT participants described their experience with the mixture samples at an EPA-hosted workshop in 2018, which included discussions amongst the attendees. One of those discussions resulted in the formation of a working group called “Benchmarks and Publications for Non-Targeted Analysis” or BP4NTA. The group has the ultimate goal of publishing a white paper describing terms, definitions, recommendations, and best practices surrounding NTA studies. Topics of particular importance and relevance within this white paper will include recommendations on how to characterize an NTA method’s performance and minimum reporting information should be published for transparency and reproducibility. This presentation will provide an update on the progress of the BP4NTA group, as well as some of the “sticking” points surrounding these issues. The use of NTA data for regulatory purposes requires that practitioners use sound, defensible, and commonly accepted techniques for data collection, analysis, and reporting. Therefore, BP4NTA and other groups like it in related fields are critical for coming to a scientific-community consensus to make an impact on environmental and health policies.

WP124 Bioaccumulation and biotransformation products of pharmaceuticals in Oryzias latipes

H. Cha, Changwon National University / Department of Eco-friendly Offshore Plant FEED Engineering; J. Jeon, Changwon National University

So far, studies on pharmaceuticals in the aquatic environment have focused on their occurrences in water system. These substances are threatening to aquatic organisms because of the continuous existence in water. Under this circumstance, the bioaccumulation of pharmaceuticals and the identification of metabolites in organisms can be evidence for the exposure to those substances. This study was aimed to identify metabolites of the four selected pharmaceuticals, atenolol (ATN), carbamazepine (CMZ), metoprolol (MTP) and venlafaxine (VFX) in Japanese medaka (Oryzias latipes). The in vivo exposure test was performed during 4 days to allow the formation of metabolites following bioaccumulation process. We collected exposure media samples and whole body tissue of fish at the beginning and every 48 hours until the end of the experiment. Each samples were pretreated and analyzed using LC-ESI-Orbitrap (Q Exactive plus) by target/suspect screening methods. As a result, four test compounds were quantitatively detected via target screening. The estimated bioaccumulation factor (BAF) was 0.2 for ATN, 3.6 for CMZ, 0.5 for MTP and 0.2 for VFX. Meanwhile nine metabolites were tentatively identified by suspect screening as follows: atenolol acid from ATN, carbamazepine 10,11-epoxide and iminostilbene from CMZ, α-hydroxymetoprolol, metoprolol acid and O-demethylmetoprolol from MTP, O-desmethylvenlafaxine, VLF280 and VLF 294 from venlafaxine. Among them, four metabolites (atenolol acid, carbamazepine 10,11-epoxide, metoprolol acid and O-demethylvenlafaxine) were confirmed with reference standards, while the others (iminostilbene, α-hydroxymetoprolol, O-desmethylmetoprolol, VLF280 and VLF294) were tentatively identified with MS2 library matching with mzCloud and MetFrag. The findings on formed metabolites provide information on bioaccumulation and major metabolic pathways for emerging pharmaceuticals which are often occurring in domestic river waters.

WP125 Comparison of Targeted and Non-targeted Analysis of Surface Waters from a Nationwide Survey of the United States

D. Tush, M. Meyer, R. Lane, US Geological Survey / Organic Geochemistry Research Laboratory

Surface waters are complex mixtures that contain innumerable chemical compounds from natural sources, anthropogenic sources, and degradation/transformation products from biotic and abiotic processes. Determining specific compounds or groups of compounds which produce
deleterious effects on water quality and environmental health is problematic. Even large-scale studies using a wide variety of targeted methods only measure a small fraction of the compounds in a sample. High-resolution mass spectrometry is a platform for non-targeted analysis in an effort to characterize complex mixtures but transforming the resulting data into useful information is a challenge. Samples were obtained from a range of urban and agriculturally impacted sites across the U.S. A method which included solid phase extraction, ultra-high-performance liquid chromatography, and time-of-flight mass spectrometry was used to generate positive and negative ion data. This data, analyzed with a hierarchical processing scheme, was compared to an existing suite of targeted analysis data (719 organic analytes). The comparison of data from non-targeted analysis to the existing data from targeted analysis demonstrates that although targeted analysis does not capture as much of the complexity of the samples as the non-targeted analysis does there are correlations between the two types of data.

WP126 Measurement of retinoids in freshwater fish by liquid chromatography – mass spectrometry (LC-MS)
M. Dunning, Environment and Climate Change Canada / ACRD; M.R. Servos, University of Waterloo / Biology; M. Hewitt, Environment and Climate Change Canada / Water Science and Technology Directorate

Retinoids (vitamin A) are essential for numerous physiological processes including vision and reproduction. They are stored as biologically inactive retinyl esters that are metabolized to transcriptionally-active retinoid acids (RAs) according to physiological and nutritional requirements. Disruptions to the retinoid system have been observed in several species of fish upon exposure to various contaminant sources, including pulp mill effluent and mine tailings. Assessments of retinoid status typically only consider retinol and its esters, which are easily analyzed by ultraviolet (UV) spectrophotometry as it provides acceptable detection limits. UV detection lacks the specificity that mass analyzers can provide and thus requires expensive or unavailable standards for qualitative work. Additionally, RAs are thought to be present at the sub-pmol level in fish and require high sensitivity instrumentation to attempt quantitation. A streamlined extraction and analysis workflow was developed to measure multiple retinoids in fish to facilitate further research into retinoid biology. Retinoids were extracted from liver using solid phase extraction (SPE) to generate an acidic fraction containing RAs and a neutral fraction containing retinol and retinyl esters. Liquid chromatography coupled to triple-quadrupole and high-resolution quadrupole time-of-flight instrumentation were used to analyze the two fractions. This method was applied to samples from two Great Lakes Areas of Concern (AOCs) to evaluate efficacy for detecting differences in retinoid status between populations of fish. Significant differences in retinoid abundance and distribution were measured, with achieved limits of detection < 1 ng/mL. Commercially unavailable retinoids were also tentatively identified by their high-resolution mass spectra. These investigations advance retinoid biology by allowing for a greater range of compounds which can be analyzed without authentic standards, providing qualitative and quantitative data in a single high-throughput workflow.

WP127 Mercury Speciation by Automated Derivatization and Headspace Solid-Phase Microextraction Followed by Gas Chromatography Orbitrap Mass Spectrometry
B. Tendler, University of Saskatchewan / Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences; P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre

Mercury (Hg) concentrations in fish can be of significant concern for human consumers, with exposure to methylmercury causing the greatest concern. Mercury speciation has been well studied with methods utilizing varying preparation techniques and analytical instrumentation, though the use of modern ultra high-resolution mass spectrometers (MS) has not been studied as thoroughly. This research assesses the advantages of mercury analysis by modern ultra high-resolution MS with robotic derivatization, Solid-phase Microextraction (SPME) and injection into the Gas Chromatography and Orbitrap Mass Spectrometry (GC-Orbitrap MS) system. The method is based on previous derivatization with sodium tetratetraethylborate, Headspace SPME, and GCMS methods. The use of the GC Orbitrap MS allows for the scanning of a wide range of mass/charge (m/z) in each scan with ultra-high resolution (>200,000). This scan range and resolution allow quantification of the different Hg species, and for the complete Hg isotope profile in the derivatized methylmercury (MeHg) and inorganic Hg species, as well as the Hg isotopes in the fragments created by fragmentation in the ion source of the mass spectrometer. These isotopes and their patterns can be used to identify and confirm analytes of interest. The observed mercury isotope patterns from these analyses had near perfect alignment with the theoretical isotope patterns based on the known natural abundance of Hg isotopes. Muscle samples of fish collected from the Slave and Athabasca rivers were analyzed using this technique. The mean MeHg percentage was found to be 82.4% of Hg in goldeye, 90.2% in northern pike, 87.2% in walleye, 92.3% in whitefish, and 87.5% in burbot.

WP128 Non-Targeted Analysis of Chemicals in Indoor Consumer Products
S. Kutarna, University of Toronto; H. Peng, University of Toronto / Department of Chemistry

Humans spend 90% of their time indoors, and every day are exposed to a wide variety of compounds. For example, flame retardants have been detected in furniture, chlorinated paraffins in paint and wire coverings, and perfluoroalkyl substances in non-stick coatings. Building a knowledge base is made more difficult by the fact that companies are not required to report their reagents. This means that the vast majority of compounds in consumer products are unknown to the public and limited information is available for the sources of pollutant emissions to the indoor environment. The aim of this research is the non-targeted identification of chemicals in different indoor products to determine their potential pathways in indoor environments, with a focus on halogenated organic compounds (HOCs) such as brominated azo dyes and chlorinated paraffins. The categories of consumer products include children’s toys, electronics, clothing, and furniture, all of which have been shown to contain HOCs. A one-step automatic non-targeted analysis workflow was established from raw mass spectrometry files to final compound identifications. With this method, >1,500 chemicals in ~100 samples were identified in under 2 days. In particular, many previously undetected chlorinated compounds were identified in the indoor environment for the first time. The chemical database of indoor products we construct from this research will provide an important basis for future indoor chemical management.

WP129 Suspect and nontarget screening for polar organic pollutants in drinking water source using HILIC-LC-HRMS
P. Naree, Changwon National University / Environmental Engineering; J. Jeon, Changwon National University

River water, used as a drinking water source in Korea, has been contaminated with numerous organic substances mainly discharged from waste water treatment plants. Among them, highly hydrophobic substances are of concerns because of the low elimination rate in water purification processes. The poor elimination may result in the high concentration of pollutants in drinking tap water. The present study was aimed to identify major hydrophobic substances present in drinking water source and to monitor their fates in purified water. Water samples were pretreated with SPE materials specified for hydrophobic and ionized substances. The extracted substances were then separated with hydrophilic interaction liquid chromatography (HILIC) before injection to HRMS(QExact) for suspect and non-target screening. Suspect list was filled with hydrophilic contaminants (log Kow < 3.5) which have been frequently reported as 134 aqueous pollutants in Korean surface waters, top waters and effluents. Among 27 suspected compounds were tentatively identified with MS/
MS library. After purchasing reference standards, 9 pollutants were confirmed (atenolol, atenolol acid, benzotriazole, caffeine, carbendazim, flucnazole, metformin, sulphride and tramadol). The nontarget screening enabled tentative identification without reference standards for unexpected compounds like surfactants (e.g., C12-LAS, dodocyl benzene sulfonic acid and xylene sulfonate), amine-based industrial chemicals (e.g., trisopropylamine and triethanolamine) and PFBS. Moreover, 5-methylbenzotriazole, melamine and telmisartan were confirmed for with reference standards. In view of these results, the suspect/nontarget strategies based on HILIC-LC-HRMS applied provide additional evidence for identifying unexpected compounds, which may affect drinking water. In future studies, since some tentatively identified pollutants were left unconfirmed, this compound should be updated additional confirmations. In future studies, since some tentatively identified pollutants were left unconfirmed, this compound should be updated additional confirmations.

**WP130 The Impact of Ultra-high Resolution Mass Spectrometry on Environmental Chemistry**

P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences

The recent development of new mass spectrometry technologies and instrumentation has increased the amount and quality of analytical information that can be obtained from samples. In particular, dramatic increases in mass resolution have made possible unequivocal identification of contaminants even in complex mixtures and matrices. The development of Ultra-High Resolution Mass Spectrometry (UHRMS) has made available previously unprecedented levels of mass resolution and mass accuracy in timeframes compatible with typical chromatography systems. In addition to high mass resolution and accuracy 'image current' detection systems provide full mass spectral data for each scan. When coupled to liquid chromatography systems we have used these capabilities to investigate the occurrence of various halogenated disinfection by-products (DBPs) as well as naturally occurring organohalogen compounds. The recent release of a GC/UHRMS systems brings levels of mass resolution not previously available for the analysis of environmental contaminants by GC chromatography. Here we report the use of GC-UHRMS for identification and quantification of PCDD/Fs and PCBs. The methods developed are based on standard USEPA methods (Methods 1613 and 1668) but are enhanced by use of the new capabilities provided by image current detection and high mass resolution (> 100,000 FWHM). Together these studies demonstrate the unprecedented depth of data now available from UHRMS systems. The ability of some systems to collect UHRMS and MS/MS data simultaneously demonstrates capabilities far beyond those of 'classical' analytical systems. Furthermore, these UHRMS systems are available in robust and stable systems capable of 'routine' analysis suggesting that in years to come UHRMS instruments may replace current instrumental systems used for these analyses. The availability of this additional data raises questions about the relevance of current QA/QC criteria developed on earlier MS systems and suggests that the time is right to evaluate what, if any, additional criteria we might develop to support current analytical determinations.

**Plastic Pollution Research and Solutions**

**WP131 Twitter Reveals Global Conversation Around Plastic Pollution**

H.R. Hapich, W. Cowger, A.B. Gray, University of California, Riverside / Environmental Science

Plastic pollution is taking an increasingly large toll on our natural environment. There is currently speculation about how people perceive the problem of plastic pollution, but little quantitative evidence. In this study, we used English and Spanish data extracted from Twitter over a 3 month period to investigate the public discussion about plastic pollution. As a hub for scientific conversations as well as one of the most widely used social media platforms, Twitter provides an abundance of data from a wide variety of user demographics. We first ask the question, does discussion of plastic pollution by individuals and stakeholders coincide with global hotspots of plastic pollution? Our results provide some of the first evidence for where discourse on plastic pollution is happening and which social groups are most involved (academics, government, non-profit). Within these groups we investigated plastic pollution messaging in terms of sentiment, sources of evidence used to support claims, and stated motives (e.g. awareness raising, discussing prevention, networking). We also investigated the common associations individuals make with plastic pollution by analyzing unique and linked words in Tweets. Our results provide a clearer picture of global concern surrounding plastic pollution and eliminate some of the ambiguity surrounding this discussion.

**WP133 Macroplastics in the environment**

K.J. Kulaeksi, Exponent / Ecological and Biological Sciences; S.B. Kane Driscoll, Exponent / EcoSciences; M.W. Kierski, Exponent / Ecological and Biological Services Practice; J.P. Sanders, Exponent / Ecological and Biological Sciences; W.L. Goodfellow, Exponent / Ecological and Biological Services Practice

Long thought desirable features, the durability and longevity of plastics are now often seen as problematic, as reports of plastics found impacting organisms in increasingly remote environments continue to emerge. Macroplastic debris can not only serve as a source for microplastics, as large items break down into smaller and smaller pieces, but can also be transported across environmental boundaries and interact with biotic and abiotic components of the environment as large items. We performed a state-of-the-science review on the sources, characterization, fate and transport, and effects of macroplastics in the environment. This presentation provides an overview of types of macroplastics, field and laboratory methods for their qualitative and quantitative analyses, relevant environmental transformation processes, ecological and human health exposures and effects, and research gaps. By understanding the range of environmental issues associated with macroplastic waste, we can develop better solutions targeted to each phase of its complete life cycle.

**WP134 Urban rivers as transporters and transformers of plastic pollution - Te wairere o te paratiki**

J.B. Gadd, NIWA / Department of Chemistry; A. Valois, L. Rauhina-August, NIWA; O. Pantos, ESR; S. Gaw, University of Canterbury / Chemistry

Plastics are significant pollutants in the NZ environment, as is increasingly observed around the world. We are studying plastic sources and transport in an urban-affected river, the Kaiwharawhara Stream, which discharges to Wellington Harbour, New Zealand. From the headwaters in a forested ecosanctuary, the stream becomes piped through an old landfill, then winds its way through residential suburbs to a commercial and industrial area near the mouth, receiving stormwater (largely untreated) throughout its journey. With the assistance of community groups, we are surveying the sources and types of macroplastics entering the stream via stormwater and direct littering through a mixture of catchpit inserts, end-of-pipe nets and stream surveys. We are quantifying microplastics discharged via stormwater and found at multiple locations in the stream and at the mouth. The goal is to quantify the discharge of plastic pollution from an urban stream into the harbour and ultimately the wider marine environment. A workflow led by and conducted by mana whenua (indigenous Maori people) is using cultural monitoring methods to assess both the level and impact of plastic pollution in the awa (river). The research will identify the most common sources and routes of plastic to urban streams and in subsequent steps, assess the transformation of macroplastics to microplastics within the stream network. The potential outcomes of the research include improving waste management infrastructure, reducing plastic use, and reducing littering. Our partnerships with mana whenua, community and industry will increase awareness of plastic pollution and ensure the uptake of methods to reduce it.
WP135 Identifying polymers of plastic marine debris to monitor the effectiveness of Maui’s expanded polystyrene foam food service containers ordinance

S. Weller, A. Moua, K. Teague, J. Marchiani, M. Jung, Hawaii Pacific University / Center for Marine Debris Research; C. King, Sharkastics; J.M. Lynch, National Institute of Standards and Technology / Chemical Sciences Division

Some of the largest documented quantities of marine debris occur in Hawaii. Municipal bans on single-use plastic items are becoming more common, but the effectiveness of these policies on marine debris have rarely been studied. Maui County in Hawaii enacted a ban on expanded polystyrene (EPS) foam food service containers, which went into effect on Dec. 31, 2018. The ban includes cups, plates, bowls, clamshells, and serving trays, with goals to protect wildlife, reduce plastic waste and combat climate change. The objective of the current study was to use polymer identification methods to determine whether the ban has an effect on the plastic marine debris composition on two Maui beaches: Kaehu on the northern windward side and Kealia on the southern leeward side. Three sections along the high tide drift line were surveyed monthly at both beaches from seven months pre-ban and continue. Plastic debris items >1 cm in length along the drift line were collected from the beach surface until 50 items were collected. Survey length was then measured. Plastic items were categorized by type - specifically noting if they were from an EPS foam food container, color, length, mass, weathering, and then analyzed for polymer composition via attenuated total reflectance Fourier transform infrared spectroscopy (FTIR). Preliminary results on 1511 pre-ban debris pieces show that debris amounts, types and polymers differ substantially between the two beaches. Plastic debris abundance was an order of magnitude greater on Kaehu (9 g/m) compared to Kealia (1 g/m), which is typical of windward vs. leeward beaches. The proportion of PS (regardless of expanded or extruded) on Kaehu (≈25 %) was larger than Kealia Beach (≈10 %), and the proportions did not change substantially throughout the pre-ban months. The percentage of all debris items that were visually identified as EPS food service containers was greater on Kaehu (12 %) compared to Kealia (3 %) in pre-ban months. The percentage did not change four months post-ban on Kaehu but significantly decreased on Kealia (0.3%). Additional analyses of post-ban samples will reveal how quickly and where the new policy improves the plastic pollution on Maui beaches. Since a large percentage of debris washing ashore on Hawaiian windward beaches is from distant sources, local legislation concerning particular single-use items are expected to make a small, but important, noticeable improvement in the marine debris issue on Hawaiian coastlines.

WP136 Comparing the sorption of hydrophobic organic contaminants to bio-based and petrochemical-based plastics

K. Uhlig, R.C. Hale, College of William & Mary / Aquatic Health Sciences; D.R. Luellen, Virginia Institute of Marine Science / Aquatic Health Sciences

Microplastic contamination of aquatic environments has only recently caught the attention of scientists, regulators and the public. Microplastics are typically more recalcitrant than naturally occurring polymers and so have the potential to cause a range of issues, including increased exposure of aquatic life to chemical contaminants sorbed to or leached from microplastics. Bio-based, bio-degradable polymers have begun to gain market share as an alternative to traditional petrochemical-based plastics, but not much is known about their impacts in marine environments. The objective of this work was to improve our understanding of how bio-based microplastics compare to petrochemical-based plastics with respect to the sorption of organic pollutants. This study investigated the potential of four types of microplastics, polyethylene (PE), polyvinyl chloride (PVC) and two bio-based polymers, poly-3-hydroxybutyrate (PHB) and polyactic acid (PLA), to sorb hydrophobic organic contaminants (HOCs; pyrene, PCB-153, and BDE-47) from the surrounding water column. 0.5 g of plastic production pellets (< 5mm) were added to 500ml of salt water spiked with HOC concentrations ranging from 1.0 - 4.0 μg/L and mixed at 100 rpm on an orbital platform shaker. At the end of an equilibrium period, plastics were separated from the aqueous phase, and aqueous phases were extracted using dichloromethane and analyzed by gas chromatography/mass spectrometry. The concentration of HOCs sorbed on the plastic pellets was calculated by difference. Sorption isotherms were drawn by plotting the concentration of the HOC in the water versus that on the plastic beads, and the partitioning coefficients calculated from these isotherms. The bio-based polymers used in this work exhibited a lower partitioning coefficient for the organic contaminants investigated compared to the more widely used, petrochemical-derived microplastics. This may be due to several factors including hydrophobicity of the plastic surfaces and the chemical structure of each plastic. This information could be used to evaluate the overall environmental impact of bio-based plastics as replacements for petrochemical-based plastics.

WP137 Phthalate esters in the environment: Sources and quantification

R. Adelagun, Federal University Wukari, Nigeria / Department of Chemical Sciences; O. Oritoju, Federal University Wukari, Nigeria / Biochemistry Department; A. Ushie, E. Etim, E. Aikhoje, Federal University Wukari, Nigeria / Chemical Sciences

Consequent upon their widespread use as plasticizers and high volume of production, phthalates constant diffuse release into the various environmental compartments (air, water, soil) has become noticeable. In this study, levels and presence of phthalate esters were analyzed in newly purchased plastic toys and in Polyethylene Terephthalate bottled drinking water samples. Phthalates in the samples were liquid-liquid extracted, preconcentrated and analyzed for detection and quantification using HPLC. From the data obtained, the levels of DMP, DEP and DBP in the PET drinking water samples did not exceed the stipulated threshold levels while the level of DEHP was dominant and exceeded the safe limit. PEs were detected in all the 10 plastic toys samples analyzed including mouthable ones (teethers) used by children, imported into the country from China, Taiwan etc. The values obtained revealed that the concentrations of PEs in the plastic toys ranged between 0.96 - 532 (ug/l). Also the percentage (w/w) values obtained were significantly higher than the European Union (EU) recommended limits for all phthalate esters in toys, this portends risk to children who innocently put these toys in their mouth or chew them, as the toxic chemicals could leach into their blood stream. These results can be used as reference levels for future monitoring programs for pollution studies.

WP138 To Drink or Not to Drink? Estrogenic Activity of PET Bottled Water Under Various Storage Conditions

L. Markley, C.T. Driscoll, Syracuse University / Civil and Environmental Engineering

Water bottled in polyethylene terephthalate (PET) plastic is a source of human exposure to endocrine disruptors. Current data on this exposure focuses heavily on a subset of endocrine disrupting chemicals, such as BPA or antimony. However, targeted chemical analyses neglect the combined biological effect, like estrogenic activity (EA), of endocrine disruptors present in a sample. The migration of compounds exhibiting EA from PET water bottles present a potential health risk to humans and the environment. Though previous studies have found positive EA in water samples taken from PET bottles, data on how EA varies with storage conditions is lacking. This study compares EA from multiple brands of PET bottled water using the E-Screen. Bottles were exposed to consumer-relevant storage conditions, including high temperature, UV light, and UV light with increased temperature. This analysis will further inform the human health risk associated with consumption of bottled water.
Utilizing Biodegradability Data to Effect Meaningful Interpretations

WP139 Challenges and opportunities in the application of the biodegradation deroga for microplastics under ECHA Annex XV

The European Chemicals Agency (ECHA) Annex XV Restriction Report for Microplastics aims to eliminate the use of intentionally added persistent microplastics in consumer, professional, agricultural, and industrial products marketed in Europe. ECHA has clearly outlined their intention to move industry away from persistent microplastics to biodegradable alternatives. In order to achieve this goal ECHA has defined a biodegradation deroga for microplastics. This deroga outlines a series of tests and pass criteria which move from conservative screening assessments through high tier simulation tests. While it is considered critical that biodegradation be considered a deroga strategy, the reality is that little experience exists in Industry or Academia using biodegradation test methods to assess microplastics. This talk will discuss the proposed biodegradation testing strategy as well as discuss key differences in testing microplastics and soluble chemicals (for which most of the test methods were developed). We will share experiences gained using the OECD 301B Ready Biodegradation Test to evaluate microparticle biodegradation. We will specifically address challenges in test material, dosing, intra-test replication, and the need for extended test duration. Particle size plays a large role in the surface area : volume ratio of the material. Larger particles have smaller surface areas, compared to the total volume, susceptible to microbial attack. This produces a slower measured rate of biodegradation compared to particles made of the same material but smaller in volume and higher in surface area. Test material hydrophobicity and low density can also impede microbial interaction with the test material in aqueous test systems. Finally, the low inocula concentrations prescribed in the 301B limit the number of degraders available to interact with the particles. Of particular focus will be recent work to evaluate the impact of starting particle size (63 um through 2 mm) on biodegradation rate and time to complete mineralization.

WP140 Biodegradability of Polymers and Plastics - Applicability and Limitations of Five Existing ISO Guidelines

N. Timmer, Charles River Laboratories / Environmental Sciences; M. Desmares, S. Buitenweg, M. Migchielsen, W. Westerink, Charles River Laboratories; M. Tobor-Kaplon, Charles River / GET

Synthetic polymers (i.e. ‘plastics’) are widely used around the globe. Over 300 million tons are produced annually, of which a significant percentage ends up in landfills or the environment. There is worldwide growing societal concern about the environmental and economic implications of the fate of these often poorly degradable polymers. Shifting to more easily degradable or even readily biodegradable polymers could be an important part of the solution. In order to more accurately assess the environmental impact, the guidelines used to test biodegradability of such newly developed polymers should be practical and relevant. In addition, regulatory authorities might need to provide better guidance on how to interpret experimental results. We have tested biodegradability of 20 different biodegradable polymers and one non-biodegradable polymer using the ISO 11398 protocol under standard conditions (sea sediment, activated sludge, soil). We tested several commercially available reference polymers (cellulose, polyactide, polybutylene succinate) and two proprietary polymers. Ultimate biodegradation was assessed by measuring CO2 evolution and/or manometric determination of O2 consumption. To further broaden the scope of this study, we included two types of standardized LUFAs, two types of vegetable material (coarse and silty), and activated sludge pre-conditioned overnight and up to seven days. The combined findings of these experiments will provide valuable and relevant insights in the biodegradability of the compounds tested in different environmental compartments, while simultaneously providing information on the applicability and limitations of existing guidelines. Our findings can be used to optimize biodegradability testing of polymers using ISO guidelines, and might also provide valuable insights for specific guidance by regulatory authorities.

WP141 Improving Relevance and Applicability of Ready Biodegradation Studies by Environmentally Relevant Modifications

N. Timmer, Charles River Laboratories / Environmental Sciences; M. Desmares, S. Buitenweg, M. Migchielsen, W. Westerink, Charles River Laboratories; M. Tobor-Kaplon, Charles River / GET

Standard ready biodegradation study guidelines accepted by regulatory authorities might not have been updated for the last 20 to 30 years. However, increased awareness of environmental impact of chemicals discharged in large volumes in combination with regulations such as REACH have led to biodegradability testing of increasingly complex chemicals and chemical mixtures. Such substrates might only degrade to the maximum extent if the right inoculum is present, or if steps are taken to ensure the substrate remains biodegradable during the study. To address these challenges, we have experimented with several additions to improve environmental relevance and reliability of biodegradation studies. Results show how difficult to degrade substrates respond to the use of mixed-source inoculum (soil and activated sludge), and how addition of silicon dioxide to increase bioavailability impacts biodegradability. We have applied these modifications in an attempt to test biodegradability of moderately volatile chemicals in an open, aerated test setup. The use of silicon dioxide and other sorbents was also applied to cetylpyridinium chloride, a biocide that is known to poorly degrade under standard conditions. Our main conclusion is that the proposed modifications and additions, some of which are not clearly permissible in existing guidelines, can impact biodegradability classification. As biodegradability should be an inherent property, we propose that use of mixed-source inoculum, addition of inert sorbents, and other modifications that can be justified as being based on environmental relevance should be permissible.

WP142 Environmentally relevant biotransformation testing of multiple substances using spiked incubation and non-target screening

Z. Li, Stockholm University / ACES; M. McLachlan, Stockholm University / Environmental Science and Analytical Chemistry (ACES)

Biotransformation in surface waters is often (e.g., in the OECD 309 standard method) studied by spiking a single substance into surface water, incubating the bottle in the laboratory, measuring the dissipation of the spiked substance over time, and comparing its dissipation rate to that in a sterile control. We recently showed that the dissipation rate differs between spiked tests and unspiked tests in which the dissipation of chemical already present in the surface water is measured. Since spiking modified the biotransformation properties of the water, we concluded that an unspiked test would deliver a more environmentally relevant biotransformation rate. An unspiked test also opens the possibility to study the biotransformation of many substances simultaneously. This study aims to test and evaluate the possibility of combining a non-target screening approach and an unspiked bottle incubation test to obtain biotransformation kinetics of chemicals that are already present in natural systems. An unspiked bottle incubation test based on the OECD 309 protocol was conducted using water from Norra Bergundasjon, a Swedish lake with a high WWTP effluent load. The water samples collected during the incubation were filtered and analyzed with UHPLC-Orbitrap-MS/ MS using large volume direct injection. The HRMS data were processed using CompoundDiscoverer 3.0 with compound online-searching using the database mzCloud. A spiked bottle test was conducted in parallel in which 12 chemicals were spiked into the same lake water. The ability of the non-target screening procedure to identify and quantify the dissipation kinetics of the spiked analytes was first evaluated. Then the ability of the procedure to quantify the dissipation kinetics of unspecified chemicals was assessed and the diversity of dissipation kinetics was examined. Finally, the dissipation kinetics of unspecified chemicals in the spiked bottles was

WP143 Comparing chemical persistence assessed using the unspiked OECD 309 test to field measurement

Z. Li, Stockholm University / ACES; M. McLachlan, Stockholm University / Environmental Science and Analytical Chemistry (ACES)

Biodegradation is an important removal pathway for many organic contaminants in natural systems. The OECD 309 protocol is a standard method to generate kinetic biodegradation data in surface waters for use in persistence and risk assessments. In this protocol, aerobic natural waters are spiked with test chemicals and incubated in the laboratory. However, our prior work comparing spiked and unspiked OECD 309 tests has shown that spiking surface water with test chemicals can strongly influence biodegradation kinetics, most likely due to adaption of the microbial community. This study was designed to test the environmental relevance of unspiked OECD 309 tests by comparing chemical biodegradation half-lives assessed in the laboratory against their persistence measured directly in the field using a benchmarking approach. To this end, Lake Norra Bergundasjon in southern Sweden was selected. It is a recipient for wastewater treatment plant (WWTP) effluent with a fresh-water dilution factor of ~4. For measuring chemical persistence in the field, the WWTP effluent discharged to the lake, as well as water of the lake inlet and outlet were collected over a period of 3 months in 2017 and analyzed. The data were used to assemble contaminant mass balances and calculate biodegradation half-lives. The unspiked laboratory test was carried out using a mixture of fresh lake water and WWTP effluent collected at the end of the field sampling period under conditions recommended by the standard OECD 309 protocol, lasting for a period of 60 days at 20 °C in the dark. The field study yielded a half-life < 120 d for 28 chemicals. Of these, 12 were observed to degrade in the lab test following first-order degradation kinetics, while the half-life could not be determined for the remaining 16 chemicals due to non-significant dissipation or absence of first-order kinetics. There was good agreement between the half-lives determined in the field and in the laboratory test for 5 of the 12 chemicals, while the half-lives were markedly longer (up to two orders of magnitude) in the field for 6 of the 12 chemicals. This shows that biodegradation in the lake could not be reliably measured using an unspiked bottle test based on a mixture of lake water and effluent from the dominant contaminant source.

WP144 Inoculum criteria for OECD ready biodegradability tests

D. Lyon, Shell Oil Company / Shell Health Risk Science Team; D.M. Saunders, Shell International / Toxicology; S.A. Hughes, Shell Health Americas / Shell Health Risk Science Team; C.L. Meyer, Shell Oil Company / Shell Health Risk Science Team

A primary objective of biodegradation testing of chemicals is to screen for commercial substances that are persistent. Persistent chemicals may accumulate in the environment and could result in hazardous effects, irreversible contamination, and increased possibility for long range transport. The OECD has published guidelines for biodegradation testing, such as the OECD 301 ready biodegradability tests (RBTs), in which the test substance is exposed to a microbial population (seawater, sludge), and the transformation or mineralization of the test substance is measured. While these RBTs have been heavily criticized for their conservative nature and lack of relevance to environmental systems, they provide a standardized, quick and easy screen for most substances. Unfortunately, RBTs often show variable results for a single substance, as (bio)degradation of a substance is controlled partly by the substance’s intrinsic properties but also by the environmental system used in testing, i.e., the microbial community, temperature, organic load, etc. The “Revised introduction to the OECD guidelines for testing of chemicals, section 3,” which covers biodegradation testing as well as other fate processes, names several factors that affect the performance, accuracy and replicability of biodegradation testing such as the inoculum quality. Inoculum quality can be described as the level of microbial activity, the concentration of microbes in the inoculum, and the microbial diversity in that environmental sample. Unfortunately, these factors are poorly controlled in RBTs. Microbial activity is often assessed by inclusion of a positive control, such as sodium benzoate or aniline, but this control does not guarantee the required diversity of the inoculum. Microbial load is typically assumed through use of a prescribed volume of activated sludge or can optionally be measured using plate counts or other method. However, there is large variation in the concentration of microbes from even the same environmental medium. Microbial diversity is often assumed based on the inoculum, normally being environmental samples or activated sludge. Capturing the diversity present in natural systems is key for an accurate reflection of biodegradability of a substance. In this work, we discuss criteria that could be used to qualify a microbial inoculum for use during a RBT to improve consistency and confidence in testing outcome.

WP145 Application of ready biodegradation tests for chemical mixtures

The OECD standardized ready biodegradability tests are designed to provide an estimate of a potential for a substance to degrade in the environment. These are intended to evaluate the rate of breakdown for single substances and are not indicated specifically for use in analyzing complex compositions containing different types of constituents. However, useable information can be gained by testing a mixture, such as providing insights into synergisms that may increase or decrease rates of degradation within the testing system. Various authorities require biodegradability data on complex substances, such as UVCDs, to meet policy needs, hence the necessity for mixture testing. There is, however, no specific regulatory instruction on how to appropriately address the biodegradability of complex mixtures. Furthermore, as chemicals exist solely as complex mixtures in wastewater, there is a high degree of value in understanding their behavior. To address this need, our work will propose a process for evaluating ready biodegradability testing of complex mixtures, considering 1) the minimum level of unique substance(s) that are present in a mixture that will be introduced to the test system, 2) structure similarity of the substances, 3) uncertainties associated with mixture testing results, and 4) how to mitigate those uncertainties. The process can provide valuable information regarding the biodegradability of the mixture, guidance on how to make selections of relevant mixtures for biodegradability testing and an ability to interpret the outcome of the mixture test.

WP146 Evaluation of Organic Chemical Biodegradation in Environmental Media

M. Kawa, R. Hanna, P. Howard, SRC, Inc. / Environmental Health Analysis

Organic chemicals that are resistant to biodegradation, hydrolysis, and photolysis processes are classified as persistent and are considered potential environmental pollutants. Due to the wide variability in the methodology and parameters reported in biodegradation studies, classification of an organic chemical as persistent is a challenge. Key parameters needed to determine biodegradation rates of an organic chemical include the number and identities of viable microorganisms present, the environmental conditions, and the identity of the chemical. Light, water, oxygen availability, temperature, chemical concentration, the density of the microbial population, the concentration of nutrients and other carbon sources present in the environmental media all play roles in evaluating organic chemical biodegradation studies. The best experimental indicators of biodegradation are: 1) screening tests, 2) biological treatment simulations, 3) grab sample tests, and 4) field studies. Field and grab sample studies give an indication of biodegradation in the natural environment; however, the conditions represented in these studies vary more than standardized screening tests and give more variable results. Screening studies simulate either the environment or biological treatment;
therefore, results from each give insights into biodegradation under these conditions. Data from standardized, guideline screening tests such as MITI or OECD, and multiple, consistent biodegradation results reinforce reliability; and results from these tests are used to develop biodegradation models (i.e., EPI SuiteBIOWIN 5 and 6 based on MITI test data). When experimental data are unavailable, classification based on chemical structure and comparison to analogs with experimental data can be performed. Functional groups and chemical classes that have extensive experimental data include simple aromatic hydrocarbons, Polycyclic Aromatic Hydrocarbons (PAHs), chlorinated aliphatics, phenols, ketones and phthalates. Finally, if there are no suitable structural analogs, persistence evaluation is based on estimation programs. Herein, we propose a decision process to evaluate organic chemical biodegradation studies and give a case study to demonstrate the utility of this method.

Chemistry and Exposure in the Indoor Environment

WP147 Non-targeted and suspect screening analysis of indoor environmental chemicals using SCIEX X500R QTOF system and SCIEX OS software

J. Anichina, Sciex / Product Applications Laboratory; D.M. Cox, AB SCIEX; J. Rivera, Sciex

Exposomics and human bio-monitoring (HBM) are rapidly advancing disciplines addressing risk assessment in environmental and occupational health and contributing to the development of policies and programs to protect human health. One of the tools available to the disciplines and utilized with growing popularity is non-targeted and suspect screening using high resolution mass spectrometry (HRMS). Non-targeted screening workflows enable simultaneous detection, characterization, identification (if reference was reported previously) as well as relative quantitation of multiple environmental chemicals, metabolites and other small molecules. Non-targeted screening with HRMS helps overcome challenges of characterization of thousands of compounds present in samples of interest (e.g. environmental exposure samples as well as human samples). The workflow allows scanning extensive mass ranges to determine molecular weight, elemental composition, and molecular structure information. In the study presented here, we report on the analysis of non-targeted screening of household laundry drier lint. Lint samples were selected as a representative source of human exposure to environmental contaminants, including polycyclic aromatic hydrocarbons, polychlorinated biphenyls, organophosphate flame retardants, plasticizers, pesticides etc. Lint samples were collected from two households in Ontario, Canada. Initial extraction and clean-up procedures were performed using methanol and acetonitrile. Solid-phase extraction procedure was conducted using Strata GSB cartridges from Phenomenex. HPLC separation of analytes was performed both on a reverse phase and HILIC analytical columns in gradient regimes. Mass spectrometry analysis was performed with a SCIEX X500R QTOF System. SCIEX OS 1.5 software was utilized for data processing in non-targeted workflow. Our results demonstrate the advantages of the non-targeted and suspect screening analyses of for comprehensive characterization of multiple chemicals present in indoor environment. Specifically, high confidence identification was achieved for suspect compounds from the expected environmental chemical classes as well as true unknown features.

WP148 Effect of particle-bound polycyclic aromatic hydrocarbon on dermal absorption: Barbecue as a case study

J. Lan, Jinan University; E.Y. Zeng, Jinan University / School of Environment

Up to now, there is still a big knowledge gap between particle-bound polycyclic aromatic hydrocarbon (PAHs) and dermal absorption. As high molecular weight PAHs are on basis of existing in fine particles, especially in ultrafine particles which have higher deposition velocity and could be much more easily absorbed by skin. Thus, it is necessary to figure out the effect of particle-bound PAHs on dermal absorption and then fill the knowledge gap. To address this issue, we conducted an indoor barbecue in Guangzhou, China. Particle and gaseous samples of background and barbecue fumes, and forearms-wipe samples of 12 participants were included to be analyzed. Particle and gaseous concentrations of PAHs increased from 4.2 and 37 ng m^-3 to 612 ± 17 and 949 ± 79 ng m^-3, respectively. For lower molecular weight PAHs, coarse particles played a greater role on their dry deposition flux, while those of high molecular weight PAHs were greatly controlled by fine particles. The logarithms of gas-particle partitioning were well correlated to logarithms of octanol-air partition coefficients (r^2=0.9504) and the subcooled liquid-vapor pressure (r^2=0.9393), indicated that both adsorption and absorption were contributed to the transport and fate of PAHs derived from barbecue fumes. There are considerable amounts of PAHs were detected on forearms-wipe samples, which were in good linear correlation with dry deposition flux of coarse particles (r^2=0.9915, p < 0.01), but not with fine particles (r^2=0.1389, p > 0.05). It definitely gave an good insight to minimize the effect of particle-bound PAHs.

WP149 Heterogeneous Ozonolysis of Cigarette Smoke and Nicotine Deposited onto Indoor Surfaces

C. Ling, A. Wylie, J. Abbatt, University of Toronto / Department of Chemistry

Indoor air pollution can lead to significant exposures to toxic compounds (e.g., harmful gases and particulate matter), especially for populations who spend a majority of their time indoors. Despite the importance of indoor air, chemical transformations indoors are relatively understudied compared to those that occur outdoors. One defining feature of the indoor environment is the large amount of surface area available (typically orders of magnitude higher than the outdoors) for semivolatile compounds to deposit onto and the variety of surface materials. Compounds deposited onto surfaces can continue to react through heterogeneous reactions with atmospheric oxidants over long timescales (days to weeks) since they are less subject to removal by building air exchange. In this work we focus on the heterogeneous ozonolysis of tobacco smoke and individual components of cigarette smoke (e.g., nicotine) in a set of laboratory flow tube experiments. Gas-phase products produced from the heterogeneous ozonolysis of cigarette smoke are measured by depositing smoke onto a variety of indoor surfaces and monitoring gas-phase composition with an acetate ion time-of-flight chemical ionization mass spectrometer (CIMS) during ozone exposure. Over a wide range of environmental conditions, isocyanic acid (HNCO) is detected as a major product, showing the capability of surface reactions to be an additional source of exposure to toxic compounds indoors. Condensed phase products such as nicotine 1'-oxide, cotinine, and N-formylnornicotine, are identified by high-performance liquid chromatography with electrospray ionization tandem mass spectrometry (HPLC ESI-MS/MS). Additionally, the surface behavior of nicotine on glass and cotton surfaces is monitored to determine whether oxidation by ozone can compete as a loss process with volatilization for this relatively volatile component of cigarette smoke.

WP150 Indoor Chemistry of Ammonia and Amines: A Need for Quantitative Non-invasive Passive Sampling

L. Salehpoor, T. Vandenhoor, York University / Department of Chemistry

Analytical techniques to quantify amines are newly emergent outdoors and will play a pivotal role in assessment of the chemistry and exposure of indoor atmospheres. Ammonia and amines may form inhalable particles which can lead to respiratory effects such as occupational asthma. They may also present toxic and carcinogenic effects on human health by conversion to nitrosamines in the presence of nitrogen oxides and nitrite. The study of ammonia and amines as atmospheric pollutants is therefore critical in the indoor atmosphere. This is because people spend ~ 90% of their time indoor where sources of amines can be emitted from tobacco smoke, pets’ excrement, cooking meat, cleaners, and consumer products. The purpose of this work is to collect aliphatic amines quantitatively by passive samplers. To do this, a measure of the passive sampling rate of aliphatic amines with respect to relevant indoor parameters of temperature
and relative humidity must be captured. The chemistry controlling the rate and stability of amine reaction product formation will be explored through environmental chamber studies. These new analytical developments will allow us to quantify the concentration of ammonia and amines in new and existing homes, which is not possible with existing technology. Passive sampling used to collect amines both indoors and outdoors also has advantages over active sampling for measuring ultra-trace analytes because it is simple, safe, cost-effective, and non-intrusive to the activities of indoor occupants. We have built a custom permeation oven to generate up to four independent controlled gaseous concentrations of parts-per-billion-by-volume (ppbv) of the most abundant atmospheric alicyclic amines (C1-C6). Calibration concentrations of a gaseous amine (or mixture) can then be introduced to a Teflon environmental chamber to determine amines passive sampler rates and product stability against common oxidants such as O3 and OH. All the analytes were measured quantitatively by ion-chromatography coupled with a conductivity detector. Alicyclic amines collected and quantified by passive samplers and annular denuder devices in both indoor and outdoor environments will be used to validate the accuracy and robustness of passive sampler measurement. The performance and concentration of ammonia and amines quantified by this passive technique in homes will be discussed.

WP151 Developing a Robust, Reliable, and Reproducible Nitrous Acid (HONO) Calibration Source for Indoor Chemistry

M. Lao, T. Vandenboer, York University / Department of Chemistry

The ranges of outdoor nitrous acid (HONO) under sunlit conditions varies from a few pptv in less polluted areas, up to 15 ppbv in polluted areas and 10 ppbv in fire plumes. Indoor air quality is affected by HONO because it is a pollutant which photolyses to release oxidizing hydroxyl (OH) radicals. Inhalation HONO is linked to respiratory damage, can react to form carcinogenic nitrosamines, and initiate oxidation of volatile organic compounds. Photolysis of HONO has been shown to occur under indoor light conditions (λ=≤405 nm). Recent publications have observed peak HONO accumulation of 100 ppbv indoors from gas stoves – greatly exceeding maximum outdoor concentrations. The potential chemistry of HONO indoor is therefore of concern due to humans spending 90% of their lives indoors. To support future research on understanding exposure, making accurate measurements, and indoor modelling of HONO, an in situ HONO calibration source was developed to provide high reproducibility, selectivity and accuracy. Previous HONO calibration sources required a bed of powdered sodium nitrite (NaNO2), with a limited lifetime and experiences of unstable emission rates. The desorption of HONO at high concentrations results in dissociation and low conversion efficiency, producing gaseous interferences such as NO and NO2. Our new HONO source is designed to produce a large order of magnitude calibration range across all environmentally relevant concentrations. The use of an NaNO2 coated device requires lower salt quantities, resulting in less waste and stable conversion efficiency. The source is a fully thermostated system and uses a new configuration of the acid displacement reaction between gaseous hydrochloric acid and NaNO2 at ~50% relative humidity. The resulting high purity HONO is released into ultra-pure zero air for calibration of gaseous sampling devices. The stable HONO output was measured across all experiments by a gas-phase chemiluminescence detector. The HONO source was confirmed to be of high purity through a series of negative control experiments. The robustness of the system was determined by simulating field transport of the calibration system before initiating the experiments. Under these testing conditions, the HONO calibration system has a precision of +/- 30% on start-up, with one-minute precision within a calibration period near 10% when generating 0.2 to 2 ppbv calibration quantities.

WP152 Atmospheric Pollutants in Vehicle Cabins

C. Kroptavich, S. Zhou, S. Koval, Syracuse University / Chemistry; T. Kahan, University of Saskatchewan / Chemistry

North Americans spend approximately 90% of their time indoors, and close to 7% of that is spent in vehicles. Air quality in vehicle cabins may therefore have an impact on human health. We measured time-resolved concentrations of the common gaseous pollutants ozone (O3), nitric oxide (NO), nitrogen dioxide (NO2), nitrous acid (HONO), and carbon dioxide (CO2) in a parked vehicle under different conditions (e.g., engine on and off, various fan settings, occupant present and absent). Spectral irradiance was measured inside the vehicle, and photochemical hydroxyl radical (OH) formation rates were determined. Pollutant concentrations in the vehicle were generally influenced by, but different than, outdoor levels. In contrast with several chamber experiments that report greatly reduced ozone levels indoors in the presence of people (due to reactive uptake of ozone to skin oils), O3 concentrations in the vehicle were not affected by the presence of an occupant. Under sunlit conditions, HONO photolysis could be an important hydroxyl radical (OH) source.

WP153 Developing Novel Instrumentation to Measure Total Chlorine in an Indoor Environment

T. Furlani, York University / Chemistry; T. Kahan, University of Saskatchewan / Chemistry; T. Vandenboer, C. Young, York University / Department of Chemistry

The typical modern person spends approximately 90% of their life indoors, and therefore understanding the air quality impacts in these environments is crucial to understanding overall human health. Reactive chlorine (Cly = Sum of all chlorinated species that yield Cl after common atmospheric transformations) plays an important role in outdoor air quality and may be important indoors as well. Consumer cleaning products are known to have a variety of chlorine containing compounds due to their strongly oxidizing properties. The chemistry at these surfaces is not well understood but has been shown to yield common reactive chlorine species such as HCl, HOCl, and Cl2. Currently, reactive chlorine evolved from normal residential or workplace activities has an unknown impact on indoor air quality. Due to the complexity of the indoor air matrix and the need for an unobtrusive measurement that can be deployed in occupied indoor environments, a simple and robust technique to measure the total chlorine in indoor air is needed to explore the extent of total chlorine, present a novel instrument design to be used in tandem with an acidic gas scrubbing technique or in situ HCl instrument. Complete combustion of reactive chlorine is achieved through a heated platinum catalyst. The chlorine atom released from this process abstracts hydrogen from a hydrogen source producing 1 HCl molecule per 1 Cl present. The objective of this project is to demonstrate complete combustion of the carbon chloride bond, and to produce a stable HCl signal for quantifying a total chlorine mixing ratio in an indoor environment.

WP154 Measurements and reaction pathways of reactive chlorine in a college athletic facility

Chlorine chemistry in indoor environments is poorly studied, while there is evidence that it could play a significant role in indoor air chemistry. Due to the overall low abundance of the hydroxyl radical indoors, the chlorine atom may be an important contributor to indoor oxidation. Since chlorine containing compounds are used in cleaning products, they can be released in significant quantities in the indoor environment. Yet it is largely unknown to which extent they impact indoor air oxidation. The processes of chlorine chemistry were studied in a workout room facility of the University of Colorado Dal Ward Athletics Center. Measurements were performed over a period of two weeks, while the workout room was being used by University athletes. The facility was equipped with a HVAC system that delivered air into the workout room; cleaning of equipment was carried out on a regular basis. Measurements of both the room and supply air were rapidly alternated to determine the enhancement indoors relative to outdoor air, and the origin of emissions. Since hydrogen chloride (HCl) is a tracer for chlorine chemistry in the atmosphere, HCl measurements were performed using a high time resolution...
cavity ring-down spectroscopy analyzer. Baseline HCl mixing ratios were typically below 20 pptv, while during cleaning events distinct peaks of HCl reaching up to 1.3 ppbv were observed. The increases of HCl were accompanied by elevated mixing ratios of other reactive chlorine compounds, which were measured by time-of-flight chemical ionization mass spectrometry utilizing iodide reagent ion. A wide suite of supporting gas and particulate measurements were also collected. In our presentation we will discuss the formation and removal mechanisms of HCl and other chlorine-containing compounds and how they are affected by cleaning and ventilation of the indoor environment.

WP155 Acetylcholinesterase activity evaluation as a biomarker for determination of occupational exposure to hexavalent chromium

Z. Panjali, Shahid Beheshti Medical University / Occupational Health and Safety; Z. Fazli, R. Zendehdel, Z. Mohammadi, Shahid Beheshti Medical University / School of Public Health / Occupational Health Department

Increasing need for industrial development in recent decades, cause unwanted health risk among employees. In this regards, monitoring and engineering control should be applied in the workplaces, which highly depend on air contaminant concentrations. Hexavalent chromium as approved carcinogen mainly used in electroplating. In this study, chromium air levels were determined by the application of NIOSH 7600 method (0.014 - 0.051 mg m⁻³). Also, the acetylcholinesterase (AChE) activity as a biomarker of chromium toxicity was measured by Elman method in taken blood of exposed group (35.88±10.44 years old) and control group (35.80±7.58 years old). Results showed that there was a significant relationship between AChE activity suppression and concentration of hexavalent chromium in the workshops. The AChE activity in exposed and control subject was determined 33.82±26.5 and 44.98±2.56, respectively, which was statistically significant (P=0.008). In comparing with control group AChE is a suitable biomarker for occupational exposure even in the presence of another root of exposure such as environmental and food intakes.

WP156 Passive sampling across environmental compartments: A glimpse on the bioaccumulation of organic pollutants and its relation with trophic level

E. Rojo-Nieto, Helmholtz Centre for Environmental Research GmbH - UFZ / Department Cell Toxicology; M. Maz, UFZ - Helmholtz Centre for Environmental Research / Effect Directed Analysis; J. Watzke, T. Wernicke, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology; A. Jahneke, Helmholtz Centre for Environmental Research - UFZ GmbH / Cell Toxicology

Passive Sampling Devices based on polymers such as silicone, operated in equilibrium mode, offer a superior approach to assess bioaccumulation to traditional exhaustive extraction, since they avoid the need for normalization of the total concentrations of hydrophobic organic compounds to the main sorptive phase, e.g. lipids or organic carbon. Recently, a new approach for passive equilibrium sampling (PES) in lean tissue has been proposed, allowing to reach equilibrium in biota tissue with low to medium lipid content, and thus to compare bioaccumulation across trophic levels. In this study, a well characterized closed ecosystem has been selected, a small Swedish lake (Angen), and five different biota species were studied: crayfish, perch, roach, bream and eel. For crayfish and eel, the selected tissue was the muscle. For perch, roach and bream, the entire fish were analyzed. The samples were homogenized, and the lipid content was determined. In order to calculate the trophic level, δ15N was also determined. The homogenized tissues were sampled using silicone with three different thicknesses: 125, 250 and 350 um to confirm equilibrium partitioning between the samples and the silicone, relocating the samplers six times per day over five days. The silicone was extracted, and the extracts were cleaned-up using EMR-Lipid cartridges (Agilent Technologies). Six sediments from the study area were sampled using coated glass jars, a well established method for PES in this matrix. The analysis and quantification of a wide range of compounds, including PAHs, PCBs, PBDEs, pesticides, musk compounds, sunscreens and antioxidants, were achieved with a gas chromatograph coupled to a high-resolution mass spectrometer (GC-HRMS Orbitrap Q-Exactive, Thermo Fisher). The present work accomplished the study of 160 compounds using PES in biota, from lean tissue to lipid-rich tissue. The equilibrium was confirmed for the compounds quantified in the different tissues, using silicone of different thicknesses. The results of this study showed that PES allows to compare concentrations of contaminants in biota from different trophic levels directly and, thus, assess biomagnification. This so-called “chemometer” technique, using silicone as common reference phase for direct comparison across media, also allows to compare these concentrations with those found in abiotic compartments (e.g. sediment).

WP157 Butyltins in surface water using polydimethylsiloxane

J. Lima da Silva, FURG Federal University of Rio Grande / Escola de Quimica e Alimentos; G. Fillmann, FURG Federal University of Rio Grande / Instituto de Oceanoografa

Tributyltin (TBT) was used in antifouling paints for more than four decades and, due to its intensive use and high toxicity, it was banned by the International Maritime Organization (IMO) on January 1, 2008. However, recent studies have been detecting TBT and its degradation products in different environmental matrices (i.e. sediment and biota) from Latin America. On the other hand, water column studies assessing current use of TBT, its freely dissolved concentrations and measuring time-weighted average concentrations are rare. Thus, polydimethylsiloxane (PDMS) sheets (with individual total surface area of 100 cm²) were used as passive samplers to measure levels of TBT, dibutyltin (DBT) and monobutyltin (MBT) in the water column of Pato Lagoon estuary (southern Brazil), the world largest cooked lagoon. Five 8 weeks-long samples were taken during 2018. Prior to exposure, the PDMS were spiked with Performance Reference Compounds covering a wide range of partition coefficients, which are used to calculate the analytes exchange rates between sampler and water. An analytical method was developed and validated for the determination of butyltins. PDMS were extracted by Soxhlet (acetonitrile with 2% (v/v) acetic acid), derivatized using sodium tetraethyl borate, cleaned-up with silica and analyzed by GC-MS. Surrogate (tetrabutyltin) recoveries varied between 58 and 105%. Analytes were quantified at all samples, with amounts ranging between 15.9 and 68, 8 and 251, and 5.8 and 363 pg Sn sampler⁻¹ day⁻¹ for TBT, DBT and MBT, respectively. Results indicate that fresh inputs of TBT are still taking place in the study area. Since passive sampling can mimic bioconcentration in organisms, the freely dissolved concentrations of butyltins found in the water phase during all the monitoring period pointed out their bioavailability and possible exposure risks to the local biota.

WP158 Exposure assessment of indoor and outdoor air quality within the informal settlement neighbourhoods

S.R. Madonsela, R. Baatjies, Cape Peninsula University of Technology / Environmental & Occupational Studies; A.M. Dalvie, University of Cape Town / Centre for Environmental and Occupational Health Research

Poor indoor and outdoor air quality is a major challenge facing developing countries. Half of the human population based in the developing countries experienced in developing countries. The main goal of this study is to assess and compare seasonal exposure of indoor and outdoor air quality within the informal settlement neighbourhoods. Weekly indoor and outdoor air quality exposure assessments of PM2.5, O3, CO and NO2 were conducted in the households of four informal settlement neighbourhoods for one month each in summer and winter. PM2.5 measurements
WP159 Active passive sampling for pesticides to include recording of sampled water volumes

S. Droge, S. Abdalla, C. Schwenken, L. Maas, S. Nijdam, R. Prijden, University of Amsterdam

Water quality monitoring is an essential part of decision making within health and environmental issues. Contamination levels of dissolved organic pollutants can be determined with chemicals analysis and/or biological response assays. Traditional grab sampling of water may not accurately represent spatiotemporal trends of the contaminant levels if emission fluxes are variable. Grab sampling also requires complex transport and storage logistics. Passive sampling with various polymeric sorbent materials could provide for time-weighted average concentrations. Clean solvent extracts can be used both in chemical analysis and bioassays. However, the uptake kinetics of chemicals in commonly deployed samplers such as POCS/chemcatcher/speedisk are not constant, and depend largely on the water flow. The volume of water that has passed such samplers in situ needs to be identified by the depletion curves of series of pre-loaded performance reference compounds (PRC) that cover a representative chemical domain, which requires additional chemical analysis, undesirable chemicals in extracts for the bioassays, while still rendering rather uncertain sampling volumes. The PRC approach can be circumvented if water is continuously pumped through a sorbent filter and the passing water volume is tracked. The rechargeable Continuous Low-level Aquatic Monitoring (CLAM) sampler provides these options, with a pumping rate of ~1.5L/h in clear water and HLB packed filters. We aimed to use the active passive CLAM sampler to assess the levels of dissolved pesticides in various Dutch agricultural regions. To evaluate the efficacy of the CLAM sorbent filters, we first evaluated the potential pre-filter losses, breakthrough volumes, and comparison to parallel aqueous samples of 100 spiked common pesticides in the first 10L passing the CLAM. Secondly, we analyzed 24h CLAM extracts from various field locations using LC-MS/MS and bioassays primarily with water flea Daphnia magna, potentially extended with other assays, to identify whether contamination levels in these locations pose a potential risk. The glass pre-filter retained <5% of the HLB accumulated amount for all tested pesticides. Many acidic herbicides demonstrated >60% breakthrough if more than 10L water passed, while neutral pesticides with a logKow>2 had <10% breakthrough even after 10L water passed. Field samples will be assessed during the summer period of 2019.

WP160 PCB levels in the surface water, sediment porewater, and benthic organisms in Back River watershed

S. Joshee, M. Bokare, University of Maryland, Baltimore County / Chemical, Biochemical and Environmental Engineering; W. Schmidt, K. Brittingham, Baltimore County / Department of Environmental Protection and Sustainability; U. Ghosh, University of Maryland, Baltimore County / Chemical, Biochemical, and Environmental Engineering

Polychlorinated biphenyls (PCBs) are major contaminants of concern in Back River, resulting in fish consumption advisories in Maryland. In collaboration with the Baltimore County and the Maryland Department of Environment (MDE) we are performing a pilot assessment of ongoing contribution of PCBs from several streams in Back River watershed. Direct measurement of sparingly soluble chemicals like PCBs in the water phase is challenging due to the ultra-low aqueous concentrations and interference with colloidal particles. However, the freely dissolved concentrations are indicative of biological uptake, toxicity, and flux of pollutants between sediments and water column. In addition, the freely dissolved concentrations provide an indication of potential sources or hot-spots of PCB release in a watershed. Passive sampling has emerged as an alternative technique to assess freely dissolved concentrations of hydrophobic chemicals without interference from colloidal particles. In the present project we deployed polyethylene (PE) passive samplers at 4 tributaries and in the main stem of Back River to measure the freely-dissolved concentration of PCBs and to understand potential sources of the pollutants. PCB concentrations ranged from 0.027 - 2.6 ng/L during the deployment period from June 2018 to August 2018, with Bread and Cheese Creek tributary showing the highest dissolved PCB concentrations among the sampling sites. PCB levels at two locations in Back River itself were 0.99 and 0.56 ng/L. Concentrations at five out of nine sampling locations exceeded the USEPA Water Quality Criteria of 0.64 ng/L, associated with a carcinogenicity risk of 10 in a million. These monitoring results will be used to investigate potential legacy sources of contaminants in upland areas that may be impacting water quality. Benthic organisms were collected from sediments in the Back River and are being analyzed for PCB concentrations to assess accumulation at the base of the aquatic food chain. Ongoing analysis of PCBs in sediment porewaters will be used to obtain greater insight into exchange of PCBs between surface water and porewater and also allow quantification of bioavailability of PCBs to benthic organisms.

WP162 Characterization of the Variation in Dissolved Organic Matter and Agrochemicals in an Agricultural Stream Using Passive Sampling

J. Abraham, J. Longstaffe, University of Guelph / School of Environmental Sciences

Dissolved organic matter (DOM) is a heterogeneous mixture of various organic biopolymers derived from the degradation of terrestrial and aquatic biomass. DOM plays a crucial role in the environment as a mediator of several key ecosystem functions, including carbon cycling, nutrient cycling, and the fate of many environmental pollutants. This poster describes the use of DEAE anion-exchange resins as a passive sampler tool to monitor the spatial and temporal variation in the composition of DOM in an agricultural stream. The composition of DOM is analyzed using NMR spectroscopy and is compared to the presence of agrochemicals in the stream to explore the role that variation of DOM composition due to different land-use practices plays in the behaviour and occurrence of agrochemicals in an agricultural impacted stream.

WP163 Characterizing freely dissolved polychlorinated biphenyls and organochlorine pesticides in San Diego Bay (CA, USA) using polyethylene passive samplers

Determination of the freely dissolved concentration (C_free) improves our ability to assess and predict bioaccumulation of hydrophobic organic contaminants (HOCs) in aquatic environments. San Diego Bay is an urbanized embayment listed as impaired due to the presence of HOCs such as polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs). To characterize the contribution of contaminated sediments to HOCs present in the water column, C_free for PCBs and OCPs were dedicated at 10 stations throughout San Diego Bay using polyethylene (PE) passive samplers. PE samplers preloaded with performance reference compounds (PRCs) were deployed at mid-water depth and in bed sediment at each station for 1 month during the wet and dry seasons in 2018. The PE samplers in sediment were deployed using a device that allowed for estimation of C_free both above and below the sediment-water interface.
Seawater and sediment grab samples were also collected and analyzed for comparison to $C_{\text{free}}$. Forty-two PCB congeners and 12 OCPs (5 chlordane insecticides, dieldrin and 6 DDT and its degradates) were determined by GC/MS. Water-column $C_{\text{free}}$ for the sum of 42 PCBs ranged between 58 ± 3.9 to 1250 ± 130 pg/L, whereas the $C_{\text{free}}$ for the sum of 12 OCPs were 7 to 23 times lower. The sum of 42 PCBs in the sediments ranged between 0.84 to 690 ng/g dry weight, but the sum of 12 OCPs were 4 to 162 times lower. The highest levels for the sum of 42 PCBs were found at stations 1, 3, and 5 for water-column $C_{\text{free}}$ and bulk sediment concentration ($R^2=0.88$ and 0.82 for wet and dry season events, respectively, $n=10, p<0.05$). Water-column $C_{\text{free}}$ for the sum of 42 PCBs in the dry season were 1.7 to 4.9 times higher than in the wet season. Mass flux of PCBs across sediment-water interface indicated transport out of sediment into the water column. Results from this study will used to quantify the contribution of sediment HOCs to bioaccumulation by resident fish in San Diego Bay.

WP164 Using integrative passive sampling devices to obtain more meaningful and cost-effective data on metal-associated impacts from stormwater runoff

N. Hayman, G. Rosen, NIWC Pacific / Energy and Environmental Sustainability; J. Strivens, Pacific Northwest National Laboratory / Marine Sciences Laboratory; G. Anguiano, Naval Facilities Engineering and Expeditionary Warfare Center

In many cases, stormwater compliance monitoring is labor intensive, expensive, and largely unsuccessful in providing the data needed to support informed stormwater management goals. To help address these issues, time weighted averaging (TWA)/integrative metal passive samplers, Diffusive Gradients in Thin-film (DGTs), are being used to monitor stormwater runoff for copper (Cu) and other stormwater relevant metals in various monitoring approaches, primarily focused on stormwater management. In current studies, DGTs were co-located with traditional autosamplers, within the stormwater conveyance systems at Naval Base San Diego (NBSD) and a hybrid-Low Impact Development (LID) Best Management Practice (BMP) objective at Naval Base Point Loma (NBPL), to provide a direct comparison DGT-labile TWAs and composite sampling of the operationally defined dissolved fraction. In a more controlled fashion, DGTs were exposed in the laboratory to composite samples from NBSD stormwater conveyance systems. These controlled experiments showed increasing uptake over time (range = 1.5 to 24 h) for Cu, with statistically significant positive, linear correlations ($r^2=0.9890$) between time exposed and metal mass accumulated. Under laboratory testing, corresponding calculations of the DGT-labile fraction relative to the dissolved fraction fluctuated with exposure duration; giving an indication of necessary equilibration/minimum deployment windows. In general, trends observed for DGT-labile measurements from the field were consistent with trends in the lab DGT exposures and traditional dissolved metal measurements from composite samples. TWA Cu concentrations from DGTs deployed for the first and second half of a storm event were within 30% of measurements from DGTs that were deployed for the entire storm event in the same stormwater vault at NBSD. Finally, comparisons between flow-weighted composite samples collected before and after the LID BMP at NBPL showed convincing agreement with the DGTs deployed in the influent and effluent sampling locations. Cumulatively, these results show promise for continuous monitoring with DGTs as an approach that produces concentrations more representative of those in the receiving environment during episodic events than those concentrations measured from traditional grab or composite chemistry sampling, as well as a cost-effective method to measure BMP efficacy.

WP165 Non-Targeted Fingerprinting of Contaminated Waters Using Passive Samplers Analyzed Using Benchtop NMR Spectroscopy

J. Longstaffe, L. Sunderland, University of Guelph / School of Environmental Sciences; J. Konzuk, C. Cheyene, Geosyntec Consultants

Nuclear magnetic resonance (NMR) spectroscopy offers unique advantages for the non-targeted characterization of contaminated waters. Adding to these advantages is the practicality and reduced expense of benchtop NMR spectrometers. Nevertheless, benchtop NMR spectrometers lack the sensitivity necessary to effectively characterize dilute environmental samples. Passive sampling is a highly practical solution to this issue which allows for the preconcentration of contaminants improving the sensitivity of the NMR method. Through the implementation of passive sampling, the concentration of coal-tar and PFAS contaminated samples were increased allowing for 2-dimensional NMR experiments to be performed using benchtop NMR instrumentation. The use of passive sampling coupled to benchtop NMR shows the potential to be highly valuable to the fields of environmental monitoring and remediation, as a practical and affordable tool for the characterization of contaminated sites.

WP166 Development and Testing of a Novel Passive Sampler for Methylmercury in Sediment and Soil Porewaters

J.P. Sanders, Exponent / Ecological and Biological Sciences; S.B. Kane Driscoll, Exponent / EcoSciences; U. Ghosh, University of Maryland, Baltimore County / Chemical, Biochemical, and Environmental Engineering; A. McBurney, Alcam; C. Gilmour, Smithsonian Environmental Research Center; G. Schwartz, Oak Ridge National Laboratory / Environmental Sciences; J.D. Farrar, US Army Corps of Engineers Engineer Research Development Center; S.S. Brown, Dow / Environmental Remediation & Restoration

Aquatic mercury can pose a significant risk to ecological and human health if it is converted to the more toxic and bioaccumulative methylmercury (MeHg) by anaerobic microorganisms near the sediment-water interface. As such, quantitative measurements of the bioavailability of MeHg to benthos are critical for risk assessment of contaminated sites. Existing technologies designed to function in a kinetic mode (e.g., DGT) have not achieved wide acceptance for generating such measurements. We are developing a novel passive sampling technology to emulate the steady-state (pseudo-equilibrium) mode of benthic bioaccumulation. A target range for sampler-water partitioning (log K) was set at 3.0-4.5 in view of analytical detection limits, the logistics of sampler deployment in the field, and typical sediment-water partitioning coefficients. Custom polymers containing reduced sulfur functional groups or embedded activated carbon (AC) particles were prepared and evaluated in a series of increasingly environmentally realistic experiments, culminating in a sediment exposure alongside a benthic test organism. In mildly saline water isotherms, many of the polymers showed strong, log-linear partitioning of MeHgOH across an environmentally relevant range of concentrations. Partitioning of MeHg complexed with dissolved organic matter was somewhat lower (log K = 2.83 to 3.31) but still in or near our target range. In slurries of contaminated soil, polymer-predicted porewater concentrations ($C_{pw}$) were within factors of one to five of directly measured (centrifuged) water samples. In beaker soil microcosms, accumulation of MeHg by our AC-based polymer reflected temporal variations in $C_{pw}$ as well as reductions due to amendment of soil with AC. Polymer-derived and directly measured $C_{pw}$ agreed equally well at 8, 14, 21, and 28 d of exposure, indicating an approach to steady state on the order of one week. In sediment microcosms, polymer uptake of MeHg was correlated with bioaccumulation by the test amphipod L. plumulosus at 21 d. Mechanistic studies showed that MeHg uptake by AC polymers is relatively rapid, characterized by internal diffusion rather than surface adsorption, and at least partially reversible. These findings indicate the potential for dynamic equilibrium sampling. Compared to existing alternatives, this novel passive sampler could permit more reliable predictions of benthic MeHg bioavailability and improved risk assessment and management for mercury-impacted systems.
WP167 Relevance and limits of passive samplers for monitoring priority micropollutants in surface waters: Results of a French national scale study

B. Mathon, Irstea Lyon; A. Togola, BRGM / Laboratory Division; A. Dabrin, Irstea Lyon-Villeurbanne / UR MALY; S. Lardy-Fontan, LNE; J. Ghestem, BRGM / Laboratory Division; I.J. Allan, Norwegian Institute for Water Research; A. Yari, Irstea; M. El Mossaoui, BRGM; J. Gonzalez, IFREMER; N. Mazzella, Irstea Bordeaux / UR EABX; C. Miège, Irstea Lyon

The implementation of the Water Framework Directive (WFD) requires the monitoring of micropollutants in the aquatic environments to prevent any damages to both human health and ecosystems. In this context, a number of 105 organic and inorganic compounds have been selected as priority pollutants and their measurement is necessary to ensure that water-quality standards are maintained (EC, 2008; EC, 2013; EC, 2015). For two decades, passive sampling methods have been developed for the monitoring of organic and inorganic compounds. Passive samplers allow measuring these compounds at trace levels by accumulation and concentration over long-term exposure. Moreover, the use of integrative passive samplers allows a better representativeness of measurements because it takes into account the episodic pollution. Such passive sampling techniques have been recommended in the European Commission Guidance Document on surface water chemical monitoring, as complementary methods to improve the level of confidence in water monitoring data in comparison with conventional spot sampling. In this context, French government relied on the expertise of AQUAREF consortium to set up a national scale study in order to demonstrate the relevance and limits of passive sampling for the regulatory monitoring of contaminants in fresh and marine surface waters. To achieve this objective, (i) a total of 427 POCIS and 276 DGT were deployed during one year, every 2 weeks on 3 different sampling stations (temporal approach) and (ii) a total of 342 POCIS, 106 DGT and 229 SR were deployed during 2 weeks on 20 sites spread throughout France (spatial approach). For these 2 approaches, spot samples were systematically retrieved during deployment and recovery of IPS. Mean concentrations obtained by the IPS and grab water samples were compared in order to assess the limits and the relevance of these two methods in the frame of regulatory monitoring. The results of this national scale study aim at proposing guidelines for the monitoring of micropollutants by the IPS. Especially by concluding on the relevance of using replicates, the use of field blanks, the determination of exposure times and to propose recommendation such as the necessary number of campaigns in the year. The results also showed that IPS are relevant to obtain a spatial ranking of micropollutant contamination by a unique deployment on several sites.

WP168 Alternative passive samplers for non-invasive assessment of human pollutant exposure

S. Abel, A. Jahnke, Helmholtz Centre for Environmental Research - UFZ GmbH / Cell Toxicology

Persistent and bioaccumulative organic pollutants remain a risk factor for human health around the globe. Monitoring the human exposure to these pollutants, however, relies heavily on invasive sampling methods. Shifting towards non-invasive sampling methods can therefore increase the accessibility of samples for environmental and human health research. Recently, silicone wristbands have been established as passive samplers to describe human exposure to hydrophobic chemicals. A shortcoming of this approach is the lack of information on the origin of sampled compounds, as the wristbands are exposed to both external (e.g. dust-associated or airborne) and dermally excreted compounds, making the assessment of external vs. internal exposure difficult. To address this problem, our project aims at the development of a non-invasive sampling method that focuses on exposure measurement via skin contact and thus more accurately represents internal contaminant burdens. For this purpose, silicone sheets are directly attached to the skin and shielded from the surrounding environment with an isolation layer. Two protective layers are tested for their contaminant-blocking capability: fabric layers, creating a passive, physical barrier, and activated carbon-impregnated fibers that can trap compounds before they reach the silicone sampler. The tests are initially carried out as “sandwich” experiments, in which the test materials are positioned between a donor medium spiked with model contaminants, and the silicone passive sampler sheet as a receptor. In a second step, the isolated silicone sheets are tested in comparison to non-shielded silicone sheets and simultaneously worn wristbands on volunteers. The function of the isolation layer will be verified with an additionally worn silicone sheet isolated towards the skin. Unlike the established sampler, these controls are expected not to accumulate tracer compounds that are excreted from human skin, but not present in the environment (e.g. soy flavonoids). Altogether, the newly developed samplers have the potential to reduce random effects on data variation in non-invasive human exposure assessment. In addition to the potential of focusing on internal exposure, the silicone sheets permit a larger sampling area and a more reproducible skin contact than wristband samplers. In larger-scale applications, this setup can help to increase the potential for identifying exposure risks to the general public.

WP169 Silicone Wristbands as Personal Passive Samplers: Evaluating Exposure to Organophosphate Flame Retardants Based on Electronics Use

D.M. Molenagar, M. Ross, MacEwan University / Physical Sciences

Organophosphate flame retardants (OPFRs) are used as additives in a variety of industrial and commercial products, such as furniture and electronics, to meet fire resistance standards. However, OPFRs have been associated with health effects, including neurotoxicity, hormonal changes, and cancer; therefore, insight into levels of exposure is necessary for health and risk assessments. An individual’s exposure to OPFRs can be measured using silicone wristbands as passive samplers, which utilizes equilibrium partitioning of a chemical between the solid phase (the sampler) and air to measure personal exposure to contaminants over time. Because OPFRs are frequently used in electronics, this study aimed to examine correlations between electronic use and personal exposure to OPFRs. Silicone wristbands were cleaned to remove surface contaminants and deployed to participants to wear for one week. Following deployment, the wristbands were extracted and 8 OPFRs were quantified using gas chromatography-mass spectrometry. While deployed, participants filled out a questionnaire indicating their weekly electronic use, which was used to draw correlations between electronics and exposure to OPFRs. Preliminary experiments with wristbands worn for three days found a variety of OPFRs including triphenyl phosphate, tris(2-chloroethyl) phosphate, and ethylhexyldiphenyl phosphate. The average concentration of OPFRs found on the wristbands was 356 ng/g with an average exposure rate of 118 ng/day. This project will be one of the first in Canada to use silicone wristbands as personal samplers to address exposure to OPFRs in relation to electronic use, and thus will prove useful in risk assessment due to the increasing use of electronics in society.

WP170 Using Contaminant to Polymer Mass Regression Relationships to Confirm PRC-inferred Equilibrium Concentrations in Passive Sampling

R.M. Burgess, US Environmental Protection Agency / Atlantic Ecology Division; A. Joyce, Duke University / Civil and Environmental Engineering; S.N. Schmidt, US Environmental Protection Agency / Atlantic Ecology Division

For passive sampling-based measurements of the freely dissolved concentration (C_{free}) of nonpolar organic contaminants to be accurate, equilibrium conditions between the sampler and the surrounding environment must be established. Currently, methods for validating equilibrium for passive samplers include temporal sampling and polymer mass comparisons. While performance reference compounds (PRCs) are used to correct for equilibrium conditions. Both temporal sampling and polymer mass comparisons involve extra samples and deployments which have adverse logistical and financial costs. Using PRCs is the most logistically and financially sound method to infer equilibrium concentrations.
However, few investigations have independently validated if the PRC modelled estimates of $C_{\text{free}}$ are accurate. In this study, PRC-based estimates of polymer concentrations (used to estimate $C_{\text{free}}$) were validated using polymer mass comparisons to confirm the equilibrium status of target contaminants. At equilibrium, a strong linear relationship exists between target contaminant mass and polymer mass resulting a high coefficient of correlation ($r^2$) and low $r^2$ when equilibrium does not occur. Four thicknesses (i.e., masses) of low-density polyethylene (LDPE) were deployed in the water column of a PCB contaminated Superfund site. After 30 days with several $^{13}$C-labelled PCB PRCs, 27 target PCBs were quantified. Raw concentration data was analyzed using three commonly-applied PRC mass transfer models: first order (FO), non-linear least squared (NLS) and diffusion (DIF). When simply assuming equilibrium (no PRC modelling), lower molecular weight congeners had $r^2$ values from 0.65 to 0.97, confirming the assumption was viable. For all congeners above PCB52, the $r^2$ values were low (e.g., 0.00 to 0.58) indicating a linear relationship did not exist for 81% of the congeners. High $r^2$ values were highly inaccurate. For higher molecular weight congeners and assuming equilibriums above PCB8 to PCB126 (i.e., 0.79 to 0.96), for PCB8 to PCB126 and above, $r^2$ values ranged from 0.59 to 0.53 and representing 35% of congeners. These results validate the NLS and DIF models will generate $C_{\text{free}}$ values reflecting equilibrium conditions and correctly estimate exposures in aquatic environments while the FO model was unreliable for higher molecular weight congeners and assuming equilibrium was highly inaccurate.

**WP171 Developing a Polar Chemical Integrative Sampler for Neonicotinoid Pesticides with New Sorbent**

Y. Yabuki, K. Noro, A. Banno, Research Institute of Environment, Agriculture and Fisheries, Osaka; S. Endo, National Institute for Environmental Studies (NIES) / Center for Health and Environmental Risk Research

Polar Organic Chemical Integrative Samplers (POCIS) have been used as a passive sampler to measure time-weighted average concentrations of various chemicals. However, efficient trapping of neonicotinoid pesticides with aquatic passive samplers such as POCIS can be challenging due to their hydrophilic nature. In a previous study, ENVI-Carb (EC), a non-porous graphitized carbon sorbent, was proposed as a possible receiving phase that has high affinity for neonicotinoids on the basis of the results of batch sorption experiments. In this work, sampling rates ($R_s$) for neonicotinoids by POCIS with EC were obtained and compared with those by POCIS with Oasis HLB (HLB). The POCIS used in this study was comprised of a receiving phase (220 mg of HLB or EC) sandwiched by PES membrane filters. To estimate $R_s$ of POCIS with EC and HLB, static renewal calibration experiments were conducted. The experiments were carried out in glass beakers containing 1 L sample solution with a stirring speed of 400 or 1500 rpm, placed in a thermostat at 20°C under a dark condition. The sample solution was prepared by tap water contained 200 ng/mL each of seven neonicotinoids, which were acetamiprid, clothianidin, dinofeturan, imidacloprid, nitenpyram, thiamethoxam, and thiacloprid. POCISs including EC or HLB as sorbent were placed in the glass beakers covered by aluminum foil. These samples were sacrificed for 1, 3, 7, 14, 21 and 28 days in triplicate. The sample solution was replaced every day with fresh sample solution to avoid effects of possible contamination and degradation of neonicotinoids on the experimental results. The flow velocities in the 1 L glass beaker under 400 and 1500 rpm calculated by alabaster mass losses were 1.0 and 18 cm/s, respectively. The higher velocity condition (1500 rpm) was considered to be similar to aquatic environmental conditions. The $R_s$ of neonicotinoids, except for nitenpyram, obtained by the calibration experiments of POCIS with EC and HLB were 0.039 ± 0.031 to 0.070 ± 0.024 and 0.077 ± 0.013 to 0.12 ± 0.048 L/day, respectively, under the low velocity condition, and 0.10 ± 0.011 to 0.18 ± 0.068 and 0.11 ± 0.16 to 0.26 ± 0.11 L/day under the high velocity condition, respectively. $R_s$ tended to be higher in the higher flow velocity. The notable result was that the time periods of the linear phase obtained using EC were longer than those obtained with HLB. The periods of linear phases were 7 to 28 days for EC and 3 to 14 days for HLB under the high velocity condition.

**WP172 New Methods and Applications of PUF Disk Samplers for Investigating Particles and Associated Chemicals in Air**

T. Harney, Environment and Climate Change Canada; A. Saini, P. Shahpoury, Environment and Climate Change Canada / Air Quality Research Division; J. Li, E. Wang, University of Saskatchewan; D. Barbe, Environment and Climate Change Canada / Air Quality Research Division; V. Celo, Environment Canada; S. Halappanavar, Health Canada; T.M. Holsen, Clarkson University / Civil and Environmental Engineering; E. Mackay, Environment and Climate Change Canada

Polyurethane foam (PUF) disk passive air samplers - including the conventional PUF-PAS sampler for ambient air as well as the dry deposition sampler (PAS-DD) - are simple to use, cost-effective and their electricity-free operation allows them to be deployed anywhere. The passive sampling approach trades-off temporally resolved data, possible with high volume active air samplers, for spatially resolved data that is relatively easily to obtain. In many instances, the spatially resolved data is a more relevant and pragmatic approach for investigating abundances in air, long-range transport behaviours, effectiveness of chemicals management measures (temporal trends), and for validating models. Very recently, the use of the PUF-disk samplers has been extended to investigations of particulate matter, including trace metals, black carbon, and microfibers. Particle deposition on PUF-PAS and PAS-DD samplers has been characterized through field calibrations, through particle deposition mapping studies using microscopic methods and by using computerized fluid dynamic models. Methods are also being developed to link contaminant burdens with indicators of toxicity for the mixture of chemicals in air (e.g. mutagenicity, cytotoxicity, oxidative potential) by using in vitro and chemical assays. These developments greatly extend the application scope of PUF disk samplers.

**WP173 Monitoring Emerging Contaminants in Wastewater-Impacted Vernal Pools Using Passive and Grab Sampling Techniques**

K. Hayden, H. Gall, Pennsylvania State University / Agricultural and Biological Engineering; K. Elkin, USDA-ARS Pasture Systems and Watershed Management Research; J. Watson, Penn State Univ / Ecosystem Science and Management; T. Veith, USDA-ARS Pasture Systems and Watershed Management Research; H. Elliott, The Pennsylvania State University / Agricultural and Biological Engineering

Some of the active ingredients in pharmaceuticals and personal care products (PPCPs) can persist through wastewater treatment plants and be released into the environment. With recent advancements in analytical techniques, PPCPs are increasingly detected in wastewater effluent. However, PPCPs remain largely unregulated in the environment due to a lack of monitoring and understanding of the toxicological impacts they pose on the environment and human health. While research has focused on the presence of PPCPs in lotic waters (rivers and streams), this study aims to evaluate the temporal variability of PPCPs in lentic waters (specifically vernal pools) impacted by treated wastewater, using integrative and grab sampling techniques. In this study, the use of Polar Organic Chemical Integrative Sampling (POCIS) membranes will be compared to grab sampling techniques to monitor the presence and persistence of 40 selected PPCPs in 3 vernal pools receiving treated wastewater from spring through fall 2018 and 3 non-irrigated control sites. Overall, 35 of the selected compounds were detected at the study sites. In general, we note that POCIS tend to detect more compounds compared to grab water sampling. As POCIS can act like amphibian skin, we anticipate that POCIS may be used to interpret toxicological impacts of PPCPs on the declining amphibian population. In this way, we hope that future studies may be able to better inform researchers and policy makers on how PPCPs should be monitored in lentic systems and how vernal pools are evaluated as critical habitats for amphibians.
Micro- and Nano-Plastic Methods Research: Harmonizing Methods and Addressing Challenges

WP174 Identification and Classification of Microplastic Particles Using Machine Learning Algorithms

S. Tan, University of Toronto / Department of Chemical Engineering and Applied Chemistry; J. Taylor, University of Toronto / Electrical and Computer Engineering; E. Passeport, University of Toronto

The widespread distribution of microplastics has attracted increasingly more attention due to their potential effects on human and ecosystem health. One fundamental step in microplastic studies consists of the identification and classification of microplastic particles in a given sample. Currently, this process relies heavily on manual labor, including picking the possible microplastic particles under a microscope and confirming their nature using infrared or Raman spectroscopy. This process is time-consuming, prone to human error, and requires expensive spectroscopic techniques and expertise to interpret data. The goal of this research is to propose an alternative method based on machine learning algorithms to predict the microplastic composition of a given sample. For that, we are using data that can be readily measured, for example, the total mass of particles in a given size range. A model relating microplastic counts to simple descriptors such as mass will be developed. Training data from our laboratory and nearby research groups will then be collected and a variety of methods will be applied to the model, including linear regression, logistic regression, and kernel method. The hypothesis is that with the tuned model, more than 90% of the microplastic particles in a given sample can be identified without undertaking complex experimental procedures. If successful, this method can save a large amount of time and effort for people who need a preliminary report on microplastic count in a given sample, in particular in underdeveloped areas where advanced laboratory equipment is unavailable.

WP175 Comparison of microplastic isolation and extraction methods for marine sediment

K.T. Ho, M.A. Cashman, S. Robinson, US Environmental Protection Agency / Atlantic Ecology Division; S.M. Russo, Oak Ridge Associated Universities / USEPA; T.B. Boving, University of Rhode Island / Department of Geosciences; R.M. Burgess, US Environmental Protection Agency / Atlantic Ecology Division

Microplastics are a growing concern in our environment. Methods for the isolation and extraction of these small particles (1-1000nm) from environmental media vary widely and prevent meaningful comparison among reported environmental concentrations. As microplastics become biofouled and aggregate in the water column, sediments become their ultimate sink. We quantified recovery among five commonly used extraction/isolation methods for sediments that were chosen to represent a wide range of approaches in the literature. We tested each of the five methods with five polymers: polyethylene (PE), polystyrene (PS), polyvinyl chloride (PVC), polyethylene terephthalate fiber (PET) and polypropylene (PP) rope in a variety of shapes and sizes including flakes, fibers and spheres ranging from 40-700 mm. All combinations of methods and plastics were tested in two marine sediment types (i.e., sandy and silty). In addition to the five tested methods, we used Nile Red staining post extraction on all methods to determine if the stain increased recovery of spiked plastics. Mean recoveries of microplastics ranged from 0-87%, depending on method, polymer and sediment type. No one method recovered all plastics with the same efficacy, and all methods had mean recoveries <70% per plastic type. As expected, denser plastics were not recovered by lower density salt solutions. Organic matter present in silty sediments increased the complexity of recovery and probably reduced method success. The Nile Red stain increased the fluorescence background in complex, organically rich samples further confounding recovery. Lessons from this investigation provide valuable information for developing a hybridized method for the isolation and extraction of MPs from marine sediments (see Cashman et al. 2019 poster). In addition, we recommend using a standardized mixture of weathered microplastics to quantify method performance.

WP176 Microplastics in the St. Lawrence river: Methodological development for extraction and identification in biota

E. Lacaze, Environment and Climate Change Canada; A.D. Gendron, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R. Gouge, Environment and Climate Change Canada; L. Hernandez, McGill University / Chemical Engineering; N. Tufenkji, McGill University / Department of Chemical Engineering; F. Gagne, Environment and Climate Change Canada; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division; G. Triffault-Bouchet, Centre d’Études en Écotoxicologie et Évaluation du Risque; N. Dassylva, Environment of Quebec; S. Roberge, MDDELCC

Microplastics are increasingly considered as priority substances because of their ubiquity and their potential toxic effects on the environment. These particles are extremely diverse in size, shape, composition, chemical additives, associated contaminants, and fate in the environment. It is essential to develop methods of analysis, monitoring and toxicity evaluation to accurately identify the sources of microplastics and to assess their impact for the aquatic environment. Currently, very limited data are available for the St. Lawrence River, Canada. This study aims to: 1) develop methods of extraction and analysis of microplastics in water and aquatic organisms representative of the St Lawrence River ecosystem 2) To evaluate the bioavailability of model particles under controlled exposure and 3) To identify sources of microplastics in the river through caging experiments in urban effluent-impacted sites and agricultural-impacted sites. In a preliminary work, two protocols of extraction were compared for several types of freshwater bivalve tissues (Elliptio complanata and Dreissena bugensis). The effect of digestion techniques on microplastic analysis by fluorescence microscopy and infrared spectroscopy was assessed. In a second step, zebra mussels were exposed in laboratory to two types of polymers (PA6 and PMMA) in order to characterize the kinetic uptake and tissue distribution of these particles. To identify potential sources of microplastics in the St. Lawrence River, Elliptio complanata, an indigenous and ecologically important freshwater mussel collected from a pristine site, was caged in several effluent-impacted sites and agricultural-impacted basins. Digestive gland and gills were dissected to quantify and characterize microplastics caged organisms. Our findings validate a method for extracting microplastics in freshwater bivalves, without compromising the characterization of polymers and provide information on the ingestion mechanisms of model microplastics. This is also the first assessment of microplastics in freshwater mussels in the St. Lawrence River.

WP177 When ‘natural’ microfibers are not natural: A method for identifying anthropogenic cellulose-based microfibers in different environmental media

J. Adams, S. Athey, University of Toronto / Earth Sciences; L. Erdle, University of Toronto / Department of Ecology & Evolutionary Biology; M.L. Diamond, University of Toronto / Department of Earth Sciences

Microfibers in the environment can be categorized as synthetic, semi-synthetic or natural based on the material of origin. Microfibers classified as ‘natural’ fiber are often assumed to be an environmentally friendly material compared to synthetics, however cellulose textiles can often contain additives and dyes which may influence its persistence and toxicity in the environment. In addition, cellulose fibers have been found in higher concentrations in the environment than synthetics where reported. Characterization of microfibers through spectral analysis, via Raman or FT-IR spectroscopy, can help differentiate between material types. However, different cellulose materials, such as cotton, linen or hemp, all contain varying proportions of cellulose, and spectral analysis techniques lack the ability to differentiate between specific types of cellulose fibers, resulting in a non-specific cellulosic spectral signature. Here we propose a decision-tree method for identifying different cellulose-based fibers using a combination of their spectral signature and morphology. Further, we propose categorization of cotton fibers as ‘anthropogenic’ or ‘unknown origin’ based on the presence of man-made dyes or additives. This method
was tested for cotton by comparing cellulosic-based fibers found in various environmental compartments to cotton fibers released when washing 98-100% cotton textiles. Moreover, the method was successful in identifying cellulosic microfibers across various environmental compartments, including sediment and biota, despite varying extraction techniques. Use of the method has indicated that cotton made up ~85% of cellulosic fibers found across environmental samples, with ~75% of these fibers being of anthropogenic origin. In order to accurately identify sources, evaluate persistence, and assess solutions to the widespread contamination of cellulose fibers, there is a need to be able to accurately identify cellulosic-based microfibers.

**WP178 Development of a non-invasive technique for estimating microplastic ingestion in a large carnivore: Polar bear**

M. Dias, Queen’s University / School of Environmental Studies; J. Provencher, Environment and Climate Change Canada / Canadian Wildlife Service; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology; S.C. Lougheed, P. van Coeverden de Groot, Queen’s University / Department of Biology; D.M. Orihel, Queens University / Department of Biology / School of Environmental Studies

Polar bears (Ursus maritimus) are known to bioaccumulate some of the highest concentrations of contaminants of all Arctic species, yet little is known about ingestion and excretion of microplastics in these large carnivores. A newly published review of polar bear ecotoxicology emphasizes how little knowledge exists on this, but suggests that polar bears are unlikely to ingest considerable amounts of plastics through their prey because they mainly feed on seal blubber. However, as sea ice extent shrinks as the Arctic warms, the polar bear diet could be changing and exposing them to more plastics through ingestion. Considering the ubiquity of plastics in the Arctic, coupled with the possibility of climate-induced shifts in polar bear diet, it is prudent that exposure of polar bears to plastics in the Canadian Arctic be assessed. To our knowledge, there are no peer-reviewed publications that have empirically assessed microplastic exposure in polar bears, nor are there standardized techniques used to assess microplastics in large carnivores using non-invasive sampling. With a fast-changing northern landscape, conducting an assessment of polar bear scat, specifically focused on plastics, would assist in better defining the extent of this issue. In this pilot project, we use hunter-collected scat from Nunavut as a means of evaluating exposure of polar bears to plastics, and generate the first spatially resolved data set on contemporary levels of plastics in polar bear scat in the Canadian Arctic. This project is part of a larger effort called ‘BearWatch’ (http://bearwatch.ca/) that seeks to develop non-invasive, scat-based tools to assess numerous aspects of polar bear health.

**Engineering, Remediation and Restoration**

**WP179 The challenge of measuring activated carbon dose in sediments**

J. Damond, U. Ghosh, University of Maryland, Baltimore County / Chemical, Biochemical, and Environmental Engineering; C. Gilmour, Smithsonian Environmental Research Center

Activated carbon (AC) is used as an amendment for in situ remediation of persistent organic pollutants (POPs) in contaminated sediments. In situ application of AC at a dose of 1-5% by weight has been demonstrated to significantly reduce bio-uptake into aquatic food webs. The most important factors in the success of the technology are the application of the correct dose of AC, uniformity of the dose in the treated area, and persistence of the applied AC dose over time. However, there is no standard method to measure the amount of AC in sediment, and researchers have used a variety of techniques including measures of total organic carbon, loss on ignition, traditional black carbon determination, and a specialized method for AC. In this work, two different carbon treatments (AC and Biochar) were measured for the amount of black carbon after several years of implementation in multiple field pilot studies. Three analytical methods (loss on ignition, total organic carbon, and specialized AC measurement) were compared for the efficacy of measuring the amount of black carbon present in the sediments for several different sites. A comparison of the accuracy and precision of each method and recommendation for adoption is presented in this study. Accurate measurement of AC in sediments as demonstrated in this study is necessary to build confidence in the adoption of in situ remediation of sediments.

**WP180 Naphthalene Desorption Kinetics and Degradation Rates in Activated Carbon**

G. Pannozzo, K. Millerrick, D.D. Reible, Texas Tech University / Civil and Environmental Engineering

Sequestration of hydrophobic organic contaminants (HOCs) in sediments by activated carbon represents an efficient and well-established practice to reduce mobility in the environment, control bioavailability, and minimize biomagnification. Desorption can diminish the effectiveness of the sequestration, impacting risk assessment and design feasibility. The presence of HOCs facilitates the in situ development of indigenous microbial communities able to biodegrade such toxic compounds. Biological degradation coupled to desorption improves the performance of activated carbon placements, as desorbed toxic compounds are transformed into benign products by the growing microorganisms. The objectives of this study are to elucidate desorption and biodegradation kinetics of HOCs sorbed onto activated carbon, and model biodegradation rates in a system mimicking in situ capping or treatment. Batch experiments were prepared using activated carbon, artificial water, and cultures enriched from lake sediments heavily contaminated by HOCs. Sand and sterile microcosms were used as controls. Naphthalene was used as model contaminant because of its high mobility within solid and aqueous phase. Aerobic and anaerobic microcosms were monitored for naphthalene concentrations, and microbial community composition was examined to follow the impact of desorption rate on the indigenous microbial community. Substantial increases in naphthalene mineralization is observed in activated carbon amended systems, even under anaerobic conditions. No significant degradation enhancement was observed in sterile or sand microcosms. Desorption from activated carbon facilitates sustained biodegradation rates, while batch systems containing inert materials such as sand cannot support degradation.

**WP181 Adsorption of Malachite Green from Aqueous Solution of Binary Dye Mixture using Carbonized Weeds (Gliricidia sepium and Chromolaena odorata)**

A.A. Giwa, D.O. Aderibigbe, Ladoke Akintola University of Technology, Ogbomoso / Department of Pure and Applied Chemistry

Rising industrial activities and human population has brought about the introduction of different pollutants into the environment. Water pollution mostly comes from wastewaters containing different types of contaminants, including dyes. The discharge of highly coloured effluents into natural water bodies is aesthetically displeasing, and reduces light penetration thereby affecting biological processes in the aquatic environment. Some dyes are also toxic to humans, and can be resistant to natural biological degradation. Hence, their removal from effluents is of great importance to human and environmental health. Adsorption has been recognized as an efficient wastewater remediation technique. However, the high cost of commercial activated carbon is a concern. As a contribution to the efforts towards getting low-cost but adsorbents, this study investigated the potential of carbons prepared from two weeds, Gliricidia sepium and Chromolaena odorata, for removing dyes from aqueous solutions by adsorption. Leaves of the two weeds collected from and around Ladoke Akintola University of Technology, Ogbomoso, Nigeria were washed with distilled water, dried, ground and carbonized in SX-4-10 England Labsciences Furnace at 300 °C for 20 minutes to obtain the adsorbents. The two adsorbents were characterized using SEM and FTIR; and batch adsorption experiments were conducted to study the influence of different parameters on the adsorption of Malachite green dye from
single and binary systems. The experimental data subjected to different isotherm and kinetic models were better fitted to Freundlich isotherm and Pseudo-second order kinetics models. The adsorption processes were thermodynamically spontaneous (except for the binary system at low temperatures) and increased with increasing temperature (-0.585 to -9.81 kJ/mol); they were endothermic and with increased entropy. The presence of crystal violet had synergistic effect on the adsorption of Malachite green.

**WP182 Selective sorbents for the in situ immobilization of iodine-129 and technetium-99 at the Four-Mile Branch Seepline**

*M. Baker, Savannah River Ecology Laboratory; C. Logan, J.C. Seaman, University of Georgia / Savannah River Ecology Laboratory*

Long-lived isotopes like iodine-129 (129I) and technetium-99 (99Tc) are the primary risk drivers at the Savannah River Site (SRS) and other Department of Energy (DOE) facilities. As high yield fission products, both isotopes are generally found together in nuclear waste materials, and both display very limited adsorption to common soil minerals. On the SRS, facilities in F Area discharged hazardous waste from 1955 through 1988 to a series of unlined seepage basins located up-gradient from Fourmile Branch Stream. Recent studies have demonstrated the difficulty in developing a single remediation strategy that targets multiple contaminants with disparate chemical properties, more specifically 129I and 99Tc. In an effort to address this complex problem, a series of criteria were identified to aid in choosing an appropriate in situ remediation strategy to specifically address 129I and 99Tc based on their disparate chemical properties. Additionally, the remediation strategy must be cost effective, compatible with ongoing remediation efforts and acceptable to stake holders. The primary objective of this study was to evaluate selective sorbents for the in situ immobilization of 129I and 99Tc. Sorbents tested include Porous Iron Composite (PIC) materials (with some that incorporate copper (Cu) and silver (Ag) into the materials), granular activated carbon sorbents impregnated with various metals (i.e., Cu, Ag, Fe), reagent grade Zerovalent Iron (ZVI), and a commercial Fe-oxide based sorbent. A limited set of batch sorption tests were conducted using both 129I and 99Tc and non-radioactive analogues to evaluate the sorption capacity for each of the tests sorbents. Iodine-129 and 99Tc concentrations were chosen to reflect current conditions at the seepline. The samples were repeatedly spiked until the retention capacity was exhausted. After each contaminant exposure period, pH and ORP of each sample was measured, and a small aliquot of the batch solution was analyzed by low-energy gamma analysis or liquid scintillation counting (LSC). Samples were analyzed to evaluate the fate of various nitrogen species that occur within the plume. Trends with respect to batch pH, ORP and nitrogen speciation were used to test whether the non-rad batch tests were directly comparable to those using 129I and 99Tc.

**WP183 Biosorption of cadmium from aqueous solution using Cunninghamamella bertholletiae isolated from soil**

*C. Ezema, University Of Calabar / Pure and Applied Chemistry*

Heavy metals discharge from industrial effluent of different industries has become a serious environmental problem. Cadmium (Cd) is one of the most deleterious trace heavy metals to plants and animals. The objective of this study was to evaluate the utilization low-cost biomass of Cunninghamamella bertholletiae in the removal of Cd2+ from wastewater. In this investigation, the performance of C. bertholletiae biomass was checked at different biosorbent doses, pH, temperature, contact time and agitation speed were checked. Four isotherm models were selected to fit the experimental data, namely Langmuir, Freundlich, Sips and Redlich–Peterson isotherm models. Using the expression \( \Delta G = RT \ln k \), the spontaneity of the process was evaluated. The Cd2+ removal was optimal (absorptive capacity (Qe) of the biosorbent was found to be 91.3) at pH 4.2, temperature =350C, biosorbent dose=0.35g, contact time=20 min, and agitation speed=140rpm. The biosorption of Cd2+ was estimated using Freundlich isotherm (n=1.8; KF=3.27; R2 = 0.911) and was thermodynamically feasible (\( \Delta G_0 = -45.2 \text{mol}^{-1} \)). Thus the reaction was spontaneous and the biosorption process followed pseudo-second order kinetic pattern. The outcome of the current study showed that the dried biomass of C. bertholletiae has potential for removal of Cd2+ from wastewater.

**WP184 Response surface methodology approach for the optimization of removal of Pb2+ from aqueous solution by immobilized cells of Sporobolomyces sp**

*K.O. Chukwu, C.O. Onwosi, University of Nigeria, Nsukka / Department of Microbiology*

Owing to the progressive development in technological and industrial activities, heavy metals are unavoidably introduced into the environment. Since a significant amount of these heavy metals are toxic, it is crucial to find an appropriate solution for their disposal. Microorganisms are reliable option for removing heavy metals from a contaminated environment. The objectives of this study are to assess the effectiveness fungi isolated from waste battery dumpsite in removal of lead from aqueous solution and to optimize the biosorption process using relevant models. The strain, identified as Sporobolomyces sp. immobilized on Careca papaya fibrous network was applied in bioremediation of Pb2+ in aqueous medium. The central composite design (CCD) was used to optimize the biosorption process, with three factors: pH, initial metal concentration, concentration of the biosorbent. The ability of the isolates to remove heavy metals from aqueous solution was evaluated using isotherm (Langmuir and Freundlich), kinetics (Pseudo-first and -second order) and the thermodynamics (AGo). The CCD revealed that the absorptive capacity (Qe = 81.9) can be achieved using the combination of the following factors: pH = 4.5; initial cadmium concentration= 141.9mg/L and bioborbent dose = 0.2g. The biosorption of Pb2+ was estimated using Langmuir isotherm (qmax = 144.24; KL = 0.04; R2 = 0.962) and was thermodynamically feasible at high temperature (AGo = +79.69 Jmol-1). The biosorption followed pseudo-second order kinetics. In conclusion, the isolate from waste battery dumpsite has potential for heavy metal removal from wastewater.

**WP185 Bioremediation of petroleum-polluted soil using rhamnolipid biosurfactant produced by Pseudomonas nitroreducens**

*C.O. Onwosi, University of Nigeria / Department of Microbiology*

Oil pollution has caused untold hardships to the oil-producing nations such as Nigeria. Efforts have been made to find suitable means of controlling this pollution. One of such ways is the use of microbial-derived surfactants. The objective of this study was to produce rhamnolipid biosurfactant using Pseudomonas nitroreducens isolated from petroleum-polluted soil and to compare the produced biosurfactant with chemical surfactants in the remediation of oil pollution. The production of rhamnolipid in laboratory batch shake flask using P. nitroreducens isolated from petroleum contaminated soil was investigated in the present study. The emulsification properties of the rhamnolipid were monitored. The effects of pH, temperature and salt concentration on the emulsification properties of the biosurfactant were monitored. The maximum activity of the rhamnolipid was recorded at pH 5. Increase in salt concentration (2 - 10%) enhanced emulsification activity while variation in temperature from 30-70°C had a slight effect on the emulsification properties of the rhamnolipid. pH and temperature also had effects on the ability of the rhamnolipid biosurfactant to stabilize olive oil and kerosene. The maximum stabilities of - 4.9d-1 and - 5.89 d-1 were recorded at temperature of 60°C and pH 8 respectively for olive oil. And for kerosene, the maximum stabilities of - 4.578 d-1 and - 4.622 d-1 were recorded at pH 5 and temperature 100°C. Also the activity of the rhamnolipid was compared with other chemical findings show that the rhamnolipid can be utilized in both petroleum and industrial (oil mill) wastewater remediation.
WP186 Identification of genes involved in per- and poly-fluoroalkyl substance metabolism in the soil bacterium, Gordonia sp. NB4-1Y

E.M. Bottos, Thompson Rivers University / Biological Sciences; E. Alshabib, University of Regina; D. Shaw, Thomson Rivers University; B.M. McAmmond, Thompson Rivers University / Biological Sciences; D.M. Suchan, A. Sharma, A.D. Cameron, University of Regina; J. Van Hamme, Thompson Rivers University / Biological Sciences

To date, perfluoroalkyl and polyfluoroalkyl substance (PFAS) biodegradation pathways have been inferred by studying mass loads in sewage treatment plants, or determined experimentally with in vitro studies examining PFAS biotransformations using mixed sewage inocula, sediment in microcosms, or in mammalian cell cultures, and extracts. While these studies are valuable, developing a deep understanding of the biochemical machinery driving biological PFAS biotransformations in the environment demands detailed examination of the specific genes and proteins involved. Building on pathways elucidated for fluoroelotolomer sulfonamidooalkyl betaine (6:2 FTAB) and 6:2 fluorotelomer sulfonate (6:2 FTSA) metabolism by the soil bacterium, Gordonia sp. NB4-1Y, the present study compared gene expression profiles of NB4-1Y exploiting either 6:2 FTAB, 6:2 FTSA, octane sulfonate and magnesium sulfate as the primary source of sulfur for growth. High-throughput sequencing of mRNA from exponentially growing NB4-1Y allowed for the identification of 2 nitrotolriacetate monoxygenase genes (ntaA) as being differentially expressed on exposure to 6:2 FTSA, enzymes which are hypothesized to catalyze 6:2 FTSA desulfonation, a novel activity for this enzyme class. Other genes that were observed to be differentially expressed include: 4 genes putatively involved in C-N bond cleavage in 6:2 FTAB; 4 genes putatively involved in dehalogenation and acetyl-CoA addition to the fluorinated alkane backbones of 6:2 FTAB and FTSA; 17 stress response genes; and 8 genes related to sulfur starvation. Of 14 genes annotated as taurine dioxygenase (tauD), alkane sulfonate monoxygenase (ssuD) or nitrotolriacetate monoxygenase (ntaA), 4 were upregulated on 6:2 FTSA, 6:2 FTAB and octane sulfonate, 6 were upregulated on 6:2 FTSA and 6:2 FTAB, 1 was upregulated on 6:2 FTSA, and 3 were not expressed under any condition. In combination with proteomic analyses, genes of interest are being cloned and expressed to allow for identification of structural features that allow the enzymes to interact with PFAS breakdown products. This work is improving understanding of the molecular mechanisms of PFAS metabolism and will allow for the development of site assessment tools to inform remediation practitioners of the biological potential for PFAS removal, thus guiding treatment decision making processes.

WP187 Biochar reduces the toxic effects of imidacloprid to Eisenia fetida

N.W. Nyoka, P. Voua Otomo, University of the Free State / Zoology and Entomology

The effects were assessed by introducing E. fetida biochar amendment on the toxicity of imidacloprid to life cycle parameters and biomarker responses of an oligochaete species, Eisenia fetida. The effects were assessed by introducing E. fetida in non-amended soil and soil amended with 10% biochar, spiked with 0, 1, 3, 3.5, 4, 6 and 4 mg imidacloprid/kg for 28 days. The LC50 value of 5.4 mg/kg was only computed in the non-amended soil yet not for biochar amended soil because of insignificant mortality. Moreover, EC50 of 1.83 mg/kg for no-amended and 1.96 mg/kg for amended soil was obtained. Significant weight loss was observed at two highest treatments for non-amended soil and only at the highest treatment for amended soil. CAT activity decreased significantly at two highest concentrations of non-amended soil yet in the amended soil a significant increase was observed at two highest concentrations. In all non-amended treatments, there was a significant AChE inhibition while lower inhibition percentages were observed in biochar amended soil. Nevertheless, more studies would be needed to optimize the easing effects of biochar on the toxicity of these chemicals.

WP188 Upgrading biochar via co-disposal of agricultural biomass and polyethylene terephthalate wastes

S. Oh, University of Ulsan / Department of Civil and Environmental Engineering; T. Seo, University of Ulsan / Environmental Engineering

Spent polyethylene terephthalate (PETE) bottles were collected and co-pyrolyzed with rice straw (RS) to examine the characteristics and performance of biochar as a sorbent for various types of USEPA priority pollutants, including 2,4-dinitrotoluene (DNT), 2,4-dichlorophenol (DCP), Pb, chrome (CrO42-), and selenium (SeO42-). During sorption of contaminants to PETE/RS-derived biochar, PETE residues from pyrolysis, pH, and pyrolysis temperature greatly affect the sorption of contaminants. Depending on the types of contaminants and experimental conditions, co-pyrolysis of PETE and RS may enhance the sorption of contaminants through different sorption mechanisms, including hydrophobicity, electrostatic force, ion exchange, surface complexation, and surface precipitation. Unlike other contaminants, selenium was reductively transformed by delocalized electrons from graphic structure in biochar. Our results strongly suggest that co-pyrolysis of PETE and agricultural wastes may be favorable to enhance the properties of biochar. In addition to syn-gas and bio-oil from the co-pyrolysis, biochar may be a valuable by-product for commercial use.

WP189 Enhanced phytoremediation of industrial waste

J.O. Anyansi, University of South Africa / Environmental Sciences

The study entails an isolation of Bacterial endophyte from plant growing around a crude oil sludge dam. Based on morphological characterisation, gram reactions and 16S rDNA sequence analysis, the isolate was identified as Bacillus safensis strain CS4. Following the tests on the abiotic effects as well as the initial concentration of perylene on growth and degradation efficiency of the strain, a total degradation percentage of 87 % was observed from the initial concentration of 30 mg/l for one week. Analysis of the degradation products of perylene using GC-MS/MS, indicated a shift from the previously degradation product of other bacterial endophytes showing that the strain provided a new pathway for PAH degradation. In order to evaluate the influence of a polycyclic hydrocarbon transforming ability of the bacterial strain on the phytoremediation of petroleum aromatic hydrocarbon (PAH), B safensis CS4 was inoculated into Chromolaena odorata plants. The plants were grown for 16 weeks with or without pyrene, chrysene, and perylene (500 mg/kg soil in each 1L pot) in non-sterile peat medium. Plants inoculated with the strain CS4 were much tolerant towards the phytotoxic effects of PAHs, in terms of biomass index, leaves and stem dry weight. Although the presence of plants acted as the main effective treatment for PAH dissipation (72-89%), the inoculum with the strain lead to the highest PAH removal (up to 91%). Uninoculated plant control planted in the contaminated soil was susceptible to the phytotoxicity of the contaminants in the parameters tested. The study therefore presented the strain as a suitable plant endophyte for enhanced phytoremediation of industrial waste.

WP190 Phytoextraction Efficiency and Effects of Ascorbic Acid on the Tolerance Mechanism of Water Hyacinth (Eichhornia crassipes) in a Non-Hypotonic Medium

R.A. Shittu, O.T. Aladesanmi, Obafemi Awolowo University / Institute of Ecology and Environmental studies

The mean concentration of Cd and Mn in the root of E. crassipes were significantly (p < 0.05) higher than in the shoot across all the treatments. The bioconcentration factors for Cd and Mn were higher than 1000 with ascorbic acid treated groups having the highest values. The translocation factor values for Cd and Mn were lower than 1 across all treatment which shows that the metals were not mobile. Antioxidant enzyme activities in the Cd treated plants were enhance while a little reduction was observed for
manganese treated plants. The plants were collected from Oranyin River, Okitipupa Local Government Area of Ondo State, thoroughly rinsed under running bore-hole water (to remove dirt, sludge, and other debris) and acclimatized in plastic container of 7 L capacity with bore-hole water containing heavy metal concentrations at 0, 5.0, 10.0, 20.0, 30.0 and 40.0 mg/L for CdCl2 and 0, 5.0, 10.0, 15.0, 20.0 and 25.0 mg/L for MnCl2, for two weeks. The experiment was of two types: with and without optimization with ascorbic acid in triplicate which gives a total of 72 replications. Cadmium and Manganese concentrations in the root and shoot were measured using Buck Scientific Atomic Absorption Spectrophotometer.

Bio-concentration, Bio-translocation factors and the residual activities of selected antioxidant enzymes were determined. A major water pollutant of utmost concern is heavy metal and the phytoextraction potential of some macrophytes in heavy metals-polluted environment is based not only on their ability to uptake, translocate and accumulate metals but also on ability to mitigate toxicity. Most phyto remediation studies on aquatic plants have been carried out in a hypotonic solution. The phytoremediation potential and effects of ascorbic acid on antioxidant enzyme induction in Water hyacinth plant (Eichhornia crassipes) cultivated in a non-hypotonic medium, was investigated in this study.

WP191 Does gypsum enhance the pesticide mitigation ability of three aquatic plant species?

M. Moore, USDA-ARS / Water Quality and Ecology; M.A. Locke, USDA-ARS National Sedimentation Laboratory / Water Quality and Ecology Research Unit

Agriculture is heavily scrutinized because of potential pesticide runoff following irrigation or storm events. These potential contaminants can have deleterious effects on aquatic systems receiving agricultural drainage. While no “silver bullet” management practice exists to functionally remediate all agricultural-derived contaminants, combinations of practices are likely the industry’s best option to reduce agriculture’s contribution to global water contamination. To this end, twelve, 379 L mesocosms (1.32 m x 0.70 m x 0.66 m) were constructed by layering 16 cm of Lexington silt loam atop a base of 22 cm of washed sand. Three mesocosms (each) were planted with monocultures of either Leersia oryzoides L., Typha latifolia L., or Spartanium americanum Nutt. (n=9), while three mesocosms were left unvegetated to serve as controls. Gypsum (167 g) was added to each individual mesocosm to simulate a recommended field application (reduced for scale). Water amended with the herbicides diuron and glyphosate, as well as the insecticide diazinon (targeted exposures of 60 µg/L, 10 µg/L, and 1 mg/L, respectively) was pumped through each mesocosm using a metered piston pump to deliver an 8 h retention time for each system. After the 8 h exposure, pesticide-amended water ceased, and the system was allowed to sit for 40 h. Approximately 48 h following the original pesticide amendment initiation, the system was flushed with unamended water for another 8 h retention time to simulate effects of system flushing. No significant differences existed between the three plant species and unvegetated control when examining overall retention capacity of the systems for each of the three pesticides. For diuron, overall mitigation ranged from 56-65%, while diazinon mitigation was slightly higher (65-71%). Glyphosate overall mitigation was lowest, ranging from 45-56%. Control mesocosms lost significantly more glyphosate mass during the flush period than vegetated mesocosms. Based on the current results, gypsum amendments do not appear to enhance plants’ abilities to mitigate diverse pesticides in runoff water.

WP192 Short and long term efficacy of bioretention at sequestering PCBs in stormwater

R.A. Jack, King County / Department of Natural Resources and Parks

Stormwater has been identified as a significant ongoing source of PCBs to numerous Washington State waterbodies including Lake Washington, the Duwamish River, and the Spokane River. These loads have lead to 14 fish advisories; many recommending no consumption at all. Western Washington Municipal Stormwater Permits require the use of Low Impact Development (LID) where feasible and bioretention is a commonly utilized LID best management practice (BMP) in Western Washington. Bioretention is considered very effective at PCBs removal, but little is known about the longer-term retention rates of PCBs captured by this BMP. For Washington State stormwater design purposes, the default bioretention soil mixture (BSM) is 60% sand, 40% compost. This study used 208 L barrel mesocosms with both BSM alone and BSM plus plant treatments, each replicated three times. Mesocosms were dosed with high-traffic highway runoff for two years. The ultimate objective was to better understand how well default BSM captures and retains PCBs across seasons over a two-year period. The project addressed the following questions: 1. What is the PCB removal (capture) rate for BSM by storm, and does it vary by congener? a. Does newly installed default BSM perform differently than older BSM? 2. What is the wet season PCB sequestration (retention over multiple storm events) in the default BSM, and does this vary by congener? a. Compare sequestered mass of PCBs with estimated stormwater loads. 3. What is the PCB retention in default BSM during the dry season, and does it vary by congener? Because the chemical properties of PCBs vary by congener, PCB losses from the mesocosms were evaluated on both an individual congener basis, as well as total PCBs (sum of detected congeners). The congener-specific mass balance provides a conceptual model of PCB congener behavior in mesocosm bioretention cells, with and without plants. Combined, the conceptual model and mass balance describe the potential effectiveness of Western Washington bioretention cells over time to reduce PCB loadings to receiving water bodies. Given current large investments in stormwater infrastructure, it is important to ensure bioretention BMPs effectively sequester PCBs to reduce their circulation in the environment.

WP193 Biochemical analyses and microbial community dynamics in model constructed wetlands

S.M. Harmon, University of South Carolina, Aiken / Biology and Geology; M.R. Christianson, W. Brison, J. Yates, University of South Carolina, Aiken

Previous research has demonstrated that constructed wetlands can enhance remediation of metals toxicity through a combination of biochemical mechanisms. Organic matter derived from plant root exudates and detritus function to make divalent metals biologically unavailable by forming complexes with metals to produce molecules too large to cross cell membranes. Furthermore, sulfide, produced by sulfate-reducing bacteria (SRB) during the oxidation of organic molecules, will also complex with divalent metal ions, which are precipitated and sequestered in the sediment layer. The objective of this project was to use model constructed wetlands to compare vegetation species for their ability to produce dissolved organic material and support SRB. This model used three species of hydrophytes, Canva x generalis, Pontederia cordata, and Carex stricta, arranged in a 12-tank model system. The system was designed with three replicates of each plant type, and three non-vegetated controls. Porewater extracted from tanks was routinely monitored for sulfate/sulfide, total organic carbon, and nutrients. Microbial DNA was extracted from the anoxic sediment layer using a MioBio Powersoil kit. The abundance of the SRB, Desulfovibrio vulgaris, was determined by qPCR using primers for the dsrA (dissimilatory sulfite reductase) gene. The abundance of Desulfovibrio desulfuricans, a SRB known for its ability to methylate mercury in wetland environments was determined using qPCR. The composition of microbial communities was evaluated using both phospholipid fatty acid analysis (PLFA) and 16S rRNA sequencing. The qPCR results indicated distinct differences between vegetated treatments versus controls, as well as differences between vegetation types. This was reflected by the amount of sulfide produced and the abundance of D. vulgaris. The microbial communities were equally diverse; however, differences in community structure were detected.
WP194 Influence of a Restored Urban Wetland on Nutrient Retention and Cycling: Preliminary Trends After Three Years of Enhanced Monitoring

M.C. Ciarlo, K. Cerny-Chipman, M. Powell, T. King, M. Durbano, EA Engineering, Science, and Technology, Inc., PBC

The 6.7-acre McDonogh Road wetland restoration on Scotts Level Branch in Randallstown, Maryland was completed in 2014, with ongoing post-construction mitigation monitoring since that time. In 2016, enhanced monitoring was initiated in addition to mitigation monitoring. The objectives of the enhanced monitoring were to 1) provide supplemental data on the functionality of the site for wildlife and wildlife habitat; 2) to determine if nutrient cycling in the restored wetland was increasing toward levels found in mature wetlands; and 3) to assess the site functioning in nutrient capture and retention. The three-year study included nutrient concentration sampling in sediment and plant tissue. Sediment and tissue samples were collected from the McDonogh Road site and upstream and downstream reference sites in mature forested wetlands. Samples were collected twice per year in May and August. Tissue and sediment data were analyzed using multifactor analysis of variance (ANOVA) and multiple comparisons to assess trends in nutrient development at the McDonogh Road restoration site in comparison with both upstream and downstream reference sites. Data were also assessed to determine trends across years and due to seasonality. Initial trends in nutrient concentrations in sediment and tissue show that the McDonogh Road restoration site is similar to reference sites for several key nutrients, including total organic carbon, bulk density, and phosphorus. Total Kjeldahl nitrogen concentrations in sediment appear to be increasing at the restoration site, but levels were lower than at the reference sites. Many parameters of wetland nutrient cycling can take years to develop to concentrations found in natural wetlands, but initial monitoring suggests that the site is performing several wetland functions and developing nutrient cycling. Continued monitoring of wildlife, plant tissue, and sediments with more replicates at less frequent time intervals is recommended to provide more statistically powerful data that still continues to provide valuable information on nutrient cycling development and increased nutrient capture.

WP195 In situ evaluation of using clean dredged material as an alternative to clean sand for enhanced monitored natural recovery

G.H. Rosen, SPAWAR Systems Center, San Diego / Energy and Environmental Sustainability; I. Rivera-Duarte, SPAWAR Systems Center, Pacific; J. Carilli, Naval Information Warfare Center, Pacific; J.M. Guerrero, Space and Naval Warfare Systems Command / Energy & Environmental Sustainability Branch; M. Calvin, Naval Information Warfare Center, Pacific / Energy and Environmental Sustainability; D.W. Moore, US Army Corps of Engineers / Environmental Laboratory; J.M. Conder, M. Jalalizadeh, M. Vanderkooy, Geosyntec Consultants; R. Adams, Loyola Marymount University / Civil Engineering & Environmental Science; B. Chadwick, Coastal Monitoring Associates / Environmental Sciences; K. Markillie, Naval Facilities Engineering Command (NAVFAC), Hawaii

Thin layer clean sand placement has shown merit towards Enhanced Monitored Natural Recovery (EMNR) as an alternative to dredging at low to moderately contaminated sediment sites. The use of uncontaminated natural sediment including clean dredged material, referred to here as sediment EMNR (sEMNR), allows uncontaminated sediment with a natural level of binding capacity (primarily associated with organic carbon and fines) to sequester contaminants, and further enhance recovery when compared with traditional EMNR. This study explored the use of locally available clean dredged material at a remote site as thin cover, in comparison with other increasingly common sediment remedies, at a mesocosm scale using field-deployed Remedy and Recontamination Assessment (RARA) arrays (SERDP ER-2537). The arrays provided a site-specific, direct measurement of performance of a range of remedies (activated carbon, two sources of clean dredged material, clean sand, control) while providing increased realism compared to laboratory treatability studies and reduced costs and complexity compared to pilot studies. The arrays were placed at a site in Pearl Harbor that is moderately contaminated with PCBs and metals and may be subject to EMNR following thin layer capping. Lines of evidence included bulk sediment chemistry, passive sampler/mowerate and invertebrate bioaccumulation assessment, benthic community recolonization, and potential recontamination from upstream sources based on sediment trap characterization, and other tools. All sediment remedies evaluated exhibited significant reduction of contaminants of concern relative to the native sediment for nearly all lines of evidence, with reductions generally a factor of 2-5 or more, while also meeting preliminary remediation goals. Statistically significant reductions with respect to bioavailability measures were reliably observed at 2- and 10-month monitoring periods for all treatments, with dredged material performing nearly as well as activated carbon in the short-term. Sediment trap material and 10-month surface sediment chemistry showed lower PCB and metal concentrations, suggesting that recontamination risk was low. These results suggest that clean dredged material is a viable, and potentially better, alternative to clean sand for EMNR applications, especially at sites where clean sand is not economically feasible, and where long-term storage of clean dredged material presents site-specific challenges.

WP196 Incorporating Unique Remedial Design Features to Facilitate Community and Stakeholder Acceptance of Bank Remediation along the South River (Virginia)

C. Dixon, D. Kennedy, AECOM; J. Collins, AECOM / DCS Remediation; M.R. Liberati, Corteva / Environmental Remediation

Historically released mercury (Hg) from a textile manufacturing facility (Site) has accumulated on and adjacent to some bank areas of the South River, Virginia. Introduction of legacy Hg impacted soils to the South River through bank erosion is the most significant source of Hg loading to the system. Phase 1 Interim Measures are being conducted through a phased adaptive management approach with the objective of reducing or eliminating this source of loading to the river. The strategy is to progress from upstream to downstream, addressing areas of highest loadings in the first two river miles downstream of the Site; lessons-learned from each successive project are incorporated into the next project as appropriate. This phase of the program includes stabilization of approximately 6,000 linear feet of eroding riverbanks across several bank management areas (BMAs) with both public and private land ownership. The Shiloh Baptist Church BMA is the fourth Interim Measure project to be implemented in Phase 1. Due to its location and stakeholder preferences, several unique design features are being incorporated into the design to achieve remedial action objectives and gain community acceptance. Open communication with multiple stakeholder groups during the remedial design process identified several factors that were considered and accommodated in the final design. Additionally, lessons learned from previous Phase 1 Interim Measures were incorporated into the design and construction of this BMA to expedite construction, thereby reducing disruption to local stakeholders. This presentation will focus on progression of the unique design features for the Phase 1 IMs at Shiloh Baptist Church BMA, and discuss how these features facilitated acceptance by key stakeholders.

WP197 PCB degradation rates in soil: Results from a semi-field rhizoremediation experiment

F. Terzaghi, University of Insubria; G. Raspa, Sapienza University of Rome / Department of Chemical Engineering Materials and Environment; E. Zanardini, C. Morosini, University of Insubria / DSAT; F. Mapelli, University of Milan; L. Vergani, University of Milan / Department of Food, Environmental and Nutritional Sciences; S. Borin, University of Milan / DeFENS; S. Armiraglio, Municipality of Brescia; V.M. Sale, S. Anelli, P. Iavazzo, P. Nastasio, ERSAF; A. Di Guardo, University of Insubria / Department of Science and High Technology

In the last two decades there has been a growing interest in bioremediation technologies which use plants and microorganisms to degrade organic chemicals such as PCB in contaminated soils (rhizoremediation). Different studies have been conducted to investigate the potential of
WP198 PCDD/Fs degradation rates in soil: Results from a semi-field rhizoremediation experiment

E. Terzaghi, University of Insubria (Como) / Department of Science and High Technology; E. Zanardini, University of Insubria / DISAT; G. Raspa, Sapienza University of Rome / Department of Chemical Engineering Materials and Environment; C. Morosini, University of Insubria / DSAT; F. Mapelli, University of Milan; L. Vergani, University of Milan / Department of Food, Environmental and Nutritional Sciences; S. Borin, University of Milan / DeFENS; S. Armiraglio, Municipality of Brescia / Museum of Natural Sciences; V.M. Sale, S. Anelli, P. Iavazzo, P. Nastasio, ERSAF; A. Di Guardo, University of Insubria / Department of Science and High Technology

In the last two decades there has been a growing interest in bioremediation technologies which use plants and microorganisms to degrade organic chemicals such as Polychlorinated Biphenyls (PCBs) and Dioxins and Furans (PCDD/Fs) in contaminated sites. These techniques represent a good alternative to traditional remediation technologies, being cheaper, not disruptive and more suitable for large contaminated areas. Different studies have been conducted to investigate the potential of plant-microbe interactions in the remediation of organic chemical contaminated soils with respect to natural attenuation, providing useful data such as chemical degradation rates (Kd) or half lives (HL). Such a type of data can be used to predict soil concentration temporal trend, as well as the time needed to achieve natural attenuation considering three different areas characterized by a high spatial variability of PCB and PCDD/Fs concentrations. Geostatistical techniques were used to build up remediation time maps for the three different areas. The aims were to: 1) couple a rhizoremediation half-live dataset to spatially variable concentration data, 2) evaluate the effectiveness of rhizoremediation when a complex contamination gradient is present, 3) compare the influence of natural attenuation vs. plant/microbe interactions on remediation time. Moreover, it showed that when a complex contamination gradient (spatial variability of concentrations, contaminant mixture, etc.) is present, rhizoremediation must be accurately implemented and fine-tuned (in terms of species to be selected, their density, etc) to account for effective remediation.

WP200 Sudbury, Ontario, Canada: 40+ Years of Healing a Smelter-Impacted Landscape through Creating Novel Functional Ecosystems

P. Beckett, Laurentian University / Biology; G. Spiers, Laurentian University / School of the Environment

Sudbury houses major nickel mining and smelter complexes. The impacts of sulphur gases from roast yards before 1928 through to the more modern smelter operations emitting sulphur gases and metal particulates created a barren landscape of ca 17000 ha and an additional 64000 ha of stunted forest. The accumulation of bioavailable and potentially toxic metal levels in the acid surface soils, accompanied by soil erosion, lack of organic matter and soil nutrient depletion, impeded natural vegetation recovery. The requirement for reduction of emissions (now 95%) from the largest smelter complex led to the construction of the 381 m Superstack employing gas and particle-capture technologies.

The stage was set for an assisted landscape recovery program. Over the past forty plus years the Sudbury Regreening Story, based on effective interaction between community, government, academia and industry, describes the regional transformational program now recognized globally as a model to emulate. The Sudbury Protocol for technogenic barren landscape restoration has evolved from regreening activities that involved application of dolomitic limestone, fertilizer, seeding of agricultural grasses, legumes and planting of tree seedling to a more complete biodiverse restoration strategy.using over 80 species. By 2018, 3478 ha had received soil amelioration and ca 10 million trees and shrubs had been planted for approximately $32.7 million while employing over 4775 individuals. The outcome of the Regreening Program is a new image for the city and environs which has helped to attract new...
Activated persulfate is a strong oxidant with the potential to degrade recalcitrant petroleum hydrocarbons (PHCs). Thermally activated persulfate (TAP) is gaining popularity as it does not require additional reagents and is most efficient as compared to other activation methods. Since PHCs can be highly sorbed to soil and desorption is a slow process, bioremediation following TAP treatment may be suitable to degrade residual PHCs that did not react with persulfate. Sulfate, generated after TAP oxidation of organics, can serve as a terminal electron acceptor and promote biodegradation under sulfate reducing conditions. However, the impact of TAP on the microbial community and activity has not been intensively studied. The partial oxidation products of PHCs after TAP treatment are not well understood. In this study, we conduct a combined treatment of TAP and biodegradation to remove PHCs. We use naphthalene (Nap) and phenanthrene (Phe) as the model compounds, as they are frequently present at high concentrations at PHC-contaminated sites, relatively recalcitrant to remediation, and catalogued as potential carcinogens. In our tests, persulfate concentrations are measured by a spectrophotometric method, and the concentrations of Nap and Phe are quantified by a headspace solid-phase microextraction method using a gas chromatography equipped with a flame ionization detector. In the first phase with solely TAP in batch assays, we determine the dosages of persulfate at various temperatures that lead to incomplete oxidation of Nap and Phe for later combined treatment, and assess the partial oxidation products of Phe and Nap by a gas chromatography-mass spectrometry. In the second phase, we include aqueous cultures in batch assays with known capability to degrade benzene or Nap under sulfate reducing conditions. We evaluate the overall removals of Nap and Phe, the bio-elimination of the products from partial oxidation by TAP, and the influence of TAP on organisms by running quantitatively polymerase chain reactions targeting the universal 16S rRNA genes and specific genes. In the last stage, we introduce synthetic soil to include the sorption phase in batch assays and columns to study the impact of TAP on microorganisms and the overall removals of Nap and Phe. Our study will improve the understandings of the effects of TAP on indigenous organisms and will provide design guidelines for application of TAP for remediation of PHC-contaminated sites.

Fate, Toxicology or Risk Assessment of Materials of Interest to the Military

WP201 Evaluating the Combined Treatment of Thermally Activated Persulfate and Bioremediation to Remove Petroleum Hydrocarbons

M. Yang, University of Toronto / Department of Civil & Mineral Engineering; E.A. Edwards, University of Toronto / Chemical Engineering; B. Sleep, University of Toronto / Department of Civil and Mineral Engineering

We determined toxicity benchmarks for insensitive munition (IM) compounds 2,4-dinitroanisole (DNAN) and 3-nitro-1,2,4-triazol-5-one (NTO), developed to replace present munitions that contain highly sensitive explosives for future weapons systems. We adapted the earthworm toxicity test with Eisenia andrei (ISO 16387:2004) to determine DNAN and NTO toxicity in Sassafras sandy loam (SSL), a natural soil that has a “very high” qualitative relative bioavailability score for organic chemicals. Studies included exposures to DNAN or NTO individually freshly amended (F-A) or weathered and aged (W-A) in soil for 10 days in a greenhouse. Exposure data were analyzed using best fit regression models to determine IM concentrations producing 20% (EC20) or 50% (EC50) reduction of measurement endpoints compared with controls. Exposure to DNAN in F-A soil yielded EC20 concentrations (mg/kg) of 99, 102, and 112, and EC50 values of 128, 256, and 281 for cocoon production, juvenile production, and adult survival, respectively. The EC20 and EC50 concentrations for NTO in F-A soil were 429 and 596, respectively for cocoon production. Adult survival was not affected up to 2360 mg/kg NTO in SSL soil. Juvenile production was insufficient to determine ECx. Exposure to DNAN and NTO in W-A in SSL soil significantly increased reproduction toxicity. Exposure to DNAN in W-A soil yielded EC20 concentrations (mg/kg) of 55 and 91, and EC50 values of 91 and 67, for cocoon production, juvenile production, respectively. The EC20 and EC50 concentrations for NTO in W-A soil were 145 and 242 mg/kg, respectively for cocoon production. Adult survival was not affected up to 785 mg/kg NTO in SSL soil. Juvenile production was insufficient to determine ECx. Increased toxicity with W-A IM may be attributable to transformation products. Concentrations of the transformation products of DNAN (2-A-4-NAN and 4-A-2-NAN) increased during the test in proportion to soil concentrations of the parent material. Reproduction toxicity benchmarks determined in these studies will be used to develop individual Draft Ecological Soil Screening Levels for DNAN and NTO to fill existing data gaps.

WP202 Reproduction Toxicity of Insensitive Munitions Compounds for Soil Invertebrates

R.G. Kuperman, US Army CCDC Chemical Biological Center / Molecular Toxicology Branch; M. Simini, US Army CCDC Chem Bio Center / Research and Development Center; C. Thoennes, US Army CCDC Chemical Biological Center / Molecular Toxicology Branch; G.R. Lotufo, US Army Corps of Engineers / Environmental Laboratory

We determined reproduction toxicity benchmarks for insensitive munitions (IM) compounds 2,4-dinitroanisole (DNAN) and 3-nitro-1,2,4-triazol-5-one (NTO), developed for future weapons systems to replace present munitions that contain highly sensitive explosives. We designed our studies to meet regulatory requirements for developing Ecological Soil Screening Levels (Eco-SSL) for use in screening-level ecological risk assessment by adapting standardized toxicity test for the soil invertebrates earthworm Eisenia andrei (ISO 11268-2:1998), potworm Enchytraeus crypticus (ISO/16387:2005), and collembolan Folsomia candida (ISO 11267:1998) using exposures in Sassafras sandy loam (SSL). This soil has a “very high” qualitative relative bioavailability score for organic chemicals in natural soils. Studies included exposures to DNAN or NTO individually weathered and aged in soil (alternating wetting-and-drying cycles for 10 days in a greenhouse). Reproduction data were analyzed using best fit regression models to determine IM concentrations producing a specified percent effect (e.g., 20%) on the measurement endpoints. Reproduction of all species tested was affected by exposures to IM compounds in soil with EC20 concentrations (mg/kg) of 55 (cocoon production) and 42 (juvenile production) for earthworms, 16 (juvenile production) for potworms, and 27 (juvenile production) for collembolans. The EC20 concentrations for NTO were 145 (cocoon production) for earthworms, 16 (juvenile production) for potworms, and 63 (juvenile production) for collembolans. Reproduction toxicity benchmarks determined in these studies will be used to develop individual draft Eco-SSLs for DNAN and NTO and to fill the existing data gaps in current knowledge of the potential ecological risks of release of IM compounds into soil.

WP203 Toxicity of Insensitive Munitions Compounds to Earthworms

M. Simini, US Army CCDC Chem Bio Center / Research and Development Center; G.R. Kuperman, C. Thoennes, US Army CCDC Chemical Biological Center / Molecular Toxicology Branch; G.R. Lotufo, US Army Corps of Engineers / Environmental Laboratory

We determined toxicity benchmarks for insensitive munition (IM) compounds 2,4-dinitroanisole (DNAN) and 3-nitro-1,2,4-triazol-5-one (NTO), developed to replace present munitions that contain highly sensitive explosives for future weapons systems. We adapted the earthworm toxicity test with Eisenia andrei (ISO 16387:2004) to determine DNAN and NTO toxicity in Sassafras sandy loam (SSL), a natural soil that has a “very high” qualitative relative bioavailability score for organic chemicals. Studies included exposures to DNAN or NTO individually freshly amended (F-A) or weathered and aged (W-A) in soil for 10 days in a greenhouse. Adult survival and reproduction data were analyzed using best fit regression models to determine IM concentrations producing 20% (EC20) or 50% (EC50) reduction of measurement endpoints compared with controls. Exposure to DNAN in F-A soil yielded EC20 concentrations (mg/kg) of 99, 102, and 112, and EC50 values of 128, 256, and 281 for cocoon production, juvenile production, and adult survival, respectively. The EC20 and EC50 concentrations for NTO in F-A soil were 429 and 596, respectively for cocoon production. Adult survival was not affected up to 2360 mg/kg NTO in SSL soil. Juvenile production was insufficient to determine ECx. Exposure to DNAN and NTO in W-A in SSL soil significantly increased reproduction toxicity. Exposure to DNAN in W-A soil yielded EC20 concentrations (mg/kg) of 55 and 91, and EC50 values of 91 and 67, for cocoon production, juvenile production, respectively. Juvenile production was insufficient to determine ECx. Increased toxicity with W-A IM may be attributable to transformation products. Concentrations of the transformation products of DNAN (2-A-4-NAN and 4-A-2-NAN) increased during the test in proportion to soil concentrations of the parent material. Reproduction toxicity benchmarks determined in these studies will be used to develop individual Draft Ecological Soil Screening Levels for DNAN and NTO to fill existing data gaps.
WP204 Bioaccumulation of Insensitive Munitions in Soil and Aquatic Organisms

G. R. Lotufo, US Army Corps of Engineers / Environmental Laboratory; R. E. Boyd, US Army Engineer Research and Development Center / Environmental Laboratory; A. Harmon, US Army Engineer Research and Development Center; M. Simini, US Army CCDC Chem Bio Center / Research and Development Center; R. G. Kuperman, US Army CCDC Chemical Biological Center / Molecular Toxicology Branch

We investigated the bioaccumulation potential of the insensitive munitions (IMs) 2,4-dinitroanisole (DNAN), 3-nitro-1,2,4-triazol-5-one (NTO) and methyl-nitroguanidine (MeNQ), developed for future weapons systems to replace present munitions that contain sensitive explosives. We exposed the earthworm Eisenia andrei to Sassafras sandy loam (SSL) soil freshly spiked with sublethal concentrations of DNAN or NTO. This soil has a “very high” qualitative relative bioavailability score for organic chemicals in natural soils. Formation of 2- and 4-amino-nitroanisole (2A-4NAN and 4A-2NAN) occurred in spiked soils, but never at concentrations higher than that of DNAN. SumDNAN (sum of 2A-4NAN, 2A-4NAN, and 4A-2NAN) in soil decreased during the exposure period (14 d), more so in the presence of earthworms, likely driven primarily by irreversible binding. SumDNAN body residue in earthworms increased up to day 3 and decreased thereafter. Between days 3 and 14, the decrease in bioaccumulation (73%) was greater than the decrease in the soil concentration (23%) suggesting that irreversible binding may occur in the tissues. At day 14, DNAN accounted for only 45% of SumDNAN, with 2A-4NAN, and 4A-2NAN accounting for 55%. The highest bioaccumulation factor (BAFs: ratio of the tissue to soil concentration), 6.2 kg/kg (dry wt.) was measured at day 3 and the rate of uptake was 2.0 kg/kg/d. The rate of elimination of DNAN in clean soil was fast, 1.49 d-1. The concentration of NTO in spiked soil (initially 800 mg/kg) decrease by 57% during 14 d, likely because of formation of unknown transformation products. NTO accumulated at negligible levels in earthworms (BAF = 0.018 kg/kg dry wt.). Using spiked aqueous medium, low bioconcentration factor (BCF; 0.13 L/kg dry wt.) and extremely fast rate of elimination (2.76 h-1) were determined for NTO in earthworms, as expected considering its low hydrophobicity. MeNQ showed higher potential to bioconcentrate in earthworms and fathead minnows (BCF = 3.9 and 1.1 L/kg dry wt., respectively) and slower rate of elimination (0.40 and 0.34 h-1) compared to NTO, despite having similar low hydrophobicity. DNAN showed relatively low bioaccumulation potential in aquatic invertebrates (BCF = 0.75, 3.0, and 2.9 and 0.75 L/kg for Rana pipens tadpoles, fathead minnows and Hyalella azteca, respectively). As shown previously for conventional munition compounds, IMs have low potential to bioaccumulate in biota from soil or water.

WP205 Multi-species aquatic toxicity of insensitive munitions 1-methyl-3-nitro-1-nitroguanidine

M. Ballentine, US Army Corps of Engineers / ERDC; G. R. Lotufo, US Army Corps of Engineers / Environmental Laboratory; L. May, K. A. Gust, US Army Engineer Research and Development Center / Environmental Laboratory

Due to the unintended detonation of munitions and munition stockpiles that have caused loss of human life, infrastructure, and material, the US Department of Defense (DOD) has a stated goal of replacing traditional munitions with insensitive munitions (IM) that are chemically stable enough to withstand mechanical damage, fire, and impact of projectiles during combat operations. Munitions constituents in soil may undergo weathering, dissolution, and transport with the potential of eventually contaminating surface and groundwater. In addition, aquatic ecosystems may receive environmental inputs of munitions via wastewater from manufacturing plants. To our knowledge, the present study is the first to investigate the toxicity of 1-methyl-3-nitroguanidine (MeNQ) to aquatic vertebrates and invertebrates. Larval Pimephales promelas, Rana pipiens, Chironomus dilutes, Lumbriculus variegatus, Hydra littoralis, Hyalella Azteca, and Daphnia pulex were exposed to MeNQ in a series of acute, subchronic, and chronic bioassays. Mean control survival was 89% or higher for all bioassays, except for the R. pipens 28-d (79%). Overall, survival was high and not different from the control across all treatments, including the highest concentration tested, which ranged from 2,286 to 5,285 mg/L MeNQ. No-observed-effect concentrations (NOECs) and lowest-observable-effect concentrations (LOECs) were experimentally calculated. Sufficient mortality for the calculation of an LC50 of 1,368 mg/L was only achieved in the C. dilutes 10-d bioassay. Sublethal effects on growth were observed for C. dilutes (LOEC = 903 mg/L), H. azteca 10-d (LOEC = 1,098 mg/L) and H. azteca 35-d (LOEC = 1,446 mg/L). Significant sublethal effects on reproduction were also observed for H. azteca 35-d (LOEC = 2,775 mg/L) and D. pulex (LOEC = 174 mg/L). The toxicity of MeNQ observed and reported in this study when compared to nitroguanidine (NQ), a related munitions constituent, and other IM was lower for all species tested. Based on generic hazard categories of the US Fish and Wildlife Service, MeNQ is classified as “relatively harmless.”

WP206 Developmental pathologies associated with persistent organic pollutant exposure in arctic fish living near a formerly used defense site

R. R. Jordan, E. Adams, Northern Arizona University / Biology; C. Parrocha, University of California, Irvine / Pharmaceutical Sciences; A. Gardell, Kenai Peninsula College / Biology; D. Dillon, Northern Arizona University / Biological Sciences; P. K. Miller, Alaska Community Action on Toxics; D. Carpenter, University at Albany-State University of New York / Institute for Health and the Environment; C. L. Buck, F. A. von Hippel, Northern Arizona University / Department of Biological Sciences

Point-source contamination from formerly used defense (FUD) sites across the Arctic are of increasing concern for environmental health. St. Lawrence Island is located off the west coast of mainland Alaska in the Bering Sea and is home to ~1,600 Siberian Yupik residents. During the Cold War, the US military installed two defense sites on the island, including a radar surveillance station on the Northeast Cape. Previous research reports that significant levels of polychlorinated biphenyls (PCBs) remain downstream of the Northeast Cape FUD site. PCBs pose considerable threats to wildlife and human health because of their toxicity coupled with their ability to persist in local environments and within biological systems. This project examined the effects of PCB and other pollutant exposure on developmental pathologies in ninespine stickleback (Pungitius pungitius) living downstream of the Northeast Cape FUD site. Fish were collected from 11 contaminated and three reference sites. Liver, gonad, and thyroid tissue samples were paraffin-embedded, cryosectioned and stained with hematoxylin and eosin. All slides were imaged and analyzed using a Leica DM4500B microscope and LAX software. Histomorphological biomarkers for each tissue were compared between fish from contaminated and reference sites in order to examine differences due to FUD site contamination. Gonadal tissue analysis compared structural development of each sex, including developmental maturity. Thyroid analysis compared follicle morphologies, including shape, size, and number of follicles, as well as colloid depletion and thyrocyte dimensional. The environmental risks can be managed through the implementation of appropriate mitigation or remediation procedures.
which are unfortunately extremely expensive and lengthy. Obtaining precise, unbiased and accurate MR concentrations with soil matrices is therefore critical to adequately assess the environmental impact at stake and properly address the issue, if any. Guidelines for the soil sampling, processing and EM analysis are provided in SW-846 Method 8330b from the U.S. Environmental Protection Agency (EPA). The goal of this project was to better understand the way those guidelines were applied in commercial laboratories. To achieve this goal, samples of known concentrations were prepared by adding EM particles to general purpose sand typical of Canadian RTAs, which was then extracted and analyzed as prescribed by SW-846 EPA method 8330b. To mimic as closely as possible an actual RTA soil, EM were grinded and sieved to particles smaller than 2 mm prior to their dispersion in soil. Significant discrepancies were observed between results and spiked concentrations, due to the ineffective homogenization of solid matrices by the laboratories. The validation of the analytical method was also thought to be faulty, because commercially reference materials available for validation purpose had much lower EM concentrations than actual soil samples. However, validating a method using a reference material having much lower analyte concentrations than actual soil concentration is not suitable, because it may hide the fact that some of the EM present in the soil have reached their concentration limit and are not dissolved during sample processing. The current communications will present an overview of the challenges encountered for the analysis of MR by commercial laboratories as well as the improvements that were made to the analytical method in order to get precise and accurate MR concentrations.

WP208 Development of mitigation methods for minimizing the detonation footprint of munitions

D. Brochu, S. Thiboutot, Defense Research and Development Canada / Department of National Defence

The use of munitions in training leads to the deposition of energetic materials, either during firing or disposal. Some energetic molecules, such as 1,3,5-trinitro-1,3,5-triazinane (RDX), 2,4-dinitrotoluene and ammonium perchlorate (AP) are potentially harmful to the environment and can be dispersed surrounding areas. Those molecules are mobile enough through the soil profile to migrate to groundwater and represent a potential threat to sensitive receptors. This risk is accentuated by new insensitive molecules, designed to resist external stimuli and therefore leaving more residues when disposed of. To better assess this risk, their detonation efficiency has been measured, using a protocol that was developed in order to have replicable results by detonating munitions on pristine snow. The goal was to determine which munitions were the least contaminating. This protocol was applied to representative munitions from the Canadian Armed Forces (CAF) inventory, from 40 mm grenades to 155 mm artillery shells. Results show that various quantities of energetics were dispersed, some of which reaching disturbing levels for insensitive munitions. Some energetic molecules, designed to resist external stimuli and therefore leaving more residues when disposed of. To better assess this risk, their detonation efficiency has been measured, using a protocol that was developed in order to have replicable results by detonating munitions on pristine snow. The goal was to determine which munitions were the least contaminating. This protocol was applied to representative munitions from the Canadian Armed Forces (CAF) inventory, from 40 mm grenades to 155 mm artillery shells. Results show that various quantities of energetics were dispersed, some of which reaching disturbing levels for insensitive munitions. Therefore, mitigation methods were proposed to manage the risk posed by training with munitions, by developing remediation techniques aiming to decrease the environmental impact of training. New explosive ordnance disposal techniques were thus developed and tested on explosives; results show that demilitarization of an explosive using shaped charge greatly minimize their environmental impacts. The goal of this work is to provide the CAF with better tools and methods to decrease their footprint when training, and ultimately to maintain sustainable life-fire training.

WP209 Effect of Munitions on Tadpole Health, Skin Microbiome, and Susceptibility to fungal pathogen, Batrachochytrium dendrobatidis

K.A. Gust, K. Indest, C. Jung, US Army Engineer Research and Development Center / Environmental Laboratory; G.R. Lotufo, US Army Corps of Engineers / Environmental Laboratory; L.D. Burgoon, US Army Engineer Research and Development Center / Environmental Laboratory; S. Everman, Q. Ji, N.D. Barker, Bennett Aerospace, Inc.

This study describes the effects of chemical exposures on both an amphibian host, the leopard frog tadpole (Rana pipiens), and its skin microbiome to gain insights into tadpole health, skin microbiome composition, and susceptibility to the pandemic, extinction-inducing fungal pathogen Batrachochytrium dendrobatidis (Bd). Multiple amphibian species present on US military ranges require active management for range sustainment, thus our study investigated exposures in the larvae (tadpoles), the most sensitive stage of amphibian development, with dose-series exposures to one legacy munition, 2,4,6-trinitrotoluene (TNT), and three new insensitive munitions (IMs): nitroguanidine (NQ), methyl-nitroguanidine (MeNQ), and the IM formulation, IMX-101. The NQ and MeNQ exposures had low toxicity in acute (4d) and chronic (28d) exposures where no mortality was observed for either chemical, even at the highest chronic exposure concentrations of 2,509 and 3,447 mg/L, respectively. IMX-101 elicited mortality with LC50s of 68.1 and 12.5 mg/L in the acute and chronic exposures while the legacy munition, TNT, was by far the most toxic eliciting LC50s of 3.0 and 0.013 mg/L, respectively. None of the chemicals significantly affected tadpole development or developmental rate. Although NQ and MeNQ did not cause mortality, both decreased the alpha-diversity of the tadpole skin microbiome relative to controls, even in the acute exposures where NQ caused significant deviations from controls at 965 mg/L and MeNQ at 5,285 mg/L. IMX-101 significantly decreased alpha-diversity for all acute exposure concentrations (>=10.5 mg/L), as did the TNT exposures (>=1.0 mg/L). RNAseq assays have been completed for all acute chemical exposures in tadpoles with chronic exposures in queue. Differential transcript expression and functional enrichment analyses have begun with the purpose of providing mechanistic insights into metabolic and cell-signaling effects of each chemical exposure. Further, mutual information and frequent item set analyses will be conducted to identify correlations among tadpole and skin microbiome responses to identify potential interactions among host and symbionts. Finally, combinatorial exposures of the munitions and Bd exposures in factorial treatment arrangements have recently been completed to determine if munitions ultimately affect Bd infection rates and will be presented at the SETAC North American Meeting.

WP210 Comparing Site-specific to Literature-based Lead and Polycyclic Aromatic Hydrocarbons Terrestrial Plant Uptake Factors for a Former Firing Range

J. Hedgecock, H. Loso, AECOM / Remediation; S. McKnight, AECOM Environment

Collection of plant tissue from a former skeet range from a variety of silage plants in an agricultural field as well as ruderal vegetation coupled with 3-point composite co-located soil data have allowed for the estimation of site-specific plant uptake factors (PUFs) for selected metals and polycyclic aromatic hydrocarbons (PAHs). Due to a limited dataset, an evaluation of the representativeness of these site-specific PUFs relative to readily available literature-based PUFs was made. In addition, soil properties potentially affecting lead uptake in plants, including pH, cation-exchange capacity, organic carbon, phosphate fertilizer usage on the soils, the presence of other heavy metals, and various other factors that affect microbial activity, could be different at this site from the PUF literature studies. This evaluation also considers any noted differences in estimated PUFs derived from the variety of plants growing on or adjacent to soils impacted by lead pellets and skeet targets associated with a former skeet firing range. The plant data were compared to other research that has suggested that forage grasses do not tend to be hyperaccumulators of lead. Lastly, the lead and PAH PUFs based on plant data at firing ranges will be compared to PUFs developed for sites with different sources of these contaminants in other environmental settings that lack lead pellets and clay targets to assess whether plant PUFs are influenced by the source of lead and PAHs. It is anticipated that the findings will be useful in identifying appropriate lead and PAH PUFs for human and ecological risk assessments where site-specific plant tissue data are not collected.
WP211 Derivation and Assessment of Site-Specific Plant Uptake Factors for Lead and PAHs in Agricultural Plants at a Former Firing Range
H. Losa, J. Hedgecock, AECOM / Remediation; C. Wong, AECOM / Modelling/Statistics Dept.; K. Schwach, AECOM / Environmental Remediation

The presence of lead shot and skeet in soils of a former firing range surrounded by agricultural land prompted the need to collect plant tissue and co-located soil samples to assess the potential for chemical uptake into plant tissue. Samples were collected from a variety of silage plants in an agricultural field with the goal of estimating site-specific plant uptake factors (PUFs) for selected metals and polycyclic aromatic hydrocarbons (PAHs). Depending on the distribution of the plant and co-located soil samples, three different approaches to calculating PUFs were explored: simple linear regression analysis, averaging across co-located sample pairs, and calculating the average and high-end uptake factors from a range of sample pairs. Soil properties potentially affecting uptake of lead and PAHs in plants, including pH, cation-exchange capacity, organic carbon and phosphate fertilizers (particularly for lead) were incorporated into the PUF development process. The presentation will include plots of chemical concentrations in plants and soil to test for a significant functional relationship (e.g., lead concentrations in plants could also be plotted against pH and/or phosphate levels), as appropriate. This type of multivariate statistical approach will be considered if the data are amenable. In order to establish cost-savings, plant samples were not collected within each study area, and the rationale to extrapolate these PUFs to other study areas where only incremental soil sampling data are available will also be presented. Characteristics of each study area considered in this extrapolation process will include lead pellet density and depth, and soil properties such as pH and organic carbon to assess the potential for pellet oxidation. In addition to presenting PUFs for lead and PAHs that may be considered to assess risk at former firing ranges, the outcome of this evaluation may also support the addition of soil amendments as a potential in situ remedial strategy.

Pharmaceuticals in the Environment - Science Innovation and Current Regulatory Developments

WP212 Analytical Method Development for the Quantification of Selected Pharmaceuticals using Liquid Chromatograph-Mass Spectrometer
E.O. Omotola, UKZN / School of Chemistry and Physics; O.S. Olatunji, University of KwaZulu-Natal, Westville / School of Chemistry and Physics

Recent advancement in medical sciences has brought about improved human health. However, this has been accompanied by adverse effects resulting from exposure to continuous discharge of pharmaceuticals from different point sources including households, pharmaceutical industries, clinics/hospitals, agricultural/livestock industries run-offs into the aquatic environment. The detection and quantitation of pharmaceutical compounds in different environmental matrices is still a challenge, due to their extremely low (ng-ug) concentrations and the lack of rapid and sensitive analytical techniques. A number of techniques such as enzyme-linked immunosorbent assay (ELISA), chromatographic, electrophoretic, and electrochemical methods have been explored. These instrumental techniques are limited with respect to their sensitivity (limit of detection). In this study, a liquid chromatograph coupled to mass spectrometer (LC-MS) method was developed and validated for the detection and quantification of seven active pharmaceutical ingredients. The sensitivity achieved for the method allowed for LODs (ng/ul): lamivudine, 0.0459; acetyaminophen, 0.0375; vancomycin, 0.0304; ciprofloxacin, 0.0347; sulphamethoxazole, 0.0240; diclofenac, 0.0949; ivermectin, 0.0343 ng/ul and LOQs (ng/ul) of 0.1531; 0.1249; 0.1013; 0.1157; 0.0799; 0.13162; 0.1142 respectively at a linear range of 0.01 to 1.00 ng/ul. Other ICH validation parameters are also discussed.

WP213 Environmental risk assessment for gene and cell therapy products: Critical issues for clinical trial and market authorisation applications
U. Jenal, Jenal and Partners; J.G. Tell, Merck & Co., Inc. / Global Safety and the Environment

The environmental risk assessment (ERA) forms a significant part of clinical trial and market authorization applications for therapies with drug substances containing or consisting of genetically modified organisms (GMO). An ERA is required regardless of the type of therapy, i.e. in vivo or ex vivo gene therapy, oncotherapy or immune therapy. This presentation addresses the most frequent and tricky questions related to an ERA, drawing from actual experiences with clinical trial and market authorization application processes. In order to prepare a comprehensive and compelling risk assessment document, an ERA should cover all characteristics of the GMO having a potential adverse effect in case of exposure of people other than the treated patients or the environment. Most importantly, a rational has to be given on a) how exposure is avoided due to safe application of the drug substance or b) how negative consequences from exposure are prevented due to safety features of the GMO or through post administration measures. To this end, information will have to be derived from specific data gained from research and development, from manufacturing processes as well as from pre-clinical or clinical trial studies.

WP214 Estimating Critical Environmental Concentrations of Pharmaceuticals: Using Human Therapeutic Concentrations or Mammalian Toxicology Endpoints
A.N. Perking, Eli Lilly and Company; N. Klüver, Helmholtz Centre for Environmental Research - UFZ / Department of Bioanalytical Ecotoxicology; S. Konradi, German Federal Environment Agency UBA

Active pharmaceutical ingredients (APIs) are data-rich molecules in terms of mammalian safety and human efficacy. However, many pharmaceuticals do not have a corresponding dataset regarding environmental risks. In the absence of ecotoxicology data, leveraging the available mammalian data is one way to prioritize the environmental risk potential of APIs. Human therapeutic plasma concentrations of APIs (HtPC) can be used to predict the critical environmental concentration (CEC) at which pharmacological effects may occur in fish. Used in a similar way, plasma concentrations associated with toxicological endpoints in preclinical mammalian toxicity studies (MtoxPC) may provide a better parameter to predict CEC causing toxicological effects in fish. We have developed a refined fish plasma model based on the parameters Dlipw or Dow in order to account for ionization state of APIs. In addition, we evaluated the accuracy of these models to predict plasma concentrations in fish exposed to APIs. Next, we use the plasma model to calculate critical environmental concentrations (CECs) for a suite of APIs with either HtPC or MtoxPC. We compare the predicted CEC values from these two datasets with the experimental ecotoxicity data (LOECs from chronic fish tests). Finally, we discuss its use with APIs of differing mechanisms of action and therapeutic classes and compare factors of the preclinical dataset including species, endpoint used (lowest adverse effect level, change in body weight, mortality), and study length.

WP215 Pharmaceutical Uptake Kinetics In Rainbow Trout From East Canyon Creek, An Effluent-Dominated Stream Influenced By Snowmelt In Park City, Utah, USA
J.L. Sims, Baylor University / Biology; S.R. Burket, M.E. Franco, L. Lovin, K.R. Scarlett, R. Steenbeek, Baylor University / Environmental Science; C. Ashcroft, Carollo Engineers; M. Luers, Snyderville Basin Water Reclamation District; R. Lavado, University of California, Riverside / Institute for Environment and Sustainability; B.W. Brooks, Baylor University / Department of Environmental Science

Whether seasonal instream flow dynamics influence uptake of select pharmaceuticals by fish is not well understood, specifically for urban lotic systems in semi-arid regions with flows influenced by snowmelt. We examined uptake of select pharmaceuticals in rainbow trout (Oncorhynchus mykiss) caged upstream and at incremental distances
downstream (0.15, 1.4, 13 miles) from a municipal effluent discharge to East Canyon Creek in Park City, Utah, USA during summer and fall of 2018. Fish were sampled over 7-d to define uptake kinetics. Water and fish tissues were analyzed via isotope dilution LC-MSMS. Several pharmaceuticals were consistently detected in water, fish tissue and plasma, including carbamazepine, diphenhydramine, diltiazem, and fluoxetine. Pharmaceutical levels in water ranged up to 151 ng/L for carbamazepine, whereas the effluent tracer sucralose was consistently observed at low ug/L levels. During both summer and fall experiments at each of three downstream locations from effluent discharge, rainbow trout rapidly accumulated these pharmaceuticals; tissue levels reached steady state conditions within 24 – 96 hrs. In addition, in situ bioaccumulation factors (BAFs) were calculated for diphenhydramine, diltiazem, and fluoxetine, and compared to model predictions. Such observations are consistent with our recent laboratory bioconcentration studies, which collectively indicate inhalational exposure from water governs rapid pharmaceutical accumulation by fish in inland surface waters.

Furthering Interdisciplinary Urban Groundwater Quality and Urban Sustainability Research

WP217 Anthropological Perspectives on Groundwater Policy in Southeast Michigan
C. Linn, Wayne State University / Anthropology

Drinking water contamination concerns is a growing issue across the country. In Ann Arbor, MI, dioxane plume contamination has been spreading from an industrial site for over 30 years. Recently, 1, 4-dioxane has been detected in the city’s surface water supply and finished drinking water. In addition to dioxane, PFAS contamination is also concerning the city and residents. This project takes a critical look at how citizens and cities are reacting to drinking water contamination concerns amid rampant findings that toxic chemicals exist in finished drinking water. This project is part of a larger research initiative that seeks to combine civil engineering modeling, toxicological testing, and anthropological inquiries into a cohesive project that can allow for holistic understanding of how groundwater contamination spreads, affects human populations, and how cities and citizens respond and manage contamination as it is spreading. Qualitative research methods were used to take a critical look at collective groundwater governance, from the city, state, and citizen-level mechanisms that grew as a response to drinking water contamination concerns and decision-making processes regarding water safety issues in a Southeastern Michigan community. Including anthropological research into broader scientific inquiries allows for a further understanding of how scientific findings are understood and reacted to by the larger community. These findings can aid in tailoring responses and communication efforts by the scientific community, and further illuminate the challenges cities and states face when responding to these problems.

WP218 Characterization of Shallow Groundwater in Detroit: Recovery Park
B. O’Leary, C.J. Miller, Wayne State University / Civil and Environmental Engineering

Groundwater plays a critical role in the vitality of the Great Lakes Basin, supplying drinking water, industrial water supply, cooling water for power generation, and irrigation water for farms in rural areas and landscape in urban areas. It also is interconnected with surface water features, including the lakes, streams, and reservoirs of the region. Therefore, the quality of the groundwater is crucial and has potential economic, health, and social implications for the region. The traditional focus of environmental and health concern, especially in urban areas, has been on surface water rather than groundwater, following the “out of sight, out of mind” mentality. The lack of data on groundwater (especially shallow, near-surface) flow, quality, and transport in urban centers is a threat to the health of the Great Lakes Basin. Urban groundwater movement along with a neighborhood scale urban water budget is currently being evaluated at Recovery Park in Detroit, Michigan. This project, centered at the Recovery Park, will serve as a model for evaluating the urban shallow groundwater movement in Detroit. This model will help develop and evaluate the potential risks posed to urban environments and human health.

WP219 Examining the Toxicity of Environmentally Relevant Concentrations of 1,4-dioxane Across the Lifespan in a Zebrafish Model

C. Akemann, Wayne State University / Anthropology; J. Shields, Wayne State University / Institute of Environmental Health Sciences; Z. Siddiqua, Wayne State University / Pharmaceutical Sciences; A. Wahls, Wayne State University / Civil & Environmental Engineering; D. Potts, Wayne State University / Pharmaceutical Sciences; S. McElmurry, Wayne State University / Civil & Environmental Engineering; T. Baker, Wayne State University / Institute of Environmental Health Sciences

Since the 1960s, a plume of 1,4-dioxane has been spreading through the groundwater underneath Ann Arbor, MI. Though not currently affecting the drinking water of most Ann Arbor residents, the plume is creeping closer to the Huron River, the source of the city’s drinking water. Though 1,4-dioxane is known to cause liver and kidney damage and is potentially carcinogenic, long-term or developmental exposure effects are not yet characterized, and it is unknown if there are transgenerational or reproductive effects. This study examines the effects of environmentally relevant concentrations of 1,4-dioxane using a zebrafish (Danio rerio) model. Zebrafish are an NIH-approved human model organism because of the genetic similarities between zebrafish and humans. Effects of developmental, acute, and long-term and transgenerational exposure will be analyzed through multiple -omic studies such as transcriptomics, as well as through morphologic, behavioral, and reproductive analysis. The results will help fill the gaps in knowledge of adverse health outcomes associated with 1,4-dioxane exposure. Additionally, the results may also give insight to potential effects on aquatic life in the event that the 1,4-dioxane plume reaches the Huron River.

WP220 Novel method for assessing biological effects of volatile organic compound exposure in zebrafish
T. Baker, J. Shields, Wayne State University / Institute of Environmental Health Sciences; Z. Siddiqua, Wayne State University / Pharmaceutical Sciences; S. McElmurry, Wayne State University / Civil & Environmental Engineering; D. Potts, Wayne State University / Pharmaceutical Sciences

Anthropogenic Volatile Organic Compounds (VOCs) have emerged as high priority environmental contaminants due to ubiquitous urban exposure and therefore play a pivotal role in several environmental and health related issues. Urban areas report increased levels of contamination due to industrial exhaust, fuel refineries, vehicle exhaust, and especially groundwater. Residents in urban areas are disproportionately exposed to potential VOC contamination as a result of indoor vapor intrusion, tap water, ingestion of contaminated fish, and ambient outdoor exposure. Inhalation, ingestion, and dermal adsorption of VOCs from indoor and outdoor sources are all routes for human exposure, and at-risk communities are often chronically exposed to complex mixtures of VOCs. A wide variety of adverse health risks have been associated with VOC exposure, which involve respiratory, cardiovascular, renal, hepatic, endocrine, immune, and nervous systems, and include cancer and abnormal birth outcomes. To date, the biggest challenge in characterizing VOC toxicity is the technological limitations that create unsafe and unreliable exposure conditions. In collaborative efforts, we have designed an innovative sealed exposure system for safely containing a VOC and analyzing behavioral changes in aquatic organisms. This novel exposure system utilizes the zebrafish animal model for exposing and evaluating VOC toxicity. Using this model, toxicant-induced behavioral changes, phenotypic abnormalities, and transcriptomic data can be compared to create profiles to not only screen VOCs, but also elucidate health concerns that could potentially translate to humans. Future studies will explore the synergistic effects of VOC mixtures and validate the translatability of these findings to humans.
WP221 Quality Assessment of Groundwater in Lagos State: A Case Study of Amuwo-Odofin/Festac Metropolitan Area
R. Alani, O. Akinrinade, University of Lagos / Department of Chemistry; O.B. Olaifa, University of Lagos; To. Waleola, University of Lagos, Akoka / Chemistry (Environmental Management Unit)

The increase in urbanization and extended industrialization has lead to a serious threat of surface water for drinking purpose in Africa with groundwater now serving as a reliable substitute. Amuwo-odofin/Festac Metropolitan Area (A/FMA) has a number of factors that could possibly affect the integrity of this groundwater sources. Such factors include the surrounding canals which accommodate tributaries and are potential sinks of pollutants that could leach into the aquifer. This study assessed 30 groundwater samples randomly collected from boreholes and hand dug wells in Amuwo-odofin/Festac Metropolitan Area. Physico-chemical parameters comprising pH, conductivity, turbidity, TDS (total dissolved solid), TS (total solid), temperature, total acidity, total alkalinity, Chloride, Hardness, COD (Chemical Oxygen Demand) and DO (Dissolved Oxygen); as well as 7 heavy metals [Iron(Fe), Chromium(Cr), Cadmium(Cd), Zinc(Zn), Manganese(Mn), Copper(Cu) and Lead(Pb)] were determined in each sample. The dominant metals were found in the order: Fe > Cd > Pb. 76.7 % and 60.0 % of the water samples indicated lead and cadmium respectively above the World Health Organization(WHO) regulatory standards - 0.01 mg/L and 0.003 mg/L. Cr, Cu and Mn were all determined very low relative to the health-based guidelines. Zn was not found in any of the samples. The groundwater of Amuwo-odofin/Festac Metropolitan Area (A/FMA) have physico-chemical parameters suitable for drinking purpose. The high level of Pb and Cd mean adequate treatments would be necessary to meet drinking requirement. There is a need for further investigation of the groundwater supply to further understand the pollution sources and trends.

Incorporating New Approach Methodologies to Improve Ecological Risk Assessment

WP222 Semantic Characterization of Adverse Outcome Pathways
R. Wang, US Environmental Protection Agency / Exposure Methods and Measurements Division

An ontology can be viewed as a graph. The semantic similarities among its classes depend on their relative positions in this graph. When the key events (KEs) from adverse outcome pathways (AOPs) are annotated as computable ontology classes, KEs and AOPs can be related to one another semantically. Based on a common integrated ontology encompassing multiple species and a wide range of knowledge domains, this ontology-based semantic mapping (OS-Mapping) approach not only effectively bridges the gap between molecular phenotypes and those at higher levels of biological organization, but also allows an independent assessment of AOPs. OS-Mapping is made possible by a wide variety of ontologies available, abundant phenotypic data from ongoing public phenomics efforts, and years of toxicity studies. To study the applications of OS-Mapping in evaluating existing AOPs and aiding their future development, over 1100 KEs belonging to more than 200 AOPs were annotated into ontology classes. Also included in the study were toxicity responses previously annotated from more than 700 exposure studies of ten chemicals in six vertebrate species. Together, they were assembled into over 200 phenotypic profiles as queries, and compared semantically to themselves, and to more than 37 thousand phenotypic profiles organized by genes, diseases, and biological pathways of human, mouse, and zebrafish by using a Java application developed in-house. Many AOPs appeared to be quite robust, as indicated by the underlying KEs having mutual similarities significantly above background. However, most of the adjacent KE pairs (i.e., KE X biologically upstream leads to KE Y downstream) had similarities of less than 0.2 (range 0-1). Some of the KEs from different AOPs were highly similar to one another, leading to their respective AOPs to become substantially related too. Many AOPs were also mapped to various genes, pathways, and diseases. These findings should help to delineate the biology underlying AOPs and provide some independent evidence for their robustness. Furthermore, semantic characterization of KEs and AOPs will also provide an approach to construct AOP networks complementary to the current reliance on the manually defined KE relationships, and aid the development of additional AOPs in the future.

WP223 Use of co-expression analysis to identify life stage-specific subnetworks in toxicogenomics data from Japanese quail
J. Ewald, Y. Jeon, J. Head, McGill University / Natural Resource Sciences; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; J. Xia, McGill University MacDonald Campus / Institute of Parasitology; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences

Early-life stage (ELS) exposures are an attractive alternative toxicity testing strategy for avian species because of time, cost and ethical advantages compared to adult exposures. Differences in responses to contaminant exposure across life stages may be partially due to changes in the way genes are regulated and how they interact with each other as an organism develops. Thus, understanding the structure of gene interaction networks in ELS and adults may help explain and predict differences in biochemical responses to contaminant exposure between organisms of different life stages. The objective of this study was to compare the topological structure of gene-gene interaction networks across multiple life stages in Japanese quail. The rationale is that understanding which biological pathway networks are more or less conserved across life stages will improve our ability to design effective molecular assays for ELS exposures. First, RNA sequencing data derived from liver tissue of ELS and adult Japanese quail exposed to a medium and high dose of 8 environmental contaminants (n = 100 samples for ELS; n = 96 samples for adult) were generated. Second, co-expression network analysis was used to “discover” the underlying interactions between genes by constructing a correlation-based network for each life stage. This involved computing the pairwise Pearson’s correlation between genes and using hierarchical clustering to find subnetworks of densely connected genes with the “weighted gene co-expression network analysis” (WGCNA) R package. The subnetworks were then annotated with KEGG pathways and GO terms using gene set overrepresentation analysis to investigate their functional relevance. Finally, subnetworks were compared across life stages using three metrics: number of overlapping genes, Jaccard index, and the WGCNA subnetwork conservation score. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

WP224 Toxicity Translation: An emerging theme for modeling to understand adverse effects of chemical exposures on wildlife populations
N. Pollesch, M. Etterson, K. Flynn, US Environmental Protection Agency / ORD NHEERL / Mid-Continent Ecology Division; S. Kadlec, NRC Research Associateship Programs

To understand the potential for adverse effects of chemical exposure on wildlife, researchers and risk assessors must synthesize chemical exposure potential, the resulting acute and chronic effects to individuals, and what those individual-level effects mean for population-level impacts. Toxicity translators are tools developed to address the challenges that arise in this process of understanding the effects of chemical exposures to wildlife populations. This poster describes the toxicity translation process, creates a vision for the conceptual development of toxicity translators, and discusses existing approach to toxicity translation as case studies. This research seeks to define the field of toxicity translation by highlighting the common challenges and approaches used in the toxicity translation process. A benefit of establishing toxicity translation as a well-defined research area will be to determine synergies among efforts and to identify tools and techniques useful to those involved in toxicity translation. Here we start the conversation by providing insight into what
is involved in the toxicity translation process and by introducing the suite of toxicity translators developed and currently under development at the EPA and elsewhere. Special emphasis will be placed on how toxicity translators leverage existing datasets, models, and theoretical approaches. We will also discuss the potential for development of a computational environment for toxicity translation that could support computational linkages between available data sources, exposure models, effect models, and population/community models.

WP225 An Alternative Approach to Fish Acute Toxicity Test
J.R. Rana, M. Kamle, E. Ansari, P. Prabhu, Jai Research Foundation / Ecotoxicology; N. Reddy, Veer Narmad South Gujarat University, Surat / Department of Biosciences

In ecotoxicity testing, acute fish toxicity is mandatory for data requirement. For acute fish toxicity test, mortality is the primary endpoint and it is often hypothesized that fish suffer distress and perhaps pain. Due to this reason acute fish toxicity test is not compatible with most current animal welfare legislation. Fish embryo toxicity test (FET) is one of the most promising alternative approaches to acute fish toxicity test. FET is mandatory test for whole effluent testing in Germany since 2005. It has been also standardized and adopted at the international level but it is yet to be implemented in India. Discussion of its application in environmental assessments on a global level was needed. In order to analyze an alternative to fish acute toxicity test, a comparative study on both fish and fish embryo toxicity was carried out for a total of 9 different industrial effluents, and results were compared to evaluate the correlation between the two data sets. Among the samples collected from three different sites of May, September and January, samples of site 2 and 3 of January were observed very toxic. Toxicity gradient among the sites of three different months were observed as site 2 of January > site 2 of September > site 2 of May > site 3 of January > site 2 of September > site 2 of May > site 1 of January > site 1 of September. Our results indicated that effluents collected from three different site in three different months were very toxic to zebrafish and its embryos at very higher dilutions. The result of acute fish toxicity test and fish embryo toxicity test are more comparable with each other. It can help to prevent the use of adult zebrafish and gives strong evidence for the use of embryos. In this study, it is proved that embryos are more sensitive as compared to adult zebrafish and FET can be used as an alternate to the acute fish toxicity test.

WP226 Investigating the applicability of the Fish Embryo Test (FET) to inform read-across for ecological hazard assessment
A.M. Strobel, Environment and Climate Change Canada / Environmental Assessment Division; J.S. Prindiville, Environment and Climate Change Canada / Ecological Assessment Division; T. Burns, Environment and Climate Change Canada; J.C. Achenbach, M.G. Morash, L.D. Ellis, National Research Council of Canada / Aquatic and Crop Resource Development

The global initiative to improve testing throughput and efficiency has led to the development and validation of new approach methodologies as alternatives to the commonly used regulatory tests for chemical risk assessment. The zebrafish fish embryo toxicity test (FET) and the general and behavioural toxicity test (GBT) are promising methods that have the potential to be used to provide chronic ecological toxicity data for risk assessment. The present study investigates the applicability of the FET and GBT assays to inform read-across for chronic ecological hazard potential between phthalates and structurally similar cyclo-hexane-based plasticizers as a case study. For the FET assay, zebrafish embryos/larvae were exposed to individual chemicals from 6-120 hours post fertilization (hpf) and from 72 - 120 hpf for the GBT assay (n=12 larvae x 3 replicates/concentration). Concentration-response profiles were generated as the definitive test for each substance. As phthalates have hard to test properties and potential stability issues, the exposure concentrations in both the external media and larval tissue were measured by liquid chromatography-high resolution mass spectrometry. Results on lethality, developmental and behavioural effects, as well as the uptake analysis, will be presented in this poster. This study seeks to identify non-traditional lines of evidence to inform read-across approaches in regulatory risk assessment.

WP227 Maternal transfer and toxicity pathways of hexabromocyclododecane (HBCD) in fathead minnow (Pimephales promelas)
S.H. Malala Iruigal Bandaranage, J. Bertucci, University of Saskatchewan / Toxicology Centre; M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre; A.J. Masse, University of Saskatchewan / Toxicology; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

Hexabromocyclododecane (HBCD) is a flame retardant that is banned but is still detected in the aquatic environment and can bioaccumulate in aquatic organisms through the food web. HBCD can be maternally transferred and has been hypothesized to hinder development by way of reactive oxygen species production and apoptosis. However, little is known to date regarding the specific molecular mechanisms that drive the toxicity of HBCD. The purpose of this study is to (1) characterize the dynamics of maternal transfer of HBCD to embryos of fathead minnows (Pimephales promelas) over the course of 49 days, (2) further our current understanding of the specific toxicity pathways of HBCD by identifying key molecular response patterns that may be altered with early-life stage exposure, and (3) link these toxicity pathways with apical outcomes of regulatory relevance. In this study, adult male and female fathead minnows were exposed to HBCD for 49 days via the diet under static renewal conditions, and the resulting eggs were collected on days 0, 7, 14, 21, 28, 35, 42 for HBCD analysis. Eggs collected between 25-49 days were reared-up and the larvae were sampled at 7 and 14 days post-fertilization, and will be subjected to ‘omics (transcriptomics, proteomics, metabolomics) and apical outcomes (meristic parameters, growth, hatching success, histology) analysis, respectively. We predict this research will identify critical biological endpoints and toxicity pathways for HBCD in early-life stages of fathead minnows, which could be utilized to develop a gene expression-based toxicity model to predict apical outcomes. Which can also be applied across different species and chemicals acting through a similar mechanism of action. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

WP228 Quantification of an AOP network for UV radiation by exploratory data analysis and probabilistic modelling
J. Mog, K. Tøllesøen, L. Xie, Y. Song, Norwegian Institute for Water Research (NIVA) / Section for Ecotoxicology and Risk Assessment

In this study, we use a Bayesian network (BN) approach to evaluate, refine and quantify a conceptual AOP (Adverse Outcome Pathway) model, which describes the adverse effect of UV-B radiation. This tentative AOP, which is the first AOP for a non-chemical stressor, is a complex network linking a molecular initiating event (MIE: cellular ROS formation) to an adverse outcome (AO: reduced survival of a crustacean), through seven potential key events (KE). A tentative AOP structure has been developed based on literature studies, and will be evaluated with experimental data. In the experiment, Daphnia individuals were exposed to UV radiation in 6 different dose-rates in the range 0 - 0.4 w/m2. All variables (the MIE, KEs and AO) were measured with minimum three repeated measurements for each dose-rate. The resulting proposed AOP network consists of four potential pathways from the stressor to the adverse outcome. The structure of this AOP network has been assessed by exploratory data analysis (regression trees and generalized additive models). It will be further developed and quantified by BN modelling in three main steps: (1) Evaluation and refinement of the proposed AOP structure: using the structure learning capabilities of BN software to suggest the most important key event relationships (i.e. their causal directions and strengths) based
on correlations in the dataset and refining the AOP model accordingly. (2) Quantification of the refined AOP model; quantifying each selected KER as a conditional probability table based on statistical modelling of the experimental data (e.g., regression analysis of dose-response curves). (3) Sensitivity analysis; ranking the pathways of the AOP network according to the strength of their influence on the adverse outcomes. The approach demonstrated here - combination of expert knowledge, experimental data, exploratory data analysis and probabilistic modelling - is a promising strategy for data-oriented selection of key AOPs and for the identification of knowledge gaps associated with these AOPs. Further development of the AOP can also include extension to population-level adverse outcomes (e.g. abundance) by population modelling.

WP229 Optimizing data requirements for calibration of simplified TK-TD fish survival models to predict effects of pulsed exposure to pesticides
S. Kadlec, NRC Research Associateship Programs; K. Flynn, N. Pollesch, M. Etterson, US Environmental Protection Agency / ORD/NHEERL/ Mid-Continent Ecology Division

The effects of pulsed and time-variable exposures to pesticides may be under- or over-estimated with risk assessment approaches based on standard, constant-exposure toxicity tests. However, calibrating models to robustly predict the effects of fluctuating concentrations may require experimental data that are resource-intensive to gather and are not routinely provided for the EPA's pesticide registration process. Development of simplified toxicokinetic-toxicodynamic (TK-TD) fish survival models for pulsed, time variable exposure to pesticides shows promise for improving environmental realism of risk assessment endpoints, even when only standard toxicity test data are available. Our team has completed a metaanalysis of survival models calibrated with a range of input datasets with varying levels of information-richness. Our goal is to quantify the increase in goodness of fit and prediction precision that results from additional survival information, such as additional exposure durations and survival observation time points. The present work uses the effects of carbachy and diazinon on fathead minnow survival as an example, but this approach may be generalized to other compounds which are present in the environment in fluctuating concentrations. We observed systematic variation in model parameters, model fit, and predictive power that depended on the test design (e.g. exposure concentrations and durations) as well as timing and frequency of census. We discuss our results in terms of the toxicity test designs that may maximize predictive precision while minimizing laboratory resources. This work has potential applications for modeling effects of pesticides on fish populations and to support risk assessment.

WP230 Evaluating the Population-level Impacts of Contaminants of Emerging Concern on Sturgeon
M. Vaugeois, University of Minnesota, Twin Cities / Ecology, Evolution, and Behavior; P. Venturelli, Ball State University / Department of Biology; S.E. Hummel, US Fish and Wildlife Service; V. Forbes, University of Minnesota / Ecology, Evolution & Behavior

Chemical pollution threatens Great Lakes' ecosystems and the wild-life that they support. Among all of the species supported by the Great Lakes ecosystems, varieties of fish species face both chemical pollution and a variety of non-chemical stressors. The lake sturgeon (Acipenser fulvescens) is one of the largest and most unique freshwater fish in North America, and was once common in most inland rivers and lakes. Ironically, many of the characteristics that make the lake sturgeon unique (e.g., late maturation, longevity, and migrations) also make them vulnerable to anthropogenic impacts including overfishing, habitat fragmentation, and degradation. Consequently, lake sturgeon populations across North America have declined or have recovered slowly in the last 100 years. Increasing knowledge about these impacts must be part of any recovery plan. Although impacts of stressors are often measured on individual fish, conservation efforts are often intended to protect populations. This is because population-level effects are difficult to observe directly, particularly given the long life cycle and complex ecology of this species. We present a research project that focuses on population-level effects of exposure to Contaminants of Emerging Concern (hereafter, CECs) on lake sturgeon. The main goals of the project are to provide a better understanding of how CECs affect sturgeon populations and to inform best management practices. For this purpose, we developed a generic, lake sturgeon population model to identify which individual-level impacts of exposure to CECs (e.g., growth, survival, reproduction) are the most impactful at the population scale. The population model is an Individual-Based model in which the energetics of individuals are described by Dynamic Energy Budget theory. Using these methodologies allows us to infer impacts at the population-level from observations at the individual-level. We present results of simulations in which individuals were impacted by a generic, non-lethal stressor affecting either the cost of reproduction, maintenance costs, the ability to feed, or the cost of growth. We will use our population model to investigate more specific research questions linked to existing research projects at USFWS (e.g., population-level consequences of CEC impacts on imprinting, larval growth and/or survival rates). This project will provide guidance on sturgeon population-level effects of CECs, and help ongoing restoration programs by informing better management guidance and practices.

WP231 In situ assessment tools diagnose which stressors matter
G.A Burton, E.C. Cervi, University of Michigan / School for Environment and Sustainability

Over the past 27 years, we have developed and used a range of in situ assessment tools to evaluate chemical exposures, bioavailability, and multi-trophic level effects. These have been used in a weight-of-evidence (WoE) based approach, whereby in situ tools supplemented the use of traditional tools of chemical criteria, literature thresholds, laboratory mesocosms and benthic and habitat assessments. Here we review, these in situ-based tools successfully used and describe their applications, strengths and limitations, along with physical displays. The most recent tool, the in situ Toxicity Identification Evaluation (iTIE) technology has been renamed the in situ Toxicity Diagnostic System (iTDS) for improved clarity and is the subject of other poster and platform presentations. These tools are essential approaches that reduce uncertainty through increased exposure accuracy. Spatial and temporal fluxes and physicochemical interactions cannot be mimicked in the lab. These tools better link ambient exposures with effects and, when part of a strategic WoE approach, allow for improved science-based decision-making.

WP232 SYSTEMLINK - tracking the effects of stressors across ecosystem barriers

The impact of matter input from terrestrial sources on aquatic systems is well known. The reverse process, i.e. the transport from water (source) to land (sink) in aquatic-terrestrial meta-ecosystems, has received less attention. In SYSTEMLINK, we focus on the bottom-up and top-down mediated interactions in terrestrial ecosystems, which propagate from aquatic environments as a result of their exposure to anthropogenic stress. We consider micropollutants (fungicides and insecticides) and invasive species (riparian plants and invertebrates) as important manifestations of multiple stressors in disturbed aquatic ecosystems. We hypothesize that I) invasive invertebrates and insecticide exposure and 2) invasive riparian plants and fungicide exposure cause top-down and bottom-up mediated responses in terrestrial ecosystems, respectively. We test these general and several more specific hypotheses through collaborative experiments in replicated outdoor aquatic-terrestrial mesocosms (site-scale) amended by joint pot experiments (batch-scale), field studies (landscape-scale), and modelling. All experimental setups will be derived from the landscape scale representing a multi-stress environment. Several scales will regularly be combined to overcome scale-specific restrictions and to ensure both cause-effect quantification as well as environmental relevance of the
results. Ultimately, SYSTEMLINK thrives to increase our knowledge on effect translation across ecosystem boundaries. By integrating biogeochemical fluxes and biological subsidies we will be able to quantify their relative importance. Furthermore, we will closely combine the often-separated aquatic and terrestrial research areas.

WP233 Population modelling for environmental risk assessments - a case study investigating potential herbicide effects on common vole populations in Europe

Laboratory tests and field effect studies for environmental risk assessment (ERA) provide information on potential effects of active substances on exposed individuals under specific conditions. For practical and ethical reasons, however, such tests and studies cannot cover all the possible exposure scenarios, and therefore computational tools can be of much value to fill data gaps and make better use of results. Mechanistic effect models are ecological models that can predict the effects of one or more active substances on non-target wildlife at different levels of biological organization and under various environmental scenarios using information on the environmental setting, species ecology and toxicological sensitivity. This poster presents a case-study that used population modelling for an ERA in Europe. The study evaluated the likelihood of long-term repercussions on common vole (Microtus arvalis) populations due to 2,4-D herbicide uses in grasslands. The approach, its reasoning and its inclusion into the higher-tier data package for decision support was discussed with the evaluating member state authorities. The spatially-explicit individual-based population model, eVole 3.0, was used. It considers the processes of reproduction, mortality and spatial behavior which are relevant for common vole population dynamics. In the model, individuals lived in landscapes that represented grasslands in which herbicides were applied, resulting in foliar residues whose fate was simulated. Individuals were exposed via their diet i.e. the contaminated grass, within their dynamic daily home-ranges. Toxicological effects resulted from individual exposure based on dose-response relationships calibrated from standard multi-generation rat studies. The population-level responses emerged from the fates of vole individuals, which constituted the modelled populations. Increased application rates were simulated in addition to the intended rates to demonstrate a margin of safety and to provide positive controls. The impacts of annual applications on population density were assessed by comparing treatment to control simulations. Treatment-related population-level effects were evaluated and, where relevant, the time needed to achieve population recovery following the cessation of herbicide applications was determined. The results for the common vole are partly transferable to other Microtus species occurring in farmland in North America due to their comparable ecology.

WP235 Aquatic Site Characterization and Monitoring Using Passive Sampling Technology in Point Pelee National Park, Ontario, Canada
T. Bortoluzzi, Fisheries and Oceans Canada / Fisheries Program; M. Ryan, Fisheries and Oceans Canada / Fisheries Protection Program; B. O’rae, Parks Canada

Point Pelee National Park (PPNP) is located on the most southern tip of Ontario, a 15 km peninsula marsh and woodland habitat bordered by Lake Erie. The park provides habitat critical for hundreds of species of migrating birds and insects including over 53 Species at Risk, but is also a designated contaminated site listed on the Federal Contaminated Sites Inventory (FCSI). The contaminants of potential concern in PPNP are associated with pesticides (mainly DDT, dieldrin and lead arsenate) historically applied during the 1940s to 1970s. As of 2016, PPNP had minimal environmental contaminant data for the aquatic marsh areas of the park. With an objective to maintain the lowest disturbance to the park ecosystem, long term monitoring and assessment of DDT was assessed through the use of Passive Sampling Devices (PSDs). PSDs bind chemicals from environmental media and provide assessments of the biologically available contaminants. The use of PSDs for monitoring concentrations of contaminants in surface waters may offer a number of advantages over conventional point/grab sampling as they measure contaminants over extended periods providing time-integrated concentrations (smoother average of exposures), and measure contaminants in very low concentrations compared to typical small-volume sample analysis. PSDs can also act as biological surrogates, reducing the need for lethal sampling of living organisms, and determining the bioavailability of contaminants that may fluctuate over time, which is critical in accurately estimating exposure for risk assessments. This research aimed to assess the potential value of passive sampling approaches to provide high-quality contaminant data to effectively and efficiently assess and monitor ecologically sensitive contaminated sites. PSDs were suspended in the water column for 30 days at 10 sites across the marsh in October of 2016 and 2017 to collect surface water data on biopharmaceuticals, metals, and pesticides. Surface water and sediment grab samples, as well as fish were also collected for comparison to PSD data. Results indicate that the PSDs were more effective at detecting DDT concentrations in surface waters of the marsh compared to conventional surface water grab samples. DDT concentrations in whole fish samples were significantly correlated with DDT water concentrations as measured by PSDs. Conversely, DDT concentrations in sediments were not significantly correlated with DDT in whole fish samples. Aside from some disadvantages of PSD deployment, the PSDs are a reasonably viable, minimally invasive method for monitoring and assessing DDT in the aquatic environment at PPNP or other ecologically sensitive sites.

WP234 Geospatial, physico-chemical and microbiological water quality data can be used to prioritize impacts of land users and determine water quality
H.J. Potgieter, North - West University (NWU); C.C. Bezuidenhout, J.J. Bezuidenhout, North - West University / Unit for Environmental Sciences and Management

Increased urbanisation and anthropogenic disturbances have caused water quality of many freshwater systems to deteriorate over the years in South Africa. This is due to domestic, industrial, and agricultural waste being disposed of into surface waters and the surrounding environment. To meet growing water requirements a monitoring program needs to be applied nationally. Monitoring the Mooi River and Wonderfonteinspruit River were the focus point for this study. By combining data mining techniques and Geospatial information systems (GIS) the determination of water quality, both historically and current, becomes possible. In the present study such an approach was used. Microbiological, physico-chemical and GIS data (temporal and spatial) were combined to explore relationships between bacterial communities and physico-chemical changes and whether a correlation between industrial pollution, agriculture and urbanisation could be demonstrated and how this impacts on water quality. The results in the present study demonstrated that the Mooi River had water usable for all purposes although nitrate-nitrite (NO3-N02) were slightly elevated, which were contributed to the agricultural activities within the surrounding area. The Wonderfonteinspruit River on the other hand was highly polluted with phosphate (PO43-), sulphate (SO42-) and NO3-N02 which were contributed to mining and agricultural activities. The Wonderfonteinspruit River sites also showed high electrical conductivity (EC) values, that connects with the high SO42- levels within the Wonderfonteinspruit River. Bacterial community composition of the Mooi River and Wonderfonteinspruit seemed mostly similar. Bacteriodetes, Proteobacteria, Actinobacteria and Cyanobacteria are the four most dominant phyla identified spatially and temporally, but the Wonderfonteinspruit River had a higher abundance of Cyanobacteria which seemed to be driven by elevated PO43- and NO3-N02. The major land-use activities that influenced physico-chemical parameters and bacterial communities were identified as mining and agriculture, with erosion also playing a role.
WP236 Defining and refining concepts of avian exposure to pesticide-treated seeds

J.D. Maul, Syngenta Crop Protection, Inc. / Environmental Safety; E.M. Peterson, Texas Tech University / Department of Environmental Toxicology; P. Smith, The Institute of Environmental and Human Health, Department of Environmental Toxicology / Texas Tech University; L.W. Brewer, Compliance Services International / Department of Wildlife Toxicology

The objective of this project is to assimilate avian species-specific life-history traits, body size, nutritional information for cultivated and wild seeds, avian feeding behavior, and additional information that can be used to refine estimates of potential pesticide exposure to avian species associated with the consumption of pesticide-treated crop seeds. The review of this information will be used to address uncertainty associated with exposure assumptions that may impact risk estimates derived from current avian risk assessment methodologies. The primary objective is to use the compiled species-specific morphological characteristics (e.g., gape limitation), physiological (e.g., bioenergetics and nutritional requirements), behavioral (food selection behavior), and breeding phenology (i.e., temporal overlap) information to refine estimates of potential exposure for individual avian species. Because this approach has a species or size-specific focus, there is potential to apply components to refine risk to threatened or endangered species in the future. An in-depth literature review and information extraction has been conducted to generate these data, which will be presented in a format transferable to current regulatory models used to evaluate risk of pesticide seed treatments among avian species.

WP237 Using Spider web as possible indicator of heavy metal polluted environment?

O. Olawale, Federal University of Wukari

Although spider webs in residential buildings are considered a menace and a possible distortion in the aesthetics values of human environment, there are possibilities that its presence in most residential buildings may be of more benefits than being a pollutant. This study therefore aimed at evaluating the potentials of using cobwebs as possible indicators of heavy metal pollution in residential buildings. Spider web samples were collected from some residential buildings in order to determine the level of trapped heavy metals indoor. These samples were digested in hydrochloric acid and nitric acid before analysis using atomic absorption spectrophotometer (AAS). The result shows that cadmium and lead were present in the cobweb samples while As, Hg and chromium were not present. However, the mean concentration of lead and Cd were found to be significant (p < 0.05) when compared with the WHO set standard for residential buildings. Similarly, the concentration of Pb and Cd decreased as the sampling locations were distant away from major roads. The result of this research has shown that spider webs are useful bio-indicator and accumulator of heavy metals in environment.

WP238 Hard counting Made Easy by Automated device in cladoceran bioassays

S. Abreu, F. Jesus, A.M. Soares, University of Aveiro / Department of Biology & CESAM; R.E. Martins, M. Oliveira e Silva, University of Aveiro / DETI IEETA

Ecotoxicology faces the challenge of assessing and predicting the effects of an increasing number of chemical stressors on ecosystems. The selection of species for laboratory tests has historically incorporated a thorough evaluation of ecological as well as methodological and economical/practical considerations. Following these considerations, Daphnia magna has been the invertebrate species most recommended for acute or chronic toxicity testing. However, in most cases this species fails the criteria of “being indigenous” and/or “being representative” of ecosystems that receive pollutants. The preference for this species is mostly because of the larger size of the neonates (easier to pick up and count) in comparison to other cladoceran species. In opposition, Daphnia longispina has been recognized as having high ecological relevance but the smaller size of their neonates difficult their counting. Accordingly, Ceriodaphnia dubia testing has also been considered attractive due to its short reproductive life-cycle; however, practical difficulties piking and counting their neonates has somehow refrained the worldwide spreading of bioassays using this species. An automated counting device would certainly simplify the application of bioassays using these species. Thus, facing the main difficulty of picking and counting neonates of such small species, we have been developing an automated device (D counter) for automatically counting of neonates of several cladoceran species. The D counter has been previously validated for counting of D. magna neonates and in this work we present the first results concerning their validation for counting neonates of D. longispina and C. dubia. The manual counting was performed by an experienced technician, whereas automatic counting was performed by the D counter, for both species. Results of the manual vs automatic counting presented a very good linear correlation for both species (y = 0.9921x, R² = 0.991, n = 41, and y = 0.9904x, R² = 0.990, n = 37, for D. longispina and C. dubia, respectively), highlighting the very good performance of the methodology, which will likely be a useful tool assisting ecotoxicology bioassays.

WP239 Microplastic Analysis with FTIR and Raman Spectroscopy

Microplastics are particulates, roughly 1 micron to 5 mm in size, originating from various man-made materials. Over the past several decades, these materials have begun to enter aquifers and been found entering the human food chain when consumed by filter feeders. This has led to a major effort in industry, government, and academia to better understand the proliferation and potential risks associated with microplastics. In this presentation we will review best practices in sample preparation, filter selection, and spectroscopic analysis of microplastics from environmental and industrial samples. FTIR and Raman microscopy are excellent for analyzing these materials non-destructively and without further sample preparation, through either point-by-point identification or through area mapping or imaging. Together, these two techniques offer researchers complementary analytical tools that are straightforward, providing particle sizes, counts, identities, and distributions.

WP240 Tiered Screening of Australian Hydraulic Fracturing Fluids for Risk Assessment Prioritization

T.M. Biksey, C. Peterson, EHS Support / Risk Assessment

A tiered screening was conducted on hydraulic fracturing chemicals used in tenure leases in the Northern Territory of Australia to identify potential human health and environmental hazards and prioritize chemicals for risk assessment. A conceptual exposure model identified potential complete exposure pathways and receptors during the life cycle of chemical usage including transportation, hydraulic fracturing, and treatment/beneficial reuse. Human and environmental exposure may occur due to accidental releases (transport/storage) and planned releases (beneficial reuse). The tiered hierarchy included Tier 1 – chemicals identified of low human health and ecological concern that do not require any additional chemical risk assessment in the tier assessment process; and Tier 2 – chemicals identified as a human health/ecological concern that require additional risk analysis to characterize potential risks. The tiered screening followed the methodology presented in the Northern Territory 2019 draft guidelines, DOE’s 2017 Chemical Risk Assessment Guidance Manual for CSG, and NICNAS IMAP framework. The challenges encountered in implementation of the tiered screening included the proprietary nature of the hydraulic fracturing chemicals and lack of robust experimental data. Critical to the tiered screening is the preparation of environmental and toxicological dossiers that compile existing information necessary to conduct the screening. The Tier 1 screening includes a PBT (persistence,
bioaccumulative, toxic) assessment and identification of potential chemicals of concern by Australian NICNAS. The potential for exposure includes estimation of concentrations of chemicals in downhole and flowback hydraulic fracturing activities as well as beneficial reuse activities. Tier 2 screening focused on chemical-specific exposure pathways and receptors identified in the Tier 1 screening. Selected Tier 2 screening will be presented including exposure to surface water resources from accidental ponded releases and infiltration/overland flow, and exposure of avian receptors drinking from open-top storage tanks. Using the tiered screening, multiple fluid systems may be accessed to identify sustainable fluid systems, or to identify chemicals within fluid systems that are a high concern and should be substituted.

**Strategies for Successful Collaboration and Communication of Human Health Risk Assessment**

**WP241 Risk Communication- Challenges, Opportunities when Emerging Contaminants are at Issue**

*J. Phillips, TRC Environmental Corp.*

**Background/Objectives.** Risk communication is an art and a science. Communications regarding emerging contaminants add several challenges to an already challenging practice. The goal of risk communication is to simply and clearly present information to interested parties regarding the potential for adverse risk and potential exposures, and also to listen. Recognition that all concerns and questions are valid assists in communications regardless if the concern is a potential risk or not. The objective of this presentation is to discuss the common challenges in communicating risk effectively and provide some suggestions which can create opportunity to build trust and set a path forward of cooperation. Approach/Activities. Through use of some key tools, risk communication and its acceptance by the public and stakeholders can be greatly improved. Key tools for discussion include: 1) determination of key messages and objectives to share early and often, particularly related to the emerging contaminant or issue 2) relationship building to earn and gain trust 3) credible technical expertise to discuss the contaminant thoroughly and responsibly, 4) do the work, understand the target audiences and their point of view and 5) be open about what you know and what you don’t know. With emerging contaminants the technical community often doesn’t have all the answers, be clear with how new information will be communicated. Results/Lessons Learned. Adding to the complexity of risk communication is the very real issue of emotional or perception of risk vs. scientific evidence and the tendency for the public not to know who to trust in impacted environmental situations. Recognition of this with the stakeholders may help in gaining credibility. Uncertainties associated with the risk and toxicity of emerging contaminants make preparation and thoughtful delivery of clear messages and responses even more critical. Sometimes saying less is more. In this presentation, the basic tools of risk communication will be presented, with the focus on adjustments necessary when discussing emerging contaminants.

**WP242 Multi-agency coordination and public education to update the fish consumption advisory in the Coeur d’Alene Basin, Idaho**

*M. Wilming, Idaho Department of Health and Welfare / Division of Public Health*

The Coeur d’Alene River Basin in Idaho has been impacted by historical mining activities and the Bunker Hill Superfund Site. Because of these historical exposure concerns, understanding human health risks from exposure to metals in fish is of particular importance for communities within the Basin. Fish were sampled across the Basin and tissue was analyzed for arsenic, cadmium, lead and mercury. Completion of this project required successful coordination among several agencies including the Idaho Department of Environmental Quality, Idaho Department of Fish and Game, Coeur d’Alene Tribe and U.S. Environmental Protection Agency. Species collected included bass, panfish, bullhead, northern pike, kokanee, and trout. As part of the Idaho Fish Consumption Advisory Program, the Idaho Department of Health and Welfare assessed tissue concentrations to determine potential human health risks due to consumption of fish and provide recommended meal limits. Stakeholder collaboration as well as public education and outreach strategies and challenges will be described.

**WP243 Health and Safety Messaging for Recreational Activities near Abandoned Mined Lands in Idaho**

*N.E. Paden, Idaho Department of Environmental Quality / Ecological Division*

Mining activity in Idaho has left a legacy of heavy metals in the environment. Some of the abandoned mined lands in Idaho are located in areas ideal for recreational activities such as camping, hiking, and off-road vehicle use. This close proximity makes recreationalists susceptible to exposures to heavy metals in the environment. This study will highlight success stories for three abandoned mined land areas in Idaho where risk investigations showed elevated levels of heavy metals in soils. As a result of collaboration with other agencies, targeted health and safety messaging and public outreach tools were created to reduce human health exposures. Messaging includes ways to reduce exposures during recreational activities and how to limit tracking of contaminants back home. These examples could be applied in similar mining sites in other parts of the country.

**WP244 A Spatially Explicit Probabilistic HHRA: Quantifying Risks to Subsistence Populations in the Vicinity of a Proposed Mining Development**

*M. Sanborn, M. Rankin, AECOM Canada, Ltd.; D. Lalonde, BBA; M. Trindade, TSMC*

Quantitative human health risk assessment is an important component of the environmental assessment and permitting requirements for proposed development projects in Canada. Risk assessment provides not only a means for quantifying potential risks, but can also provide a critical tool for the communication of potential impacts/effects to local populations and stakeholder groups. The following study presents the methodology and results of a spatially explicit probabilistic human health risk assessment conducted in support of a proposed iron mine near Schefferville, Quebec. Consultation with local First Nation’s and community stakeholder groups identified critical hunting and gathering locations within the regional project area which are visited by the Innu and Naskapi people of the region. Subsistence land users represent critical human receptors, as they are considered to be maximally exposed individuals who spend considerable time at locations in proximity to the proposed development and consume high proportions of country foods. The quantitative risk assessment was conducted in a phased approach with a deterministic assessment primarily conducted to assess risks to the general population in the local study area. Subsequently, a detailed probabilistic assessment of risks to human health was conducted for First Nation’s receptors engaged in hunting/gathering activities at 14 critical locations identified during First Nation’s consultation. Hourly predicted concentrations of fugitive dust were modelled using climatic data for a 5 year period. The resulting dataset consists of ~44,000 data points at each of the 14 critical receptor locations. Modelled results were used to create empirical probability distribution functions, which were used as inputs to assess the risk and variability of exposures at these locations using Monte Carlo simulation implemented in GoldSim. The approach allowed for direct discussion of risks and uncertainty at each critical location.

K.O. Omoyajowo, University of Lagos, Akoka / Cell Biology and Genetics / Environmental Biology; O.E. Odipe, Kwara State University, Malete / Department of Environmental Health Sciences / School of Health, Allied and Environmental Science; A.A. Adesuji, University of Lagos, Akoka / Department of Cell Biology and Genetics / Environmental Biology; K.A. Omoyajowo, Ekiti State University, Ado-Ekiti / Faculty of Law

This study in attempt to address the formidable and critically important issue on the increased pesticide poisoning scenarios in Nigeria (1958-2018) provided sustainable strategies and theoretical framework on how communities can reduce pesticide poisoning particularly the dietary exposure. Heath risk assessment studies viz-a-viz pesticide dietary exposure raised many questions. To what extent is our local foods contaminated with pesticides? What policies are needed to protect human health from pesticide contamination? What do we need as individual and as community to reduce pesticide-food poisoning and associated risks? How best can we respond to this incident as well as the consequences to decision making? This study explores answers to these questions and in doing so, illustrates how zero-pesticide foods can be sustainably produced through the insights provided by many perspectives for economic goals and community health benefits. Available data on bio-monitoring studies revealed that vast majority of local foods in Nigeria are contaminated with pesticides while the data on Pesticide Food Poisoning Scenarios in Nigeria (1958-2018) point to the fact that Government and relevant stakeholders need to sensitize the public on the dangers of injudicious use of pesticides as well as the implementation of an inclusive pesticide policy. The study reasoned that in order for food safety to be achieved in any state or nation, government and relevant stakeholders must sensitize the general public on the risk associated with poisoning by pesticide and the possible ways pesticide residues can be reduced in foods.

WP246 Knowledge of Risk Associated with Exposure to Per- and Polyfluoroalkyl Substances in Enugu State, Nigeria

C. Okudo, University of Nigeria, Nsukka / Pure & Industrial Chemistry

Per- and Polyfluoroalkyl Substances (PFAS) are a group of chemical compounds that contain mostly carbon and fluorine in their structure. They don’t occur freely in nature but are produced industrially. Recent Studies have shown that PFAS exposure to the environment are persistent, bio accumulative and toxic to both animals and humans. Also reports have indicated that some of these products are being phased-out in America and Europe but some of them still find their way to African markets and other parts of the world. The challenge is that a great number of people in Nigeria and Enugu State, the study area don’t know what PFAS is and the risk associated with the use of products that contain PFAS. Therefore the study is to ascertain the knowledge of PFAS in Enugu State and highlight the risk of PFAS exposure. A self designed questionnaire was used to obtain data using random sampling technique. A total of 400 questionnaires were distributed and only 365 were collected. The result revealed that 91% of the sampled population knew nothing about PFAS and its associated health risk while 9% have knowledge of PFAS and its associated health risk. This may point to the fact that PFAS exposure in Enugu State may not pose only localized risk but may progress to be a global risk. Therefore this paper recommends massive study and awareness programme on PFAS and also appeal for the support and collaboration of Industrialized nations towards programmes that will ensure sustainability.

WP247 Traditional Food Use by Indigenous Communities: Consideration of Nutritional and Cultural Benefits In Concert with Contaminant Risks

R. Haley, Hemmera, an Ausenco Company; D. Bright, Hemmera Envirochem, Inc.; T. Miller, M. Wilson, Hemmera, an Ausenco Company

In Canada, guidance provided by authoritative government health agencies on the conduct of HHRA may undermine the expressed interest of indigenous people to maintain and expand their use of traditional foods for nutritional, medicinal and cultural benefits. Federal and other guidelines for the conduct of human health risk assessments, whether for contaminated sites assessment and remediation or environmental effects assessments of proposed or existing projects and activities, generally discourage probabilistic assessments. Deterministic methods are favoured since they tend to be more transparent, easier to follow and review, and more amenable to less complex risk communication and risk management decisions. There is also a deep-rooted reluctance to initiate site- and community-specific epidemiological studies of environmental contamination issues, in spite of recent advances in methods for directly assessing the exposome and transcriptional/translational early health effect indicators. Thus, we are highly reliant on the conduct of deterministic health risk assessments per Health Canada’s and other agency guidance for the conduct health effects assessments. The prescribed HHRA methods, however, do not consider the broader determinants of health as would be considered in modern Health Impact Assessment (HIA). It is a HHRA best practice to use conservative assumptions for predicting individual exposures in the face of uncertainty. Typically, risk assessors will use maximum media concentrations, biotransfer factor estimates (e.g. measured gastrointestinal bioaccessibility), and dietary intake rates, or an upper estimate of the statistical distribution of values (90th %ile, 95th UCLM). This will generally result in exposure estimates that are at least an order of magnitude higher than the most probable estimates, or the actual exposure. However, overly conservative risk estimates can have unintended consequences on the realization of health benefits of shellfish, fish, plants, and game sourced from the natural environment. Detrimental effects associated with traditional foods reported or perceived to be contaminated can include increased stress and anxiety, and reduced nutrition due to the avoidance of traditional foods. Increased recognition of this issue by regulators and practitioners is required. This talk will also discuss current status of approaches for balancing risks and benefits for guiding decisions about the safety of aquatic and terrestrial food resources.

WP248 Metal and Particulate Exposures from an E-Waste Mobile Shredding Truck

M. Zhou, Harvard School of Public Health; R. Herrick, Harvard School of Public Health / Environmental Health; D. Ceballos, Boston University School of Public Health / Environmental Health

Due to increasing needs for secure data destruction of electronic devices, numerous electronics waste (e-waste) recycling facilities have introduced a novel business model of mobile shredding truck services. These trucks have the ability to shred electronics with data security concerns at remote location for a wide variety of clients. Shredding of e-waste has been documented as a source of high metal exposures, especially lead and cadmium. However, shredders in electronic recycling facilities usually operate inside large warehouses and no studies have been done to assess exposures on mobile shredding trucks. We conducted a cross-sectional exposure assessment at a mobile shredding truck (shredder operating, truck off) and two electronic recycling facilities (shredder not operating) in the Greater Boston area. The mobile shredder we evaluated did not have local exhaust ventilation and workers often carried shredding jobs hand-feeding electronics for 4-10hrs/day, 1-5 days. We performed area air and surface wipe sampling for metals in the three facilities. We also collected real-time measurements of particulates inside the mobile shredding truck. The highest metal concentration in area air (e.g., 3 mg lead/cm³) were found during mobile shredding, which was comparable to other shredding inside warehouses from previous studies. Metal surface contamination was highest around the shredder (up to 1,190mg/100cm²) and extended to other parts of the truck, similar levels to those found in the other 2 sampled facilities. During the mobile shredding job (truck back door open), the concentration of ultrafine particles was up to 250,000 particles/cm³ and did not return to background level (3,500 particles/cm³) until after 40 minutes of inactivity. The concentration of PM₂.₅ was up to 171 µg/m³. A diesel electric generator was used to power the shredder and could have contributed to some of the particulate emissions. E-waste mobile trucks are a source of metal and particulate emissions within confined spaces. Better controls, such as local exhaust ventilation, are needed to protect workers health.
Translating Environmental Science Into Improved Outcomes and Policy

WP249 Can the Unveiling of Scientists’ Values Embedded in the Controversy over Endocrine Disruptor Assessment Help to Overcome Political Impasse?
B. McIlroy-Young, University of British Columbia / Resources, Environment and Sustainability; A. Leopold, Calidris Environment BV; G. Oberg, University of British Columbia / IRES

Endocrine disrupting chemicals (EDC) alter the function of the endocrine system and, as a result, can cause negative effects in humans and wildlife. Some EDCs occur naturally, but they are also produced synthetically. There is concern that synthetic EDCs may pose a risk to human and environmental health. These chemicals are found in products used for agricultural and industrial purposes as well as in products that promote human and animal health. Scientists are divided over how to assess the risk posed by EDCs: some are in favour of a purely hazard-based approach, while others support a risk-assessment approach. This controversy has exacerbated difficulties encountered in developing EDC regulation in jurisdictions around the world. It is well documented that debates in policy-relevant science are impacted by value-judgements and therefore cannot be resolved merely by generating more data; however, there is little research about the role of value-judgements in risk assessment of chemicals involving both human and environmental health. This study investigates how differing value-judgements among scientists with expertise related to the assessment of EDC’s, may impact their scientific position. To explore this topic, we are conducting focus groups and deliberative dialogues with EDC scientists who have positioned themselves as hazard and risk proponents, respectively, as well as individuals who are in between. Our findings suggest that the groups’ value-judgements differ with regards to how the problem is framed, which evidence they find relevant, how much evidence they consider necessary and how different types of uncertainties should be handled. The goal of this study is not to produce consensus, but rather to unveil differences in underlying values between the two groups with the intention of bringing about a fruitful conversation about these differences, and finding out how the scientific community might move forward recognizing their existence. This research responds to calls for empirical studies that test theory about the role of values in policy-relevant science. It is anticipated that unveiling scientists’ values embedded in the EDC hazard-risk controversy will help overcome political impasse in order to move forward with informed EDC regulation in Europe and as well as other jurisdictions such as Canada.

Effective Science Communication in a Science Unfriendly World

WP250 Change the game for environmental research - communicate the science within
T. Seiler, RWTH Aachen University / Ecosystem Analysis; A. Leopold, Calidris Environment BV

Environmental research is aimed at the one idea: improving environmental quality. All environmental scientists certainly would agree that this goal is directly connected to every day lives. Environmental research matters to the people, to stakeholders, and to policy makers. However, since it is so close to the expectations, opinions, fears and desires of our target audiences, environmental research is difficult to communicate. These topics directly touch the sense of well-being of our audience, and are hence often taken on more emotionally than is actually necessary – or better say helpful. They have a tendency to go &lsquo;viral&rsquo; on social media platforms. Conversely, topics which may be seen as prosaic can often be under-reported and evade the popular consciousness; e.g., topics that strongly matter to mankind but are perceived as inconvenient or even superfluous, such as sustainability. As a consequence, findings from environmental research can be readily misunderstood, or simply ignored, when not communicated in a proper way. Unfortunately, science and risk communication is often neither an element of education when becoming an environmental scientist, nor part of many scientist&lsquo; job description; let alone that there is time left for this on a daily basis. Furthermore, scientific integrity is nowadays more and more under attack, especially in the social media realm. However, integrity and trustworthiness is at the heart of any communication attempt in science, as messages – especially negative ones – can only be believed if the source is considered credible. In this presentation I will review some of the basic concepts of science and risk communication that are often not known to scientists, and thus can lead from misconceptions to misunderstandings and eventually communication failures. I will dive into science and risk communication as a conflict situation, the role of cognitive dissonance and confirmation bias, the differences between a scientist’s and a non-scientist’s mind, the futile escape from the ivory tower, and my belief that we should communicate much more about our science rather than our research. The audience should leave being motivated to explore how their science and risk communication might be improved. They should have understood and be convinced that proper science and risk communication is at the heart of societal and political impact of environmental research.

WP251 How to engage with your community about scientific risk
L. Paulik, Maul Foster & Alongi, Inc. / Environmental and Molecular Toxicology

Effective science communication is becoming increasingly important in the modern age of technology and politicized science. Scientists are trained to talk about science with other scientists but are often now trained to talk about science with anyone else. This disparity creates a troubling communication gap between scientists and non-scientists. When scientists can’t, or don’t, communicate about their work and why it’s important, their work is taken less seriously by the public. When public opinion doesn’t prioritize science, there is less financial support for scientific research and scientific progress is hindered. Limiting the audience that learns about research advances also limits the impact those findings can have. During graduate school I participated in community-engaged research projects in which I talked directly with community members about the research and how its findings might impact their lives. Through these interactions I experienced first-hand some of the reasons that scientists don’t always communicate with the public about their work: it is challenging, there is minimal guidance, and outreach-specific financial support is often limited or nonexistent. I found the challenge of effectively communicating with community members about our research fascinating, so I began to seek every opportunity I could to gain more experience communicating science to non-scientists. I applied for a Science Communication Fellowship with my local science museum and volunteered to lead science outreach events for children in my community through my university. Since then I have also been working to increase SETAC’s public science outreach and to increase training opportunities for students in effective science communication. Volunteering with my local science museum has given me a platform for regularly interacting with members of my community about scientific topics. Engaging with SETAC science communication leaders from around the world has taught me about the theory and research findings about effective risk communication. If more environmental scientists prioritize seeking similar training opportunities in their communities and within SETAC, we will collectively be able to work to shift the narrative toward increased public trust of scientists and science.

WP252 Using Hands-On Exercises to Create Stakeholder Buy In: If you do it with them, they will come along
W.J. Berry, US Environmental Protection Agency / Atlantic Ecology Division / ORD/NHEERL; S. Agius, Environment Canada; J. Twichell, US Environmental Protection Agency

It is important that stakeholders have trust in the process used to make environmental management decisions and a sufficient level of understanding to be able to provide input to those decisions. This is especially
true in the current climate of distrust in both government and science. One way to increase stakeholder trust in the decision-making process is to walk them through it using hands-on exercises. The experience gained by interacting with the practical aspects of the decision-making process can also increase stakeholders’ understanding of the process, and build the confidence needed to provide input and see how it will help make better decisions. We will demonstrate the usefulness of hands-on exercises to increase the transparency of environmental management decision-making using three examples. The first is a two-hour-long game suitable for use alone or as part of a training course which illustrates the use of various sediment indicators in making sediment assessments. The game was based on the EcoChallenge game, which imposes a time and money budget, and forces the players to make choices as to what types and quantities of data they will “buy.” The second is a case study which was woven into a three-day training on the assessment and disposal of dredged material. The case study provided hands-on experience applying each of the units of the course, as it was being taught. Participants pretended to be regulatory decision makers, carrying out each step of the assessment process and comparing notes on their results. The third is a four-session participatory workshop for municipal stormwater decision makers to engage their communities in the development of stormwater management programs and funding solutions. Over the course of four months, participants learned and actively applied a practical skillset for undertaking a consensus-building approach in their communities. This built confidence in public processes and inspired continuing efforts by participants after the workshop. These three exercises vary greatly in complexity and time commitment, but all of them can increase stakeholders’ ability to influence the decision-making process, and their confidence in the ultimate decision.

Poster Only: Predictive and Statistical Toxicology

WP253 Meta-analysis of acute fish data I - Data approach and statistical analysis

H. Plugge, N. Das, Verisk 3E / Safer Chemical Analytics; J. Kostal, George Washington University

Regulatory assessments of acute fish toxicity assay data depend on numerous assumptions, only very few of which have been tested. We performed a meta-analysis of publicly available data for approximately 70,000 acute fish toxicity assays for 7400 chemicals. Preliminary data analyses very quickly demonstrated that even for chemicals with assays n>100, results were not normally distributed, but rather appeared to follow a log-normal distribution. We thus focused our high level analysis on log-normal statistics including geometric means with confidence intervals, rather than arithmetic means with standard deviations. Data analyses of the main database and data manipulation were performed in an adjacent poster. A curated database was derived and divided into more than 180 databases for chemicals with more than 50 assays (not individual assays but complete LC50 data). This accounted for approximately 30% of the total data. These databases lend themselves to a high level e.g. eliminate Klimisch scores of 3 and 4. Standardization of data normalizations and statistical analysis will be presented. The original database consisted of normalized data, from which duplicates (to avoid double counting) were eliminated. QA was performed at a high level e.g. eliminate Klimisch scores of 3 and 4. Standardization of duration (e.g. 24, 48, 72 and 96 hour) and taxonomy were also performed. The curated database was divided into nearly two hundred databases of chemicals with more than 50 assays (not individual assays but reported LC50 data). These databases accounted for approximately 30% of the total data. The results for the individual chemicals are presented in an adjacent poster. Metals were not only split out into the n>50 database but also combined in one giant sub-database for metals. Assignment of metals as metals was done mostly manually. Organometals were assigned as organics by default. Standard statistical analysis was also performed for this database in order to demonstrate the (perceived) differences between metals and all other chemicals. Species level information was also analysed, and organized by both absolute and relative toxicity. Absolute and relative toxicity assays required a minimum of three datapoints. Relative toxicity was indexed on 96 hour assays for pimenesa promalas aka fathead minnow. In addition to data for 24 and 96 hour duration, a 96/24 ratio was also calculated. An in silico uncertainty analysis was also derived and is presented elsewhere.

WP254 Meta-analysis of acute fish data II -- Chemical specific data

H. Plugge, N. Das, Verisk 3E / Safer Chemical Analytics; J. Kostal, George Washington University

Regulatory assessment of toxicity assay data depends on numerous assumptions, only very few of which have been tested. We performed a meta-analysis of 70,000 acute fish toxicity assays for approximately 7400 chemicals. Preliminary data analyses very quickly demonstrated that even for chemicals with assays n>100, results were not normally distributed, but rather appeared to follow a log-normal distribution. We thus focused our high level analysis on log-normal statistics including geometric means with confidence intervals, rather than arithmetic means with standard deviations. Data analyses of the main database and data manipulation were described in an adjacent poster. A curated database was derived and divided into more than 180 databases for chemicals with more than 50 assays (not individual assays but complete LC50 data). This accounted for approximately 30% of the total data. These databases lend themselves extremely well to detailed statistical analysis and interpretation - where else can one find 200 replicates of an LC50 assay i.e. derivation of an LC50 value. Influences of species and duration on sensitivity can “easily” be derived. Species level information was analysed, and organized by both absolute and relative toxicity. Absolute and relative toxicity assays required a minimum of three datapoints for further statistical representation. Relative toxicity was indexed on 96 hour assays for pimenesa promalas aka fathead minnow. In addition to data for 24,48, 72 and 96 hour duration, a 96/24 ratio was also calculated. For one of the major individual chemicals i.e. n> 100, an in silico uncertainty analysis was also derived and is presented elsewhere.

WP255 Variability in in vivo Toxicity Studies: Defining the upper limit of predictivity for models of systemic effect levels

L.L. Pham, ToxStrategies, Inc.; R. Judson, US Environmental Protection Agency / National Center for Computational Toxicology; R.W. Setzer, USEPA / Office of Research and Development; K. Paul, Friedman, US Environmental Protection Agency / National Center for Computational Toxicology

New approach methodologies (NAMs) to predict hazard are often evaluated via comparison to results from animal studies; however, variability in these in vivo reference data limits NAM accuracy. The USEPA Toxicity Reference Database (ToxRefDB) enables consideration of in vivo mammalian point-of-departure (POD) variability from subacute, subchronic, chronic, multi-generation reproductive, and developmental toxicity studies. The lowest dose at which an effect was observed in a study, termed the lowest effect level (LEL), and the lowest observable adverse effect level (LOAEL), for in-life observations and pathology, along with associated study descriptors, were used to understand variability across studies. The objective of this work was to quantify the variance within systemic LEL and LOAEL values, defined as potency values for effects in adult or parental animals only. Using the study descriptors and potency values from ToxRefDB, multiple linear regression (MLR) and augmented cell means (ACM) models were used to quantify the total variance, and the fraction of variance explained by the available study descriptors, for systemic LEL and LOAEL values. The MLR approach considered each study descriptor as an independent contributor to variance, whereas the ACM approach combined all categorical study descriptors, i.e. chemical, study type, species, sex, and administration method, into cells to more stringently define replicates. Using these approaches, total variance in systemic LEL and LOAEL values (in log10-mg/kg/day units) ranged from 0.74 to 0.92, and the unexplained variance, approximated by the residual mean square error (MSE), ranged from 0.20-0.39. Restricting the datasets to subchronic, chronic, or developmental study designs reduced the dataset size, but resulted in similar values. Based on the relationship between MSE and R-squared for goodness-of-fit, the maximal R-squared...
for a systemic POD model using these data may approach 73 to 78%.
The root mean square error (RMSE) ranged from 0.41 to 0.59 log10-mg/ 
kg/day, and suggests that a prediction interval for systemic PODs may 
have a width of 40 to 200-fold. These findings suggest an upper bound 
on predictive performance of NAMs based on these data and may have 
important implications for the evaluation criteria used for NAM predic-
tions of systemic POD values. This abstract does not necessarily reflect 
USEPA policy.

WP256 Prediction of soil adsorption coefficient of pesticides via 
experimental values

Y. Kobayashi, T. Uchida, K. Yoshida, University of Tsukuba / Graduate 
School of Business Sciences

The soil adsorption coefficient (Koc) plays an important role in the envi-
ronmental risk assessment of the pesticide registration. On the basis of the 
risk assessment, the applied and registered pesticides might be prohibited 
in EU. In order to obtain the Koc value of one pesticide, it requires nearly 
one year study and costs approximately 100,000 dollars. Therefore, it 
is necessary to estimate Koc value efficiently and conveniently in the 
early stages of research and development. In this study, experimental 
values of physico-chemical properties and molecular descriptors of the 
chemical structure were collected. The Quantitative Structure-Property 
Relationship (QSPR) models were developed using these values to evalu-
ate the prediction performance. We developed multiple linear regression 
(MLR) model, support vector machine (SVM) model, and random 
forest (RF) model respectively. With respect to the MLR model using 
experimental values from laboratory experiments, R2 of the test set 
corresponded to 0.717. Conversely, with respect to the MLR model using 
the molecular descriptor, R2 of the test set corresponded to 0.771. The 
experimental results suggest that a QSPR model with high performance 
could be developed only with the molecular descriptor calculated from the 
structural formula. Therefore, it is possible to carry out risk assessment 
without carrying out laboratory experiments which require long study 
period and large cost.

WP257 Developing an efficient pipeline for transcriptome assembly, 
annotation and pathway detection

P. Liu, J. Xia, McGill University

RNA-Seq is increasingly applied to identify perturbed biological 
pathways in environmental toxicology. For many non-model organisms, 
however, reference genomes are either not available or in poor quality. 
Transcriptome based analysis could be an alternative way to overcome 
these difficulties. However, most of transcriptome de novo assemblers 
are time-consuming, computationally intensive, and of low accuracy 
for transcript reconstruction. Moreover, gene annotation and pathway 
 mapping are extremely slow and require high-performance computing 
resources. To address this bottleneck, we performed a detailed investiga-
tion on currently available tools for transcriptome de novo assembly, gene 
annotation and pathway mapping. Two RNA-Seq (Illumina paired-end 
reads) datasets from zebrafish (~ 104 million) and chicken (~ 240 million) 
of different development stages were used and sub-sampled 50 million 
reads for each species only for transcriptome assembly. Transcriptome 
were assembled by SOAPdenovo-Trans (version 1.04) and Trinity (version 
2.6.6) on a machine with 64G RAM and 8 Cores. Salmon (version 0.13.1) 
was used for RNA-Seq quantification for both assembled transcriptomes 
and reference transcriptome. The raw count tables were submitted to 
our NetworkAnalyst for differentially expression analysis and pathways 
detection. Our preliminary results showed that SOAPdenovo-Trans 
finished both transcriptome de novo assembly within one hour. Moreover, 
SOAPdenovo-Trans detected 15 true, 5 false positive and 1 missing path-
way comparing with reference-based analysis for zebrafish dataset. For 
chicken dataset, SOAPdenovo-Trans recovered 11 true, 1 false positive 
and 5 missing pathways in comparison with reference-based analysis. 
We are currently assessing the performance of Trinity, SOAPdenovo-Trans, 
and gene annotation and pathway detection. Based on the findings, we 
aim to create a pipeline to enable efficient mapping of raw RNAseq data 
to biological pathways without requiring reference genome.

WP258 Equal genotoxic potential and different gene expression 
induced by organic extracts of total particulate matter from differ-
ent diesel blends

L. Orozco, Pontifical Bolivarian University / Facultad de Medicina; F. 
Molina, J. Palacio, University of Antioquia / Facultad de Ingenieria.; D. 
Cuesta, I. Ortiz, Pontifical Bolivarian University / Facultad de Medicina

The principal contaminant in the air of most cities is particulate matter 
(PM) from engines that use fossil fuels like diesel. The PM is causally 
correlated with morbi-mortality with different respiratory, cardiovascular, 
immunological and neurological diseases, among others. The offer of dif-
ferent mixtures of bioalcohols or with biodiesel with fossil diesel around 
the worldwide as alternatives to pure diesel, but the toxicity of PM emitted 
by these mixes are not taken into account. It is important to determine 
the mechanisms of toxicity of PM alternative fuel mixtures because it 
permits to predict the hazard to environmental and human health exposed 
to those emissions. The present research compares the toxicity of organic 
extracts of PM emitted by a pre-Euro I with pure diesel, blend diesel with 
10% sugar cane ethanol or blend diesel with 10% palm biodiesel, used 
commercially. The toxicity analyses are done in vitro taking into account 
the mutagenic potential in bacteria (Salmonella/microsome test), the 
genotoxic potential in the HepG2 cell line (Comet and chromosomic aber-
ration assay) and the differential global expressions of genes by means of 
the RNA sequence. The analyses showed no difference among the organic 
extracts of PM in diesel and the mixtures with 10% ethanol and 10% 
biodiesel in so far as mutagenic and genotoxic potential in the comet test. 
With respect to differential gene expression, the organic extract of PM in 
biodiesel regulated 343 genes, while 10% ethanol 177 and diesel 96, the 
majority overexpressed with respect to the control group. The principal 
functional routes impacted by the 10% biodiesel extract were principally 
related to cytokines and interleukins of the immune system and trans-
duction signals mediated by the receptor of factors in fibroblast growth 
(FGFR2). The 10% ethanol affected the extracellular matrix, in carbohy-
drate metabolism and transduction signals related to vascular epithelia, 
while diesel perturbed the routes related to embryogenesis, masculine 
reproduction, immune system and cellular aging. The results of evaluat-
ing toxic potential of particles, could integrate with the different health 
effects and be used to predict the environmental and human impact from 
exposure to PM in the short, medium and long term.

Poster Only: Systems Approaches

WP259 Subsurface dissolved and colloidal phosphorus flux in well-
drained forest soils

K. Henshaw, J. Judy, University of Florida / Soil and Water Science; J. 
Vogel, M. Cohen, University of Florida / Forest Resources and 
Conservation; A. Bacon, University of Florida / Soil and Water Science

Phosphorus (P) is an essential macronutrient for both plants and animals 
and changes in P concentrations and fluxes inevitably affect population 
growth and balance among dependent organisms in a shared watershed. 
It is therefore critical that P cycling is studied with a holistic approach 
that considers all possible pathways and parameters which influence P 
transport through soils and water. Ultrafine soil colloids (particles < 1 μm 
in diameter) are relatively mobile in surface water and in the subsur-
face. Inorganic and organic compounds can bind to mobile soil colloids. 
Colloid-facilitated transport is therefore a potential pathway for P move-
ment through soils. The following study aims to characterize subsurface 
transport of dissolved and colloidal P from the forest floor into ground-
water-fed lakes in well-drained forest soils. Our central hypothesis is 
that P flux in well-drained forest soils is strongly influenced by colloidal/ 
colloid-facilitated subsurface transport. We seek to test this hypothesis 
through measurement of the colloidal and total P content of groundwater,
forest litter, and litter leachate. We will also characterize P speciation and co-localization with other elements using synchrotron-based analysis X-ray absorption spectroscopy (XAS) and X-ray fluorescence (XRF) mapping. Using lysimeters and wells, litter leachate and groundwater samples were collected from soils of two long-leaf pine forests and one hardwood forest located in a primarily groundwater-fed watershed. Portions of these samples were filtered with 3 kDa filters and subsequently analyzed, along with unfiltered samples, to quantify dissolved and total P. The data on subsurface P fluxes and P cycling generated by this project will address key knowledge gaps related to forest ecosystem nutrient fluxes. Forest biomass and P demand is expected to increase in the future as a result of increased atmospheric nitrogen deposition and global temperatures; the data collected by this project will help inform future nutrient management decisions and improve our ability to predict future ecosystem change.

WP261 Using Multivariate Analysis to Characterize Toxic Pollutants Impairing Water Quality in the Willamette River Basin, Oregon

M. Borgens, AECOM / Environmental Science and Management; D. Sobota, E. Foster, Oregon Department of Environmental Quality

Identifying and characterizing pollutant sources are critical for restoring water quality. However, conducting these assessments can be data- and time-intensive, delaying implementation of restoration activities. Here, we examine point and nonpoint sources of 48 toxic pollutants impairing 6,000 kilometers of Oregon’s Willamette River Basin (WRB) rivers. Our goal was to develop a strategy for developing total maximum daily loads (TMDLs) in the WRB based on a combination of pollutant geographic location and chemical characteristics. TMDLs are the primary mechanism for restoring water quality under the United States Clean Water Act. We compiled information describing sources (based on geographic location and source type) and key characteristics affecting environmental behavior (water solubility, vapor pressure, Henry’s Law Constant, octanol-water partition coefficient (K(W)), and organic-carbon-water distribution coefficient (KOC)) for metals, polycyclic aromatic hydrocarbons (PAHs), volatile organic compounds (VOCs), polychlorinated biphenyls (PCBs), organochlorine insecticides, and organophosphorus insecticides for WRB water quality impairments. We used cluster analysis and non-metric multidimensional scaling (NMDS) to analyze pollutant characteristic similarities. Based on available data, permitted point sources in the WRB included 2,050 industrial storm/wastewater discharge facilities, 81 mines, and 522 road outfalls. Nonpoint sources included 937 toxic stock, flows, and emissions in 2000-2017; 2) projects future trends of the PFAS flows, stocks, and emissions under different scenarios until 2030. By incorporating the “stock” of carpet into the estimation, this study achieves a more accurate and systemic estimation of product-specific PFAS use and emissions to inform regional-level risk assessment and policy design.

WP263 Life cycle assessment of the impact of drilling fluid used by oil companies in Nigeria

M.E. Onwurah, Nasarawa State University, Keffi / Environmental Geology; I.N. Onwurah, University of Nigeria / Biochemistry

During oil drilling, cutting piles are discharged to the surrounding environment and they eventually end up in the sediment. This usually modifies the physical structure of the sediment, which invariably affects the benthic community and hence the primary food chain (productivity) in the aquatic environment. Life cycle assessment (LCA) is a good and very complex tool for determining the effects of a product on the environment, especially today when there is more and more awareness of environmentally friendly technologies, renewable energy and eco-efficiency. To successfully develop high quality data sources for LCA, all the inputs and outputs of different materials used including energy consumption and the amount of pollutants and emissions produced are required. However in this preliminary study we limited our data to toxicity in terms of the effect of the drilling fluid used with respect to some impact parameters in the aquatic environment studied. In generating our data, we considered some basic characteristics of Life cycle analysis reminiscent of forestry. Hence we developed a modelling approach that will enable the creation and collection of representative data for the LCA. The following impact categories were considered in our modelling approach: (i) oxygen depletion (total oxygen demand); (ii) rate of FeS2 production; (iii) biodegradation rate of drilling fluid; (iv) biodiversity (abundance and distribution of micro benthos), (v) chemical oxygen demand (COD) emissions to water and (vi) environmental loading (inert solid waste). It is hoped that this work will engender more research into LCA of the impact of several drilling fluids because according to Food and Agric. Organization (FAO), it is a useful tool for comparing the environmental aspects of specific products as it enables the ecological comparison of two or more products made of different raw materials but used for the same purpose.

Promoting Healthy Pollinator Communities Under Changing Landscape Conditions

WP264 Aluminum ingestion in honey bees: A subspecies perspective of exposure risk

A. Chicas-Mosier, Oklahoma State University / Integrative Biology; T.E. Black, Oklahoma State University / Psychology; L.P. Belzunce, INRA / Abeilles & Environnement; J. Agosto, University of Puerto Rico / Rio Piedras / Biology; C.I. Abramson, Oklahoma State University / Psychology

Poor mining practices and soil acidification increase bioavailability and uptake of aluminum by flora. Plant products such as pollen and nectar are then ingested by honey bees and stored in the hive where larval bioaccumulation can occur. This presentation discusses free-flight choice-making, captive survival, motility, and acetylcholinesterase activity experiments in honey bees exposed to aluminum. Using free-flight experiments such as artificial flower patches and floral nectary analogs, color preferences were determined to vary after exposure dependent on subspecies of honey bee (Apis mellifera mellifera, Apis mellifera carnica/caucasia and an Apis mellifera mellifera/scutellata hybrid). Additionally, captive experiments in Apis mellifera mellifera have shown that exposure makes circadian rhythmicity unstable, causes hyperactivity, and decreases lifespan. Behavioral and free-flight data have been corroborated by bee-head acetylcholinesterase enzyme activity and suggest a hormetic response in Apis mellifera mellifera while some tolerance is demonstrated in Apis mellifera ligustica. Additionally, we will be conducting Inductively
Coupled Mass Spectrometry and expect to observe minimal excretion of aluminum and dose-dependent head and body concentrations. The severity of the response to aluminum exposure is tied to subspecies but effects of aluminum exposure have occurred across Apis mellifera spp. We conclude that aluminum exposure from floral products is likely a limiting factor to pollinator health and may contribute to population decline; however, further understanding of subspecies tolerance to toxics is needed.

WP265 Comparative sensitivity of adult mosquitoes and butterflies to the mosquito control insecticides permethrin and naled

Permethrin and naled are both applied in ultra-low volume sprays in Florida for the control of adult mosquitoes. Application areas for both insecticides include or are adjacent to habitats in which imperiled butterfly species occur (Florida leafwing, Bartram's hairstreak, Miami blue, sawgrass skipper, and Shaus' swallowtail butterflies). The State of Florida and the U.S. Fish and Wildlife Service are concerned about the potential for adverse effects from these insecticides to existing populations of those butterflies and to management efforts focused on their conservation. Acute contact toxicity studies (24h LD50) are being conducted with adult mosquitoes and both adult and larval butterflies to increase our understanding of the relative sensitivity of the target and non-target organisms to the two insecticides. To date, toxicity studies have been completed for two mosquito species (Aedes aegypti and Culex quinquefasciatus) for permethrin. The 24h LD50s for A. aegypti and C. quinquefasciatus were 0.49 (SD = 0.178) and 0.98 µg/g (0.394), respectively. Both values approximate the 24h LD50 values reported for several adult (0.18 - 1.60) and larval (0.08 - 0.46 µg/g) butterfly species indicating mosquitoes and butterflies have a similar sensitivity. While preliminary, these data indicate a similar level of effect would occur to butterflies and mosquitoes in the field given identical exposures. Additional toxicity studies are ongoing with naled and permethrin to a third mosquito species (Anopheles quadrimacula) and to butterfly species whose sensitivity to these insecticides has not been reported.

WP266 Toxicology of two pyrethroid insecticides in the monarch butterfly (Danaus plexippus) and interactions with host plant defense chemicals

A.J. Krueger, University of Nebraska, Lincoln / Entomology; H. Moyer, Lock Haven University / Department of Biology; T. Spencer, A. Veláz, T. Weisstling, T. Anderson, University of Nebraska, Lincoln / Department of Entomology

Monarch butterfly (Danaus plexippus) population declines have caught the attention of the country and prompted nation-wide pollinator restoration activities. The USFWS has identified insecticide exposure and loss of milkweed (Asclepias) reproductive habitat as primary threats to the monarch. In the Corn Belt specifically, there may be a spatial and temporal overlap of insecticide usage and monarch larvae where milkweed is present near agriculture. Monarchs are not only exposed to insecticides in agriculture but also the insecticidal cardiac glycosides in milkweed, which target the Na⁺/K⁺-ATPase. In pharmacology, potassium has been shown to antagonize these compounds. Due to this mechanistic congruence, we are exploring interactions between cardenolides in the monarch larval diet, pyrethroid insecticides and potassium fertilizers on detoxification processes of monarch caterpillars. To understand these interactions, we are conducting laboratory experiments detailing the toxicology of bifenthrin, a Type 1 pyrethroid, and beta-cyfluthrin, a Type 2 pyrethroid, in 5th instar monarch caterpillars with and without coexposure of 1) a lipophilic cardenolide, ouabain, 2) a more hydrophilic cardenolide, digoxitin, and 3) a potassium fertilizer KCl. After identifying significant two-way interactions altering pyrethroid sensitivity, we will further explore the potential three-way interaction. Here we present the dose response curves, carboxylesterase activity, ATPase activity, and general physiological effect findings.

WP267 Bumble bee acute oral toxicity to four systemic insecticides and the diversity and abundance bumble bees within field crops in South-Central Ontario

K.A. Mundy-Heisz, R.S. Prosser, N. Raine, University of Guelph / School of Environmental Sciences

Bumble bees (Bombus sp.) are generalist pollinators supporting a wide array of flora within the Northern Hemisphere. These bees also contribute to agricultural production of many fruits, berries and vegetables. Bumble bees are facing a myriad of risks which vary in intensity of interaction across space and time, including habitat loss, disease, invasive species and pesticides. A specific category of pesticides, systemic insecticides, can be used as seed treatments, foliar sprays or soil drenches within greenhouses, blooming crops and field crops. All applications can result in non-target movement of insecticides into the soil, water, and plant materials. Although typically not considered as a route of exposure to bumble bees, field crops use systemic insecticides and can be surrounded by suitable nesting habitat and floral resources. Using in lab lethal toxicity testing, we assess the acute toxicity of the Common Eastern Bumble bee (Bombus impatiens) to four systemic insecticides (cytantraniliprole, flupyridafurione, sulfoxaflor, thiamethoxam) and use field work at paired farms and natural areas to assess the abundance and diversity of bumblebees present. We found that systemic insecticides differed in toxicity, with thiamethoxam, sulfoxaflor, flupyridafurione and cytrantraniliprole as the most to least acutely toxic. Further, field work found that bumblebee abundance was higher within natural areas, but diversity was highly similar between farms and natural areas. Our findings add to the growing body of literature around non-honeybee pollinator risk assessment and the differences in toxicity that may be found between species. Our work is also opening up a new channel of research into field crop exposure to native bumblebees that has been overlooked thus far as focus has been placed upon native bumblebees or commercially produced hives pollination services in flowering crops. Further analysis of foraging flowers and bumblebee collected pollen samples for pesticide residues is underway.

WP268 Field-exposure of neonicotinoids to wild bees in the Southern High Plains region (Texas, USA)

S. Longing, Texas Tech University / Plant and Soil Science; E. Peterson, Texas Tech University / Environmental Toxicology; K. Wooten, Washington State Department of Ecology / Environmental Toxicology; S. Subbiah, Texas Tech University / Department of Environmental Toxicology; P.N. Smith, Texas Tech University / Environmental Toxicology; N.E. McIntyre, Texas Tech University / Biological Sciences

In agricultural and urban systems, use of chemicals to control pest species can unintentionally result in exposure routes among non-target foraging insects. Across these systems, neonicotinoids are among the most widely used insecticides and are known to be highly toxic to bees, key pollinators in both wild and managed systems. The objective of this study was to quantify neonicotinoid concentrations across different bee genera and examine exposure in relation to taxon, habitat and body size. In May-June 2016, 282 wild bees were collected from 32 habitat patches (within dominate cropland, grassland or urban landscapes) and analyzed for occurrence and quantities of three neonicotinoid insecticides: thiamethoxam, clothianidin and imidacloprid. Twenty bees (7.45%) contained one or more of the neonicotinoid compounds above the limit of detection (i.e. 0.02 µg/bee), and neonicotinoids were detected in bees from 7 of 32 habitat patches across the area of interest. The most commonly detected neonicotinoid was imidacloprid, followed by thiamethoxam and clothianidin. Eight of fourteen bee taxa had at least one neonicotinoid above the limit of detection. Apis (honey bees) was the bee genus collected most frequently, also having the greatest number of occurrences of neonicotinoids above the limit of detection, followed by the long-horned bee Melissodes sp. with four individuals having neonicotinoids above the limit of detection. The small-bodied bees in the genera Perdita, Lasio glossum and Halictus were relatively abundant and had neonicotinoids above the limit of detection. Across bee genera, number of detections within a genus and the average body mass of genera showed a marginally significant trend
towards larger bees having a greater frequency of neonicotinoid detection (Pearson correlation: r = 0.45, P = 0.09). Cropland dominated landscapes were represented by four of the seven sites having bees with neonicotinoids above the limit of detection. Conservation practices focusing on ruderal habitats in agroecosystems and urban landscapes could assist in mitigating chemical exposure to foraging bees, while body size and other species traits could influence the frequency of exposure. Further studies are needed to address research questions aimed at documenting the spatial and temporal variability of chemical exposure to bees and other pollinators, and according to species traits and habitat resource use.

Plants in Environmental Risk Assessment: Assessing and Predicting the Effects of Chemicals on Plant Communities

WP269 Biochar and Other Amendments to Enhance Tree Seedling Growth for Mine Revegetation
D. Oleszky, M.G. Johnson, M. Bollman, US Environmental Protection Agency / NHEERL/WED; T. Shiroyama, Senior Environmental Employment Program; J. Novak, D. Watts, USDA ARS / CPRC
Biochar is the carbon-rich material remaining after pyrolysis (heating in a low oxygen atmosphere) of organic feedstocks. As a soil amendment, biochar has the potential to sequester heavy metals, improve soil water-holding capacity, and increase nutrient retention, thereby enhancing soil conditions to benefit plant growth. Thus, biochar can enhance the establishment and growth of plants for mine site revegetation. This was a preliminary greenhouse pot screening study with different amendments, to determine effects on soil and plants before initiating a full-scale on-site revegetation study. We evaluated the potential for biochar, along with agricultural lime and nutrient sources (biochars or mineral fertilizers), to enhance the survival and growth of Douglas fir [Pseudotsuga menziesii (Mirb.) Franco] seedlings in mine spoils from the Formosa mine Superfund site in southern Oregon. We made biochar by high temperature gasification of comifer softwoods, and applied it at 2.5% by weight to the spoil soil. The soil had an extremely low pH (~2.6). Addition of 0.5% or 1.0% lime (w/w) raised soil pH to 5.8 and 7.2, respectively. Increasing the soil pH was necessary for seedling survival and growth, and decreased concentrations of heavy metals (e.g., Al and Cu) in the soil leachate. However, a high level of added nutrients (2%, vs. 0.5% or 0.25% w/w of biochars or fertilizer) inhibited plant growth, especially at the higher pH. The addition of biochar enhanced biochar seedling survival, root growth, water usage, and new tissue potassium concentration, at least in part by reducing the detrimental effects of high nutrients. This study indicates that biochar, along with lime and nutrients, can enhance early seedling growth in mine affected soils by improving soil physical and chemical characteristics.

WP270 Improved Experimental Design for Non-Target Terrestrial Plant Studies
J.W. Green, JohnWGreen-ecostats.com / Data Science and Informatics
Regulatory guideline studies for Non-Target Terrestrial Plant (NTTP) are Seedling Emergence (OECD TG 208) and Vegetative Vigor (OECD TG 227). Both have growth responses (dry or wet weight and shoot height) and survival (TG 227) or emergence (TG 208). An extensive database was explored to find what experimental designs allowed adequate ability to estimate ECx, x= 10 to 50, and determine a NOAER. Design considerations were the number of application rates, replicate test vessels (pots) per application rate, plants per rep, and whether to have the same number of reps at all rates or to increase the number of control reps (e.g., using a square-root allocation rule). The decision criteria were the power of multiple comparison methods to establish a NOAER and the distribution of ECx estimates and their confidence bounds. The database determined the distribution of the within- and between-rep variances (VAREP and VAREEP, respectively) and the ratio VAREP/VARERR, as well as the range of rate-response shapes in such studies. A realistic simulation study was then developed to explore alternative designs. For emergence studies, a design with 6 application rates (including a zero-rate control), 8 reps/rate, 5 plants/rep, with equal allocation of reps to rates, provides NOAER determination and EC10 and EC25 of comparable power and quality to those possible from larger designs. For Vegetative Vigor studies, a design with 8 rates with 5 reps of 4 plants each, with equal allocation of reps to rates allows NOEC determination and EC10, EC25, and EC50 estimation with comparable power or quality to that possible under larger standard experiments. These conclusions must be qualified: Shallow rate-response curves occur frequently and vary across species and chemicals in mostly unpredictable ways. Both NOAER and ECx estimates suffer for such data. Quality of results depends on the statistical models and model selection criteria, and multiple comparison tests. Specific recommendations are provided.

WP271 Model Selection Criteria for Growth Responses in Non-Target Terrestrial Plant Studies
J.W. Green, JohnWGreen-ecostats.com / Data Science and Informatics
Growth responses in NTTP studies are dry or wet weight and shoot height. There is no apriori model for such data and for a single dataset, ERx estimates can vary substantially across different models that are plausible, at least in the abstract. It is thus necessary to define objective goodness-of-fit criteria and model selection criteria to select which, if any, model from an appropriate suite of models, provides reliable estimates of ERx and for what values of x. The suite of models explored are Bruce-Versteeg “probit type,” 3-parameter log-logistic, Brain-Cousens hermetic, and 2- and 3-parameter exponential models with and without an additional parameter defining a minimum level possible or “floor.” Including a floor is sometimes useful avoid estimating responses below any biologically plausible level (e.g., a plant will die before it shrinks to 1% of normal weight). Goodness-of-fit criteria include the following. ERx is estimated as a change from the model estimated control mean, so model agreement with the observed control mean is important. Somewhat less important is agreement of the model with observed treatment means, especially near the estimated ERx rate. If notable low dose stimulation is observed, the model should reflect it, since otherwise, the estimated control mean tends to be pushed towards the stimulated value. The width of the confidence intervals for ERx and the predicted response at ERx should not be overly wide. The model should not be sensitive to one or two observations and all model parameters should be significantly different from zero. Model selection criteria include Akaiki’s AICs or BIC and an assessment of how well models being compared meet the goodness-of-fit criteria. Results from a large NTTP database indicate the relative success of these models in fitting NTTP growth data using the stated criteria and the size effects that can be estimated from such studies under current test guidelines.

WP272 Rhizobacteria Mediate the Phytotoxicity of a Range of Biorefinery-relevant Compounds
R. Herbert, University of California, Berkeley; T. Eng, Lawrence Berkeley National Laboratory; U. Martinez, San Francisco State University; B. Wang, Lawrence Berkeley National Laboratory; S. Langley, K. Wan, Berkeley Lab; V. Pidatala, E. Hoffman, Lawrence Berkeley National Laboratory; J. Chen, San Francisco State University; M. Bissell, Lawrence Berkeley National Laboratory; J.B. Brown, Faculty of LBNL / Molecular Ecosystems Biology; A. Mukhopadhyay, J. Mortimer, Lawrence Berkeley National Laboratory
Advances in engineering biology have expanded the list of renewable compounds that can be produced at scale via biological routes from plant biomass. For sustainable chemical and fuel production, the industry needs to transition from fossil to renewable carbon sources, resulting in unprecedented expansion in the production and environmental distribution of chemicals used in biomanufacturing. In most cases, these chemical products have not been evaluated for effects on biological systems, defined here as bioactivity, that may be relevant to their manufacture. Further, while some relevant chemicals have been assessed for...
mammalian toxicity, environmental and agricultural hazards are largely unknown. Our study assessed six compounds that are representative of the emerging biofuel and bioproduct manufacturing process for their effect on plants (Arabidopsis thaliana, Sorghum bicolor). We describe the impact of the microbiome on bioactivity by testing the same chemicals against plants inoculated with individual bacterial species isolated from the roots of A. thaliana. We show that several of the test chemicals alter plant seedling physiology at sub-millimolar concentrations and that these responses change in the presence of two microbes. We additionally observe a pooled microbial community with different effects on root growth relative to its constituents individually. These findings indicate that screening industrial chemicals for bioactivity on model organisms in the presence of their microbiomes is important for biologically and ecologically relevant risk analyses.

WP273 Risk Assessments for pesticide effects on terrestrial plants
C. Habig, Compliance Services International
Terrestrial plants represent a vital component of terrestrial ecosystems, but are often overlooked in comparison to animal species found in those same ecosystems. However, due to their fundamental role in terrestrial ecosystems, adverse effects on terrestrial plants can result in indirect effects on both vertebrate and invertebrate species, including endangered species, that are present in those ecosystems. Currently, EPA evaluates potential exposure and risks to terrestrial plants from pesticides using a Tier I, screening level model, TerrPlant, which is focused on pesticide risks from agricultural uses. This model contains three distinct modules for estimating exposure and risks to terrestrial plants. One module evaluates potential effects from spray drift and runoff from a treated field to an adjacent, untreated field or area, the second module evaluates potential effects from spray drift and runoff from a larger treated area on a nearby wetland area, and the third module evaluates the potential effects of spray drift only on untreated adjacent areas. Since TerrPlant is a screening level model, there are limited inputs to the model, along with a number of hard-wired assumptions and modeling procedures. TerrPlant estimates potential effects on non-target monocots and dicots from a single pesticide application event. Key information used as model inputs are the pesticide application information, including the application rate and the formulation type (liquid spray or granular product), along with effects endpoints derived from standard guideline seedling emergence and vegetative vigor testing. The effects endpoints for estimating potential effects on endangered species are more stringent than those for estimating potential effects on non-endangered species. The model estimates spray drift as a set percentage of the application rate, while the percentage of applied product that runs off is estimated based on the water solubility of the pesticide. The model assumes that there is no buffer area between the treated area and the untreated area being evaluated for potential effects. Examples of TerrPlant modeling will be provided for both endangered and non-endangered species, along with a discussion of the underlying assumptions and limitations of the model. Currently, there are no set options (or tiers) for refining the risks to terrestrial plants if a product fails the TerrPlant screen. Options for refining both the estimated spray drift exposure and runoff exposure estimates will be discussed, including additional modeling options. These include using the AgDrift model to refine drift exposure estimates, and using EPA’s aquatic exposure model, PWC, to refine runoff estimates. Examples of these refinements using AgDrift and the PWC model, as well as additional options will be provided, including the effects of including buffer areas between the treated field and sensitive off-site areas.

WP274 Statistical Analysis of Survival/Mortality/Emergence Data
J.W. Green, JohnWG Green-ecostats.com / Data Science and Informatics
Survival data is a common type of response in many ecotoxicity studies. Estimation of EC50 or ECx for other choices of x is often done by probit analysis. Standard probit analysis ignores replicates and does not permit treatment of overdispersion. Background or control mortality must be taken into account to make a reasonable risk assessment. Abbott’s formula is a common way to deal with that, but it can create large errors in both ECx point estimates and confidence or credible intervals. Some software packages force use of this technique. Simple, practical easily implemented unbiased alternatives in SAS, R and other software exist to analyze survival data that uses the replicate structure, adjusts for background mortality in a direct and mathematically sound manner, and also accommodates overdispersion where present. These include probit or other generalized nonlinear models with binomial error structure and reps treated as a random factor (with an overdispersion parameter when needed), analysis of replicate proportions using regression models for continuous responses. These approaches are compared to standard probit analysis and to each other and to standard survival models from other types of studies using data from regulatory guideline studies for non-target terrestrial plants, fish sexual development, and fish early life stage studies, as well as extensive computer simulations based on realistic assumptions. All approaches will include comparisons using two ways to treat background mortality (Abbott or direct). Recommendations are made for how these and most survival data from guideline ecotoxicity studies should be analyzed in the future. Standard models for survival data from other disciplines, such as proportional hazard, Kaplan-Meyer, frailty models and sandwich estimators, are shown to be generally unhelpful in most ecotoxicity guideline studies.

WP275 Testing the emergent macrophyte, Glyceria maxima, in a water-sediment system: Progress towards development of an OECD Test Guideline
J. Davies, Syngenta / Environmental Safety; G. Arts, Wageningen Environmental Research / Environmental Risk Assessment; R.J. Isemer, Bayer Ag / Environmental Safety - Environmental Effects; J. Kubitza, BASF SE; M. Ratte, ToxRat Solutions GmbH & Co. KG
Data requirements introduced under EU Directive 1107/2009 stipulate that tests with aquatic plant species other than Lemna may be required for plant protection products which show selectively higher toxicity to either dicotyledonous or monocotyledonous plant species in terrestrial plant tests. In these cases, the recommended dicot and monocot species are Myriophyllum and Glyceria, respectively. OECD Test Guideline 239 for testing Myriophyllum spicatum in a water-sediment system was adapted to facilitate growth of the emergent, reed grass, Glyceria maxima, and ring-tested in 13 laboratories during 2016 and 2017 with the herbicide, isoproturon. Results from this ring-test were used to adapt the test protocol in terms of plant propagation recommendations, test system specification, test duration, assessment parameters and draft validity criteria. This revised protocol was used in a second ring-test with the herbicide, imazapyr, in 11 laboratories during the Summer/Autumn of 2018. Key findings indicated that shoot endpoints were less variable and more reliable than root endpoints while further work is needed to reduce overall control plant variability via increased standardisation of the test system and improved health of plant material at test initiation. In April 2019, this work was submitted to OECD and accepted as a Test Guideline project. This presentation will summarise results from the imazapyr ring-test and discuss progress towards delivery of the OECD TG.

WP276 The Evaluation of Seeding Density on Endpoint Sensitivity in OECD Vegetative Vigor Plant Guideline Testing
The OECD non-target plant testing guidance contains unclear language regarding the number of plants per replicate to be used in testing in support of agrochemical registration. This could potentially result in various interpretations of plant density by regulators, registrants and testing laboratories. A common concern across stakeholders is the effects of density on endpoint sensitivity in testing to be used for risk assessment purposes. Smithers conducted a trial exposing ten commonly used plant species at two different planting densities to a broad spectrum herbicide following standard OECD 227 vegetative vigor test methods. All plants were exposed to the same geometric series of application rates. The low
density group was generally more sensitive across species but the ECX values and related dose responses were comparable. The low density group had narrower confidence intervals for ECX values but higher coefficient of variances likely driven by increased replication. There was a 2-4 times difference in ECX values for the two density groups, which would be covered by the 5x safety factor used in EU herbicides risk assessments. The trials demonstrated that there were minor differences in the endpoint sensitivity across the two densities but that any differences would likely be mitigated in a risk assessment framework resulting in similar conclusions. Future work could include the examination of multiple planting densities as well as investigating chemicals with various modes of action.

**WP277 The strength and relevance of primary producer toxicity tests: Compelling evidence for recovery**

*C. Lau, M.L. Hanson, University of Manitoba / Department of Environment and Geography*

Herbicides are widely used in agriculture and may pose a threat to non-target plants and algae in aquatic ecosystem. Numerous studies have done to address these concerns on the effects of herbicides and the ability of plants and algae to recover following the cessation of exposure. We wanted to assess the strength and relevance of these studies; specifically as it relates to the evidence that recovery can occur in primary producers exposed to herbicide. A literature review was performed and 34 peer-reviewed journal papers were found (1984 - 2019) that examined a single compound and primary producer, with both an exposure and recovery phase. An objective scoring rubric was developed. Scores are given based on three main categories: (1) test substance, (2) test organism and experimental system, and (3) test design, statistics, and results, with a maximum score of 15. A total of 117 of test species were evaluated, that examined 35 different herbicides, with the top three tested being atrazine (n= 21), isoproturon (n=7), and cycloulsulfuron and diuron (n=3). The exposure durations for macrophyte were typically 7-14 days, with a 7 - 14 day recovery period. For phytoplankton, the exposure and recovery duration usually are 48 - 96 hours and 24 - 72 hours, respectively. The average score was 8 with a minimum and maximum of 2 and 14 marks, respectively. Half of the scores (55%) were 10 or greater, indicating a body of literature that is reasonably robust. In total, 83% of tests reported a no observed effect concentrations (NOEC; during the recovery phase) that were > 20 mg/L (which is above environmental concentrations for tested herbicides). This implies that primary producers could recover following an acute exposure to tested herbicides. We recommend that standard protocols for the assessment of recovery in macrophytes and algae be developed to improve the strength of methods for this element of data generation for risk assessment.

**Terrestrial Toxicology, Ecology and Stress Response**

**WP278 The Value of Avian Gross Pathology in Identifying Endocrine Disrupting Properties**

In June 2018, the European Chemical Agency (ECHA) and European Food Safety Authority (EFSA) published guidance recommendations that gross pathology findings from avian reproduction studies be used to support the assessment of potential endocrine disrupting properties of pesticides and biocidal active substances. These gross pathology findings should, when available, particularly reference any indications of differences observed in endocrine target organs, including thyroid, gonads and reproductive organs. In the open literature, little information is available on the utility of gross pathology data for informing endocrine evaluations. Here, we have compiled and analyzed the gross pathology data from the historical control groups of 51 northern bobwhite and 51 mallard reproduction tests to help establish the utility of such information. Evaluation of the incidence of gross morphology findings in untreated birds, may aid in the interpretation of some gross abnormalities being indicative of an endocrine interaction (e.g. reproductive condition), particularly when treatment response is pervasive. However, statistical analysis of the historical control data incidences of occurrence, indicates that gross pathology, by itself, is not likely to be useful for detecting endocrine effects as only abnormalities of relatively high prevalence (more than 20 to 30%, depending on variation in the prevalence in the control) could be reliably interpreted as a treatment response. Gross pathology changes may only be indicative, not diagnostic, of endocrine interactions making gross pathology observations due to endocrine-mediated effects, indeterminate from systemic toxicity. This work demonstrates the utility of historical control analyses in establishing the value and properties of apical endpoints for different regulatory applications.

**WP279 Heavy Metal Accumulation In the Tissue of Doves and Cattle egrets from three locations in Lagos State**

*I. Omoniyiowo, University of Lagos / VACC Technical Limited / Department of Zoology*

Heavy metals have high density and are poisonous at low concentration; they are introduced into the environment through anthropogenic sources and natural sources. This study aim to evaluate the activities of anti-oxidative enzymes and to determine the histology alteration on the liver and kidney of mourning dove (Zenaida macroura) and cattle egrets (Bubulcus ibis) which are prone to environmental exposure to lead, chromium, zinc and magnesium. A total of 12 juvenile Cattle egrets and mourning doves were collected at random at Olusosun (dumpsite), Amuwo Odofin (control site) and Ikorodu (industrial area). The birds were sacrificed and dissected. Blood samples, kidneys, livers and intestinal tract biopsy were collected. Liver and kidney were examined for histopathological alterations: level of metal was determined in the blood and intestinal tract samples using AAS. The levels of antioxidant enzymes were analyzed in the liver and blood samples. Results showed a significant difference in the value of lead in the three locations (P< 0.05). Manganese and zinc had no significance (P>0.05) and there was a significant difference between the value of chromium found in mourning dove and the locations (P< 0.05). There was also no significant difference between the Reduced glutathione Transferase (GSH) and Superoxide Dismutase (SOD) (P>0.05), with Catalase (CAT) showing a significant difference in the three locations (P< 0.05) and Malondialdehyde (MDA) value in the liver of mourning dove has a significant different between the locations. Histopathological studies showed a high level of stress in the liver and kidney of the bird. Therefore, these birds can be used as indicators of environmental pollution.

**WP280 Oxidative stress response of the seaside sparrow (Ammospiza maritima) following the Deepwater Horizon oil spill**

*A. Angel, California State Polytechnic University, Pomona; A. Bonisoli Alquati, California State Polytechnic University, Pomona / Department of Biological Sciences; S. Taylor, P.C. Stouffer, Louisiana State University AgCenter; S. Woltmann, Austin Peay University / Department of Biology*

The Deepwater Horizon (DWH) oil spill introduced massive amounts of oil into Louisiana saltmarsh ecosystems. In 2012-2013, reproductive and fledging success of the resident seaside sparrows (Ammospiza maritima) declined following oil exposure. A food-web link between oil exposure and this terrestrial ecosystem was discovered using carbon isotopic evidence. This begged the question of whether this oil exposure caused a direct toxic effect in the tissues of exposed seaside sparrows, with potential important implications for their fitness. The main toxic component of DWH oil are polycyclic aromatic hydrocarbons (PAHs), which are known to have carcinogenic, mutagenic and pro-oxidant effects in animals. Oxidation of biomolecules by radicals can alter the overall functioning of the organism, making the toxicity arising from an oxidative stress response an important one to investigate. Prooxidant action of oil stems from PAH metabolites reacting with molecular oxygen to create reactive oxygen species (ROS) via a redox cycling reaction. The unstable ROS can then cause oxidative damage to organic biomolecules, inducing oxidative
WP281 Tree Swallows as a Sentinel Species for Assessing Pre-Remediation Conditions at Randle Reef, Hamilton Harbour, Ontario

G. Barrett, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; J. Costa, Environment and Climate Change Canada / Canadian Wildlife Service; K.D. Hughes, K. Intini, K. O’Hare, P.A. Martin, Environment and Climate Change Canada / WLSD

As part of an assessment of pre-remediation environmental conditions at Randle Reef, several parameters relating to reproduction, health, and contaminants were studied in tree swallows (Tachycineta bicolor) nesting in Hamilton Harbour from 2013–2018. This species feeds on emergent aquatic insects in close proximity to its nesting site and has been used widely as an indicator of local contaminant conditions in the Great Lakes. Twenty-five nest boxes were installed at two locations in Hamilton Harbour, Randle Reef (adjacent to the proposed remediation site) and Bayfront Park (3 km west of Randle Reef), and at Long Point on Lake Erie (reference site). Various measures of reproductive success, e.g., clutch size, hatching success and fledging success per nest, were generally high at all study locations. Concentrations of sum PCBs and sum PBDEs were significantly higher in eggs from the two Hamilton Harbour locations compared to eggs from Long Point while mercury concentrations in eggs were not notably elevated at Hamilton Harbour locations. Contaminant burdens in eggs were below levels associated with adverse impacts on reproductive success. As a measure of PAH exposure, air monitoring was conducted from 2013–2017 using polyurethane foam passive air samplers (PUF-PAS) that were deployed near nest boxes. Concentrations of total PAHs in air were highest at the Randle Reef location followed by Bayfront Park with lowest concentrations at the reference site. Similarly, total concentrations of PAHs in stomach contents of nestlings (reflective of chick diet) were also highest at Randle Reef compared to the other two locations. Significant spatial variation in EROD activity (enzyme induced by PAH exposure and responsible for PAH metabolism) was found in liver of nestlings in one of three study years. Several other biochemical health effect endpoints associated with contaminant exposure have also been studied in nestlings. There was evidence of significant spatial differences in thyroid hormone concentrations (plasma) and oxidative stress (lungs) while no difference in immune function was found in nestlings among study locations. In 2019, monitoring plans will be scaled back when dredging of the Randle Reef site is expected to occur with post-remediation monitoring beginning again in 2020.

WP282 The Evolution and Challenges Inherent to Pesticide Testing with Passerine Species

D.L. Temple, Eurofins EAGroscience / Avian; R. Davis, P. Hubbard, Eurofins EAGroscience / Avian Toxicology; G. du Hoffmann, Eurofins EAGroscience

Passerine species comprise more than 50% of all bird species in the world. In 2008 the revised 40 CFR Part 158 pesticide data requirements (July 1, 2008; 72 FR 60957, October 26, 2007) included avian acute testing with one passerine species. The EPA 2012 OCSP 850.2100 guidelines followed up by suggesting the use of house sparrows (Passer domesticus), zebra finch (Taeniopygia guttata) or red-winged blackbirds (Agelaius phoeniceus). Eurofins (formerly Wildlife International, Ltd.) avian toxicology laboratory began testing with passerine species in 2008 and has conducted nearly 200 passerine tests to date. Testing with altricial species presents its own set of issues and concerns, including: 1) the husbandry and care of these species tends to be more complex and, 2) the interpretation and consequence when birds regurgitate a dose can be confounding. Here we examine how the use of passerine species in acute testing has evolved since the addition of regulatory requirements that include these species the development of husbandry and testing techniques that allow for the effective work with passerine species in a laboratory setting. The EPA guideline recommends against the use of wild-caught birds for acute toxicity testing. However, based on the relative ease of obtaining and keeping captive bred populations, Eurofins laboratory has chosen to work primarily with zebra finch and canary (Serinus canaria) passerine species. The environmental conditions, pen size, social behavior, and phylogenetic and taxonomic relatedness are some of the considerations when working with these species. Over the last 10 years we have conducted 98 tests with zebra finch and 86 tests with canary. Of these 184 tests conducted, regurgitation was noted during 100 (55%) of them, with 58 requiring follow-up with a dietary study due to regurgitation. The regulatory agency’s stance on how to interpret regurgitation has evolved with the issuance of 2012 OCSP guidelines and the EPA’s memo Guidance for Use When Regurgitation is Observed in Avian Acute Toxicity Studies with Passerine Species. Dietary tests are the appropriate choice when regurgitation is observed. These tests make it feasible to detect acute toxicity in passerines with regurgitation. As acute testing with passerine species continues to move forward the value and capabilities of testing with these species is likely to evolve as we expand the existing knowledge base and accrue a progressively robust historical database.

WP283 Impacts of metal contamination on the behavior and body condition of American Robin (Turdus migratorius) nestlings

K. Glynn, Eastern Michigan University / Biology

Many songbird species live in both urban and rural environments. These two habitats can have vastly different advantages and/or benefits, and thus may present tradeoffs. One songbird species that commonly lives in both habitats is the American Robin. The diet of this species consists mainly of terrestrial invertebrates, such as earthworms that reside in soil. An instance of environmental pollution such as the Flint water crisis, where lead was leached into the drinking water of residents in Flint Michigan in 2014, may have negative bio-accumulative consequences for these organisms. If American Robins are consuming earthworms in a location of known environmental pollution, they may therefore be exposed to elevated levels of lead and thus be facing an impact to their overall health and fitness. Much is known about the negative consequences lead has on neural development and reproductive health. We hypothesize that if American robins in Flint Michigan are exposed to elevated levels of lead, then their nestlings might be experiencing neurological deficits resulting in less favorable behaviors and/or lower body conditions. We propose to record nestlings in Flint Michigan, at an appropriate developmental stage, to observe and assess behavior across contaminated and uncontaminated sites. Blood samples will be collected to determine blood lead content across sites, and body measurements will be used to assess changes in body condition. Preliminary work has shown that American Robins in Flint have elevated blood lead levels. However, it is unclear how this may
be impacting their reproductive success and the overall health of their nestlings. This study will illuminate how anthropogenic environmental pollutants, such as lead, impact urban wildlife. Based on the evidence implicating lead as a toxic metal and the literature suggesting its universal negative effects across species and their offspring, it seems likely that lead exposure negatively impacts songbird nesting survival, and thus population health in urban environments.

WP284 Blood lead levels of wild songbirds following the Flint, Michigan drinking water crisis
D. Zahor, Eastern Michigan University / Biology
Anthropogenic metal pollutants emitted into the environment have the potential to harm organisms residing in the polluted ecosystem. Urban birds spend much of their time in human-dominated landscapes and could serve as bioindicators of metal pollution as well as possibly reflect human exposure. The Flint, Michigan drinking water crisis arose due to a lack of corrosion control which would have prevented lead leaching from pipelines into the drinking water. While human residents were alerted to avoid ingestion of lead-contaminated water, there was not a similar caution taken when watering lawns or otherwise allowing the drinking water to exit Flint homes and enter the environment. Although water levels are now reduced, lead is highly persistent, a neurotoxin, and tends to remain in the upper layers of soil where it is bioavailable to wildlife. Songbird diets vary widely, and species that forage on soil-dwelling organisms may be more prone to lead exposure. Similarly, if young are fed preferred items there may be differences in exposure between adults and juveniles. Finally, species that associate strongly with human structures may differ in exposure to lead. We describe blood lead levels in four species of urban songbirds: two omnivores that forage frequently for soil-dwelling organisms and two granivores, including an invasive and native species of each. We will discuss the influence of diet, age and ecological niche on lead levels in these urban songbirds in an area of known lead pollution. Understanding factors that increase a species sensitivity to pollution can better guide conservation efforts and raise public awareness surrounding pollution risks to wildlife.

WP285 Biochar soil amendment and chemical toxicity in portworms and earthworms
P. Voua Otomo, University of the Free State / Zoology and Entomology
1. Introduction Biochar has been regarded as an affordable means to decrease chemical toxicity in soil and water. Biochar is biomass pyrolysed in limited or complete absence of oxygen at temperatures above 250°C. Research evidence suggests that it is able to reduce the bioavailability and phytotoxicity of heavy metals and to have sorption and partitioning effects on various chemicals. In the present contribution, we assessed the efficacy of biochar in the alleviation of the toxic effects of sewage sludge, a nanosilver colloidal dispersion and a chloronicotinyl insecticide to two invertebrates. With regard to survival, a LC50 of 16.5 (1.8-26.7) µg sludge was observed for non-biochar amended soils whereas no LC50 was determined for biochar amended soils. This implied that biochar has the ability to alleviate the toxicity of sewage to Eisenia fetida. Conclusions Although the efficacy of biochar as a means to decrease chemical toxicity seems to vary depending on the species or chemical, biochar shows potential for use in the alleviation of the toxic effects of different chemical classes including metals, nanomaterials and organic compounds.

WP286 Can local enhancement in earthworms affect the outcome of the standard earthworm avoidance test?
A. Stander, University of the Free State / Department of Zoology; P. Voua Otomo, University of the Free State / Zoology and Entomology; A. le Roux, University of the Free State / Department of Zoology
Earthworms exhibit clumping behaviour in and out of the soil. However, it remains unknown if such social behaviour ultimately influences the outcome of ecotoxicological experiments in the laboratory. We performed several overnight avoidance tests to determine whether social behaviour (i.e., local enhancement) is a factor in pollution avoidance behaviour in the earthworm Eisenia fetida. The results showed that there was no clear influence of social behaviour on the choice or avoidance of Cd contaminated soils, although we suspect that 50 mg Cd/Kg might not have been high enough to elicit a significant avoidance response. Nevertheless, when offered a choice between clean undisturbed soil and previously inhabited soil, the worms preferred the previously inhabited soil (p < 0.01). Although the level of metal pollution investigated in this study did not disrupt or help predict social dynamics, local enhancement, perhaps driven by some sort of habitat imprinting, was successfully documented in Eisenia fetida.

WP287 Comparing the sensitivity of two springtail (Collembola) species to pesticides through multiple exposure pathways
W.J. Martin, P.K. Sibley, R.S. Prosser, University of Guelph / School of Environmental Sciences
Springtails (Subclass: Collembola) are one of the most frequently studied groups of test organisms in soil ecotoxicology due to their ease of culture, ecological importance, and predictable responses to contaminant exposure. Folsomia candida (Family: Isotomidae) is a globe-spanning Collembolan whose distribution includes agricultural soils, riparian systems, caves, and forests. It currently represents the majority of ecotoxicology arthropod studies, thanks in part to standardized test methods developed by several regulatory organizations. F. candida has been identified as relatively insensitive to exposure to some contaminants compared to other soil arthropods, specifically other springtail species. Arrhopalites caecus (Family: Arrhopalitidae) shares many of the traits that make F. candida an attractive laboratory test organism; they share a worldwide distribution, parthenogenetic life cycle, and can be found in a wide range of habitats, including cave systems, and forest leaf litter. Unlike F. candida, the sensitivity of A. caecus to environmental contaminants is largely unknown. These studies aim to characterize Arrhopalites caecus in the context of soil ecotoxicology. The sensitivity of A. caecus and F. candida exposed to insecticides in a soil matrix was first compared, representing the most common springtail exposure scenario. The results of this exposure suggest that A. caecus is more sensitive to acute insecticide exposure in soil matrices. In order to further characterize differences in sensitivity, these species were exposed to the insecticides.
through contaminated food in laboratory culture conditions. A feeding assay was developed for use in this investigation in order to eliminate differences in sensitivity based on habitat preference (soil for *Folsomia candida*, leaf litter for *Arrhopalites caecus*) and to characterize potential differences in detoxification mechanisms.

WP288 Egg Production and Hatching Success in a Widely Distributed Soil Springtail as Indicators for Recovery after Imidacloprid Exposure

**S. Sengupta, H. Leinaas, K. Borgå, University of Oslo / Department of Biosciences**

Soil remediation after pesticide application should include an assessment of the responses of ecologically relevant organisms. Collembolans constitute a keystone soil community group with strong effects on soil nutrient cycling. However, life-history traits of ecologically relevant collembolans are not commonly used end points in in toxicity tests, despite the close link of life-history traits to population performance and fitness. Here, we registered essential life history responses (i.e., reproduction) and assessed the recovery after sub-lethal exposure to the neonicotinoid pesticide, imidacloprid, in *Folsomia quadrioculata*, a collembolan often dominant in major habitat types. The collembolans were subjected to dietary exposure across imidacloprid doses by spiking the feed with 0–4290 μg L−1 aqueous solutions of imidacloprid. We used five replicates per treatment, each containing 20 adult collembolans. The dietary exposure lasted for 14 days at 15°C, followed by a non-exposed recovery period of 25 days. Mortality was recorded throughout the experimental period. In addition, the eggs laid were counted, and observed until hatching or censoring (30 days after collection). Effects of imidacloprid concentration on the time until first reproduction in the clean environment, egg production, and egg hatching success were analyzed. We expected increased recovery time with dose for all the end points studied. All the end points showed a negative effect of dose, except for survival, which was high throughout the experiment. Egg production stopped in many replicates during the exposure period. However, resumption of reproduction post-exposure indicated that the collembolans recovered gradually in the clean environment. Time until first reproduction in the clean environment increased with dose. Moreover, egg hatching success increased with recovery time. The findings suggest that survival or presence/absence data from the field should be supplemented with more detailed analysis of life-history end-points for assessing the status of soil remediation.

WP289 Best Practices for Dung Fauna Ecotoxicological Studies

**D. Hurgett, M. Terneus, Boehringer Ingelheim Animal Health / Drug Safety**

Dung fauna (e.g. certain flies and beetles) are critical members of the pasture ecosystem due to their role in the breakdown of dung and incorporation of organic matter into soil, as well as nutrient cycling. Given their importance within an ecosystem, investigations into the potential adverse effects associated with chemical exposure to dung fauna are important components of environmental risk assessments for production animal drugs. Draft and finalized OECD guidelines are available to allow for standardization of methodologies and analyses used to assess the potential for a new chemical entity (NCE) to adversely impact dung beetle and fly populations. However, the methodologies and data analyses described in peer-reviewed literature often do not utilize these validated guidelines, thereby making interpretation difficult and limiting the comparative assessment of studies/data. Population/ecological models for dung species can be developed and incorporated into higher tier assessments, thus providing a needed bridge between the laboratory and field. Field studies are highly complex and effort is needed to understand natural variability of the study site, as well as describing the attributes of a quality field study. As the field of dung fauna ecotoxicology is relatively new, it is important that the scientific community conduct laboratory and higher tiered assessments of sufficient quality and standardization to allow for clear interpretation. The purpose of this presentation is to discuss best practices when conducting laboratory and/or field ecotoxicological studies evaluating dung fauna. Applying best practices will facilitate a more consistent and robust assessment of potential dung fauna effects associated with a NCE.

WP291 Impact of Seasonal Environmental Variation on 2,4-D Fate and Metabolism in Urban Landscapes

**A.E. Gonzalez Vasquez, Molecular and Environmental Toxicology Center / Molecular and Environmental Toxicology, P. Koch, University of Wisconsin, Madison / Department of Plant Pathology**

The herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) is among the most commonly used pesticides on urban landscapes in the U.S. Although 2,4-D fate and breakdown has been well documented, interactions with the soil microbiome and simultaneous assessments of its transformation products in urban landscapes under seasonal environmental variations remains poorly understood. Field and controlled environment studies will be conducted in May and July of 2018, 2019, and 2020 to evaluate pesticide degrading activity and the formation of 2,4-D transformation products under varying environmental conditions. Analytical methods have been optimized for the analysis of 2,4-D and its primary transformation products in leaf, soil, and leachate samples using Liquid Chromatography-Tandem Mass Spectrometry. Quantification analysis of a 2,4-D-degrading gene found in soil bacteria, known as the tfdA gene, was also developed and validated using qPCR. We anticipate that seasonal environmental fluctuations will shift the soil microbiome structure, function, and diversity and lead to variations in tfdA gene quantification and 2,4-D breakdown in urban landscapes.

WP292 Chemical and Species Specific Application Rate vs Response Simulations to Support Pesticide Risk Assessment

**Y.B. Atalay, B. Sackmann, R.A. Pastorok, D.V. Prestiosi, Integral Consulting, Inc.**

A multi-model framework, incorporating several modeling phases, has been developed to assess pesticide risk across multiple ecological receptors. In the first phase, species-specific population models are calibrated to laboratory test results. The models are then extended to explore population-level responses under constant (and optimal) environmental conditions. The second and third phases build on the results of the first phase models using long-term environmental/field conditions and pesticide exposure profiles to assess potential effects of pesticides on populations and aquatic food webs. Biomass effects are characterized by integrating biomass within the exposure time period (i.e., calculating the area under the curve [AUC]) and expressing the difference between the control and exposure scenarios as a percentage. AUC provides an integrated, species-specific, measure of exposure effects and by varying the chemical dose, exposure effects for different environmental regimes can be compared. This approach is useful to support risk assessment procedures for pesticides and takes into account the entire application rate and response analysis to provide descriptive effects/response levels.

WP293 Concentration addition model tested by comparing observed to predicted response of barley grown in a mixture of Ni, Cu and Co on artificial soil

**A.E. Hunter, University of Guelph / School of Environmental Sciences; S. Siciliano, University of Saskatchewan / Department of Soil Science; B.A. Hale, University of Guelph / SES**

Metal contamination in soils most often occurs as mixtures of more than one metal. Although there have been numerous studies on how single metals are taken up by plants from soil, the accumulation and toxicity of metal mixtures remains largely unstudied and unknown. In the absence of more reliable models, the concentration addition model could be applied in risk assessment, though it is not well validated. To this end, a fixed ratio design was used to compare accumulation and toxicity of Ni, Cu and Co to barley grown on OECD artificial soil, as singles and in a mixture. The concentration addition (CA) model was used to predict the additive response and compared to the observed mixture response. Toxicity of
root and shoot endpoints was well predicted by the CA approach, and the predicted mixture response was not statistically different from observed. Accumulation of the mixture of metals was less easily predicted by the CA approach. Root accumulation was over predicted by CA, while shoot accumulation was under predicted by CA, for both especially at higher exposure concentrations. The difference in response between root and shoot accumulation may provide evidence for the idea that roots are largely a cation exchange surface where competition occurs between cations for exchange sites, while translocation of trace elements from roots to shoots is largely independent of the other trace elements in the xylem stream. These data suggest the usefulness of the concentration addition model in risk assessment.

WP294 Evaluation of The Impacts of Sulfuric Acid and Nitric Acid on The Rice Paddy Ecosystem Using Mesocosm System

M. Park, J. Wee, K. Cho, S. Hyun, Korea University / Department of Environmental Science and Ecological Engineering

Damages of rice, the most consumed crop in South Korea, caused by chemical accidents have been reported, but the impacts of the accidents on rice paddy ecosystems have been neglected. Toxicity assessment of chemicals through laboratory-scale bioassay provides the limited information for the evaluating effects of them on ecosystem. We assessed the impacts of sulfuric acid (H₂SO₄) and nitric acid (HNO₃) on the rice paddy ecosystem using mesocosm composed of soil, sludge worm, rice (Oryza sativa), and golden apple snail (Pomacea canaliculata). We set up mesocosm system simulating the rice paddy ecosystem by filling 150 kg of paddy soil in pots and saturating them with water. Rice cultivation was carried out according to the cultivation technique provided by Rural Development Administration (RDA, Korea). Rice seeds were germinated in clean soil and seedlings were grown for 4 weeks. The seedlings were transplanted into the system and sludge worms and golden apple snail were inoculated into the system, on the 5th day after rice transplanting. After a week, H₂SO₄ and HNO₃ solutions were spilled into the system and the concentrations were adjusted to the predicted no-effect concentration (PNEC) and hazardous concentration for fifty percent of the species (HC₅₀) of each chemical, predicted through the previous studies. Soil pH and chlorophyll content of the rice leaves were measured for 4 weeks. On the 28th days after the chemical exposure, the species were collected, and the numbers and biomasses of living individuals were measured. The activities of soil microorganisms were also evaluated through the soil enzyme test. The impact assessment of the spilled chemicals on the rice paddy ecosystem was conducted by analyzing the effects of the chemicals and the interactions between the chemicals and species through comparison of the endpoints in the treatment and control groups. These results may provide basic information for assessing the impacts and estimating damages of the entire terrestrial ecosystem by chemical accidents.

Microcystis aeruginosa is a cosmopolitan cyanobacteria that continues to jeopardize freshwater ecosystem services by releasing the hepatotoxic microcystin-LR, which can ultimately cause death to humans and other fauna. Currently, our abilities to understand the mechanisms of microcystin toxicoology are limited by the lack of a method for producing high concentrations, which are central to large-scale and long-term research in natural systems. Here we present an efficient and affordable laboratory method to produce high concentrations of microcystin-LR and its demethylated counterpart [D-Asp3]-microcystin-LR by M. aeruginosa CPCC 300. Our observations suggest that steady production of microcystins depends on the availability of carbon throughout the experiment. Hence, we recommend experimental cultures remain axenic and vessels are ventilated to ensure the production of microcystins is uninterrupted. This method effectively demonstrates microcystin-LR and [D-Asp3]-microcystin-LR can be produced in the laboratory at concentrations found in the environment (1 to 300 μg L-1).

RP002 Determination of total microcystins (free and protein-bound) in fish tissue using Lemieux Oxidation

M. Tabatabaei Anaraki, University of Toronto, Scarborough; S. Bhavsar, Ontario Ministry of the Environment and Climate Change / Laboratory Services Branch; X. Ortiz Almirall, Ontario Ministry of the Environment, Conservation and Parks / Toxic Organic Section; R.S. Shahmohamadloo, University of Guelph / School of Environmental Sciences; A.J. Simpson, University of Toronto Scarborough / Department of Physical and Environmental Sciences

Microcystins (MCs) are cyanobacterial toxins generated from harmful algal blooms (HABs). MCs are hepatotoxins found in freshwater system worldwide and are known for being hazardous to the living organisms. Studies show that MCs are bioaccumulative and exist in two different forms in biota: free and covalently bound to proteins. These toxins can be transferred through the food web to high trophic levels and to human; therefore, MCs can have potential risk to human health. More than 200 MCs structures have been reported. All these variants exclusively contain an unusual amino acid side chain abbreviated Adda (3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4(E),6(E)-dienoic acid). Different approaches, such as Lemieux oxidation, have been explored for the extraction and analysis of free and bound microcystins in aquatic living organisms. Using this method, the oxidative product of Adda, 2-methyl-3-methoxy-4-phenylbutyric acid (MMPB), is analyzed. In this study, factorial design was applied to better optimize the Lemieux oxidation procedure and oxidize MCs in fish tissue (liver and fillet). Moreover, calibration standard, MMPB, was generated in situ by oxidizing four MCs standards spiked to blank fillet/liver. Also, matrix-matched calibration approach was applied to correct the co-elute matrix influence on ion suppression. Finally, 2DLC technique enabled to have the detection limit of microcystin as low as 5ng/g of dried fish. MMPB was analyzed using UPLC-Xevo G2-XS-QToF Mass spectrometer. The optimized oxidation condition along with the optimized solid phase extraction led to the highly linear calibration curve and the recovery ranged from 5 to 2000 ng/g.

RP003 Electron Beam Irradiation for the Remediation and Mitigation of Toxicity of Microcystin-LR in Drinking Water and Treatment Residuals

A. Folcik, S.D. Pillai, Texas A&M University / Interdisciplinary Program in Toxicology; C. Klemashevich, Texas A&M University / Protein Chemistry Laboratory

Harmful algal blooms (HABs) are increasing in occurrence due to rising temperatures and nutrient pollution. These over growths of algae and cyanobacteria pose threats to human and animal health as they often produce an array of hepato- and neuro-toxins. Drinking water sources that are affected by a HAB provide a critical human exposure scenario. The cyanobacterium, Microcystis aeruginosa, is commonly associated with freshwater HABs and is responsible for producing a class of hepatotoxins termed microcystins. Of the over 80 variants of microcystin, microcystin-LR (MC-LR) is the most prevalent and most toxic. Microcystin’s biological activity comes from the unusual amino acid (2S,3S,8S,9S)-3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid (ADDA), which results in the permanent binding and inhibition of protein phosphatase 1 and 2A in humans. Current drinking water removal strategies rely on ozonation and while this may be sufficient for drinking water, it is not a feasible technology for remediating treatment plant sludges containing high amounts of microcystin. Our underlying hypothesis is that high energy electron beam (eBeam) irradiation technology, an advanced oxidation/reduction process, could be effective for the detoxification of microcystin-contaminated water, sludges, and sediments.

Our data suggests that aqueous samples treated with low eBeam doses (< 500 Gy) completely destroy MC-LR as determined through LC-MS/MS. These results were confirmed with the EPA standard method 546 ADDA-specific Enzyme-Linked Immunosorbent Assay (ELISA). Culture samples treated with eBeam required higher doses for inactivation (2 kGy) but still showed dose dependent decreases in toxicity with eBeam treatment. Interestingly, unlike bacterial cells, M. aeruginosa cells lysed within 16 hours of irradiation treatment. eBeam technology, which relies on accelerating electrons, does not involve the use of chemicals. Thus, eBeam technology has the potential to be a sustainable and more cost-effective alternative treatment strategy for such applications.

RP004 Evaluation of algal growth potential (AGP) of Anabaena flos-aquae with water samples from Valle de Bravo to determine Harmful Algal Blooms (HABs)

D.C. Torres, Instituto Politecnico Nacional / Laboratory of Experimental Hydrobiology; F. Martinez-Jerónimo, Escuela Nacional de Ciencias Biologicas, IPN / Laboratory of Experimental Hydrobiology; M. Hernández, Instituto Politecnico Nacional / Zoology

Eutrophication in freshwater lakes are common worldwide and in Mexico; this phenomenon is mostly related to increased nutrient loading, through the discharge of crude and treated wastewaters and agriculture residuals. The excess of limiting nutrients as phosphorus and nitrogen promote the thriving of phytoplankters, some of them responsible for the synthesis of toxins, given place to HABs. The Valle de Bravo dam, located in the central part of Mexico, has a eutrophic status; in this, the cyanobacteria Anabaena has been reported as a HAB forming. The objective of the present study was to determine the AGP of Anabaena flos-aquae in monthly water samples obtained in different sampling stations from Valle de Bravo, during a 6-month cycle. The potential development of HABs was determined through the experimental variation of combinations of N, and P. Growth kinetics of this cyanobacteria was studied for 14 days, in a rich medium (BG11), a minimum medium (OECD), and in OECD medium added with PO4 (9.16x10-8M, 6.2x10-7M, 1.17x10-6M, 1.70x10-5M) at 25 °C and photoperiod 16:8. The water samples from Valle de Bravo were enriched with combinations of P (9.16x10-8M, 8.2x10-7M, 1.70x10-6M) and N (2.80x10-8M, 8.6x10-7M, 1.76x10-6M) to establish
the potential to develop HABs. Growth kinetics were performed for 96 hours at 25 °C and photoperiod 16:8. *Anabaena flos-aquae* accumulates 58% more biomass in the BG11 medium than in the OECD medium. The concentration of P that promotes the growth of the cyanobacteria was 1.17 x10^{-4}M. The maximum AGP of *Anabaena flos-aquae* in Valle de Bravo samples was achieved with the combination of 1.70x10^{-5} M P and 2.80x10^{-4}M N; this tendency was repeated along the time, so we conclude that the P is a nutrient that promotes the growth. The trifactorial ANOVA demonstrated significant differences in the biomass achieved in the water samples in the different sampling points. The differences of AGP in the water samples demonstrated the variability in the nutrients contained in the different sampling points; this could be related to changes in nutrients loading in the basin along the time. Although Valle de Bravo dam has a eutrophic status currently, HABs could be expected if P content increases; this is a factor to take into account to prevent risks during water supply for human consumption.

**RP005 Evaluation of the Algal Growth Potential of Microcystis aeruginosa in Water Samples from Valle de Bravo, México, for the Determination of HABs**

1.17 x10^{-4}M. The maximum AGP of *Anabaena flos-aquae* in Valle de Bravo samples was achieved with the combination of 1.70x10^{-5} M P and 2.80x10^{-4}M N; this tendency was repeated along the time, so we conclude that the P is a nutrient that promotes the growth. The trifactorial ANOVA demonstrated significant differences in the biomass achieved in the water samples in the different sampling points. The differences of AGP in the water samples demonstrated the variability in the nutrients contained in the different sampling points; this could be related to changes in nutrients loading in the basin along the time. Although Valle de Bravo dam has a eutrophic status currently, HABs could be expected if P content increases; this is a factor to take into account to prevent risks during water supply for human consumption.

**RP006 Generating ecotoxicity information on microcystins and prymnesins: A different approach**

There is a lack of information to estimate safe levels for aquatic life concerning the toxicity of natural toxins produced by cyanobacteria and algae. There is even less ecotoxicity information available for prymnesins, a toxin produced by the estuarine golden algae Prymnesium parvum. Given the uncertainty of standards for bacteria and algal toxins, the cost of using them to conduct acute and chronic toxicity tests and their potential impurities, a new approach is proposed using cultures and ambient samples. In this study we have used laboratory cultures of a toxin producing unicellular Microcystis aeruginosa and P parvum and non-toxin producing filamentous *Anabaena flos-aquae*. Each culture was centrifuged to remove each species from its culture media, then resuspended in moderately hard water. The toxin culture, *M aeruginosa* was then frozen/thawed three times at -80 °C following procedures used for ELISA analyses. The non-toxin strain was not lysed. Both 48-hour acute tests and 7-day short term chronic tests were conducted with Ceriodaphnia dubia. Neocloeon triangulifer, Hyalella azteca and larval Pimephales promelas on all strains. A similar lysing procedure was also used on lake water samples. Microcystin concentrations in the lysed samples as high as 74 µg/L did not cause any toxicity greater than the lab water controls to any of the 4-test species. A flos-aquae caused mortality greater than the controls to N triangulifer. For chronic tests 80 L of culture *Microcystis aeruginosa* were grown to achieve a cell density of 2.2625 x 106 cells/ml. No lysed M. aeruginosa treatment levels exhibited any adverse survival effects versus the moderately hard water controls in C. dubia, P. promelas or H. azteca tests. *N triangulifer* tests did not meet test performance criteria. The only adverse effects noted in these tests were the sub-lethal point estimate endpoints for reproduction inhibition (IC50~30.96% [1.37X106 cells/ml]) in the C. dubia bioassay. August 2017 Lake Harsha sample (total # of cells 300,000 cells/ml) was not acutely toxic to any of the 4-test species. P. parvum acute and chronic tests with the same 4 species. C. dubia tests did not meet test performance criteria. The only adverse effects noted in these tests were the sub-lethal point estimate endpoints for reproduction inhibition (IC50~30.96% [1.37X106 cells/ml]) in the C. dubia bioassay. August 2017 Lake Harsha sample (total # of cells 300,000 cells/ml) was not acutely toxic to any of the 4-test species. P. parvum acute and chronic tests with the same 4 species. C. dubia and N. triangulifer exhibited LC50s of 493,850 cells/ml and 121,761 cells/ml, respectively. Additional analyses will be provided based on toxin results and results from 2017 and 2019 whole lake sample tests.

**RP007 Non-targeted analysis of HABs: Linking chemical changes with differential toxicological response**

Harmful algal blooms (HABs) in estuaries and freshwater bodies are increasing in frequency, duration, and magnitude due to eutrophication, salinization, and climate change. However, recent work has shown that known toxins can fail to completely depict health threats of inland HABs, suggesting that additional toxins still need to be identified. Traditional bottom-up approaches to toxin identification, such as Toxicity Identification Evaluation, require time- and labor-intensive studies to systematically identify each component of a HAB mixture or simplify a toxic mixture through fractionation until the toxic component is identified. An alternative approach to hasten toxin identification was developed to alleviate the need to identify each component of the complex algal mixture. Instead, the entire chemical “fingerprint” of algal culture filtrates was examined through non-targeted analysis, and changes in the
LC-HRMS heatmap were linked to changes in toxicological response. Changes in the LC-HRMS heatmaps were then visualized using relative difference plots. These plots compare the intensities of a toxic/sample ion map to the intensities of a nontoxic/reference ion map where compounds with concentrations changing the most between samples are highlighted while compounds at the same concentration in both samples disappear. Prymnesium parvum cultures expressing various levels of acute toxicity were then analyzed using this approach to quickly identify constituents produced in higher amounts as a function of increasing toxicity. These peaks were compared to the peaks highlighted using statistical analysis available in two commercial software packages. Peaks that contributed most to correctly categorizing algal samples as toxic or non-toxic differed between the software packages, so a larger sample size of algae cultures were grown and analyzed in R.

RP008 Probabilistic Aquatic Hazard Assessment of Anatoxin-a with Bioconcentration Experiments in Ictalurus punctatus and Danio rerio

L.M. Lovin, B.W. Brooks, Baylor University / Department of Environmental Science

Water contamination from the neurotoxic cyanotoxin anatoxin-a presents risks to global public health and the environment. Using published data, we calculated expected exceedances of guideline values (GVs) using environmental exposure distributions (EEDs) of surface water data (intra and extracellular toxins) from recreational and potable source waters. Anatoxin-a concentrations exceeded common GV's of 0.1, 1 and 300 μg/L 79.62%, 48.37% and 1.42% of the time, respectively, when blooms occur. 66% of occurrences were from lacustrine ecosystems compared to reservoir, river, coastal and other systems, with almost all data from Asia/Pacific, European and North American regions, highlighting the need for more monitoring efforts in diverse systems and in developing regions. Aquatic toxicity and bioaccumulation data were examined and compared to these environmentally relevant concentrations, though a lack of high-quality data highlights major research needs. Little has been done to describe the influence of pH on the bioconcentration of this ionizable weak base (pKa 9.4). For this reason, uptake of anatoxin-a was evaluated in 1-year old channel catfish (Ictalurus punctatus) exposed to 1 μg/L at two pH levels, 6.5 and 8.5, for 96 h followed by an isochronous depuration. Water, plasma and tissue samples were taken at multiple time points during uptake and depuration then analyzed for anatoxin-a using LC-MS/MS. Contrary to previous studies, we observed no uptake in plasma or tissue during either exposure. However, the exposure concentration was two orders of magnitude lower and represented a more environmentally relevant concentration. An additional uptake study is being conducted with embryonic zebrafish (both chorionated and dechorionated) at higher exposure concentrations and at a pH of 7 and 8.5. Understanding aquatic accumulation and hazards associated with cyanotoxins is vital with cyanobacterial blooms evidently increasing in magnitude, frequency and duration.

RP009 Prymnesium parvum differentially triggers sublethal fish antioxidant responses in vitro among salinity and nutrient conditions

M.E. Franco, Baylor University / Environmental Science; B.N. Hill, Baylor University / US Environmental Protection Agency; B.W. Brooks, R. Lavado, Baylor University / Environmental Science

Significant fish kills have been attributed to *Prymnesium parvum* in coastal and inland waters around the world. However, specific mechanisms responsible for adverse outcomes resulting from this harmful algal bloom (HAB) species remain unclear. In the present study, an in vitro approach was used to examine cytotoxicity and antioxidant responses in fish liver (Hepa-E1 and PLHC-1) and gill (GIB and RTgill-W1) cell lines, following exposure to *P. parvum* grown at different salinities and nutrient concentrations. Cultures from high salinity compromised survival of hepatic cell lines exposed to high dilutions, whereas no significant cytotoxicity was observed for gill cell lines. With respect to control groups, catalase showed significant activity in both gill cell lines, especially RTgill-W1, following exposure to high salinity cultures. High levels of superoxide dismutase were measured in Hepa-E1 cells exposed to all experimental treatment combinations and in RTgill-W1 cells following exposure to high salinity conditions, with respect to non-exposed cells. Glutathione peroxidase activity was also detected at significant levels in Hepa-E1 cells after exposure to cultures from high salinity and the low salinity-low nutrients. Slight GPx increases were only observed in PLHC-1 and GIB exposed to *P. parvum* grown at high salinity. These results suggest that: 1. specific combinations of salinity and nutrient levels may contribute to production and potency of *P. parvum* toxins resulting in sub-lethal effects, and 2. sub-lethal responses are more prominent than cytotoxicity, and that oxidative stress may be a significant adverse effect of toxins produced by *P. parvum*.

Fate and Effects of Metals: Regulatory and Risk Assessment

RP010 Are international Sediment Quality Guidelines protective to tropical fish?

P. Gusso-Choueri, Department of Biology Institute of Biosciences / São Paulo State University (UNESP); G. Pustiglione Marinsek, Unesp; R. Brasil Choueri, UNIFESP / Ciencias do Mar; A. Gonçalves, Department of Biology Institute of Biosciences / São Paulo State University (UNESP); R. Mari, Unesp; L. Maranhão, University Santa Cecilia / Departamento de Ciencias do Mar; G. Guerra, UNIFESP; D.M. Abessa, UNESP Universidade Estadual Paulista Júlio de Mesquita Filho / Department of Biosciences

Sediment quality guidelines (SQGs) used in tropical environments are frequently based in values developed for sub-tropical or temperate environments (e.g. Threshold Effects Levels - TEL and Probable Effects Levels - PEL, or Effects-Range Low - ERL and Effects-Range Median - ERM). The aim of this research was to assess histopathological responses in a tropical estuarine fish exposed to low, moderate and high concentrations of metals according to TEL and PEL. To achieve that, individuals of *Poecilia reticulata* were exposed to a contamination gradient of metal-spiked sediments (Pb, Hg, Cu and Zn), under controlled laboratory conditions, for 3, 7 and 14 days. Levels of metals in sediment were (i) sediment control (no addition of metals) (ii) low level (below TEL), (ii) moderate level (between TEL and PEL), and (iii) high level (above PEL), according to Canadian SQGs. Hepatic histopathological alterations were divided in four distinct reaction patterns and integrated through the estimation of individual histopathological condition indices. Results obtained for metal-exposed organisms were compared with sediment control. The sediments with “high level” were acutely toxic to the organisms causing full lethality within six hours of exposure. Liver histopathological damage was higher than control in the “moderated level” at 3 and 7 days (KW, p< 0.05). The most frequent injuries were congestion of sinusoids, hemorrhage, intracellular edema, hepatocyte hypertrophy, hyperplasia, cholestasis and apoptosis. These results showed that the loads of metals in sediment at permissible levels (between TEL and PEL) led to injuries in the histo-architecture of liver, a vital organ. Surprisingly, the histopathology results of individuals exposed for 14 days to contaminated sediment did not show differences with sediment control individuals. It may be a result of two possible processes: (i) individuals may have defense mechanisms, such as pollutant-sequestering type detoxification system or activation of the antioxidant defense systems; or (ii) organisms may have initiated a process of metal excretion after internal levels reach a certain toxic threshold. Histopathological assessments can provide a reliable and discriminatory data even when biomonitoring is a complex media as sediments. The results of this study suggest that care must be taken to use international SQGs in the sediment management of environments different from those they were derived.
focused on sediments because they act as a reservoir for the introduction of metals into the aquatic environment, especially in heavy metals. The Cienega of Tamasopo natural wetland, which was chosen for its geological characteristics, discharges, and populations along the wetland; 2 samples were taken, before the rains (M1: February 2017) and after the rains (M2: August 2017). 10 cm of the sediment was taken with a PVC tube 30 cm long and 10 cm in diameter. They were placed in plastic containers and transported at 4 °C to the laboratory and then frozen at -20 °C in an LG brand freezer. Once frozen, they were lyophilized for 5 days at 0.060 mBar, -48 °C on a LABCONCO FreeZone6 machine, and subsequently sieved at 420 and 500 μM. Elemental analysis of the samples was performed using dispersive wavelength X-ray fluorescence (WDXRF) on a Bruker model S8 TIGER spectrometer. The results provide information on the characterization and concentration of metals (% by weight and ppm) in sediments in the following order for sampling 1 (M1): C> Ca> Si> Sr> Fe> Na> K> Al> Mg> Mn> Sr> P and for sampling 2 (M2): C> Ca> Si> Na> S> Fe> Al> K Mg> P> Cl> Mn> Sr, which are relevant for subsequent studies on the accumulation and phytoremediation of metals in the Cienega of Tamasopo wetland.

A large water quality database, intended to be used for metal bioavailability corrections, was developed for European freshwaters. The process used to develop this database, and associated preliminary results, will be described. The collated data, obtained from European Union (EU) member states, provides a useful component for future bioavailability assessments. The database will be particularly useful for providing context for individual member states, especially in situations where water bodies cross national boundaries. Additionally, the database provides an opportunity to identify gaps in data coverage and allows member states to target and prioritize resources to enable robust bioavailability compliance assessments for metals. The database was developed using a step-wise process to systematically obtain, screen, and assess the quality of all available data. Data obtained were from EU member states, via various sources including centrally hosted data archives, data compiled by the European Environment Agency, and contacts at environment agencies throughout Europe. Initial data searches focused on obtaining as much information as possible; the targeted information was separated into categories. Essential data were pH, dissolved organic carbon and Ca; desirable data were Mg, Na, K, Cl, SO4^2−, total and dissolved Cu, total and dissolved Ni, total and dissolved Zn and total and dissolved Pb, and added value data were conductivity, hardness, Fe, Al and other trace elements. After compilation, an initial screening was performed to retain data with relevant sample/site information and the specific ‘essential data’. Following the initial screen, a quality assessment was implemented, which was based on the European Chemicals Agency guidance on use of measured data. Preliminary results demonstrate that although large amounts of data are generated on water quality throughout Europe, the public availability of these data, the water quality constituents assessed, the format in which data are provided, and the quality of the data are extremely variable. Where high quality data are available, they can be used for performing bioavailability assessments, which can then identify geographic locations or areas that may be specifically sensitive to metals. Furthermore, by collating all available data, and by retaining datasets with data gaps, it is possible to identify areas where data limitations hinder adequate bioavailability assessments.

Natural freshwater wetlands are becoming scarce as a result of the impact of human activities; most freshwater wetlands show significant changes in their ecology, mainly in relation to species composition, invasion of alien species, sedimentation, pollution, and the hydrological regime. This has resulted in high costs, both in terms of lives and economic well-being, for local communities, mainly through increased flooding, lower soil productivity and increased contamination by agrochemicals. Between 23 and 93% of the contribution of mineral particles in suspension is retained by the wetlands in the form of sediment. In recent years, attention has been focused on sediments because they act as a reservoir for the introduction of metals into the aquatic environment, especially in heavy metals. For this reason, the analysis of sediments and organisms is essential to evaluate the quality of these, because metals are considered pollution indicators. Sediments are important in geochemical investigations because it is important to know the conditions and concentration of pollutants, as well as their relationship. The contamination by heavy metals in sediment has been magnified with the increase of residual discharges to water bodies and agricultural activities. The Cienega of Tamasopo natural wetland, RAMSAR site No. 1814, has suffered discharges from the 15 surrounding populations (approximately 250 inhabitants) over several years and there is no comprehensive analysis of the water-plant-sediment relationship of the site to evaluate your current status. Five sampling points (S1-S5) were designed through the wetland, which was chosen for their geological characteristics, discharges, and populations along the wetland; 2 samples were taken, before the rains (M1: February 2017) and after the rains (M2: August 2017). 10 cm of the sediment was taken with a PVC tube 30 cm long and 10 cm in diameter. They were placed in plastic containers and transported at 4 °C to the laboratory and then frozen at -20 °C in an LG brand freezer. Once frozen, they were lyophilized for 5 days at 0.060 mBar, -48 °C on a LABCONCO FreeZone6 machine, and subsequently sieved at 420 and 500 μM. Elemental analysis of the samples was performed using dispersive wavelength X-ray fluorescence (WDXRF) on a Bruker model S8 TIGER spectrometer. The results provide information on the characterization and concentration of metals (% by weight and ppm) in sediments in the following order for sampling 1 (M1): C> Ca> Si> S> Fe> Na> K> Al> Mg> Mn> Sr> P and for sampling 2 (M2): C> Ca> Si> Na> S> Fe> Al> K> Mg> P> Cl> Mn> Sr, which are relevant for subsequent studies on the accumulation and phytoremediation of metals in the Cienega of Tamasopo wetland.

The U.S. Environmental Protection Agency (EPA) updated its aquatic life ambient freshwater quality criteria (AWQC) recommendation for aluminum. These 2018 final recommended aquatic life AWQC for aluminum supersede the 1988 recommended criteria. Literature searches for laboratory tests published from 1988 to 2017 identified new studies describing the toxicity of aluminum to aquatic life. The EPA supplemented these studies with additional data made available by researchers in late-2017 and 2018. The EPA conducted a full evaluation of available data to determine test acceptability for criteria development. There were insufficient data to establish an estuarine/marine aluminum criterion. This update to the recommended aluminum aquatic life AWQC establishes freshwater criteria magnitude values resulting from the interactions of aluminum and three water chemistry parameters: pH, total hardness, and dissolved organic carbon (DOC). Multiple linear regression (MLR) models were developed to characterize the bioavailability of aluminum in aquatic systems, based on the effects of pH, total hardness and DOC on aluminum toxicity. They used a dataset comprised of 22 chronic tests with the fathead minnow (Pimephales promelas), and 23 chronic tests with an invertebrate (Ceriodaphnia dubia) to evaluate the ability of MLR models to predict chronic toxicity of aluminum as a function of pH, total hardness and DOC water chemistry conditions. These three parameters are considered to be the most influential for aluminum bioavailability and can be used to explain the range of differences in the observed toxicity values. These datasets were supplemented in 2018 with an additional nine C. dubia toxicity tests and nine P. promelas toxicity tests to expand the range of water chemistry conditions for model development. Two models, one for invertebrates and one for vertebrates, were used to normalize freshwater aluminum toxicity values. These separate models correspond to effects on invertebrates and vertebrates due to differing effects of pH, total hardness and DOC on aluminum bioavailability and toxicity, and therefore enable the criteria magnitudes to be calculated as a function of the unique chemistry conditions at a given site. The updated aluminum criteria were derived using these MLR models to normalize the freshwater acute and chronic toxicity data.
RP014 Mercury concentrations in Dolly Varden (Salvelinus malma) living downstream of a formerly used defense site on St. Lawrence Island, Alaska

E. Dominguez, R.R. Jordan, Northern Arizona University / Biology; F.A. von Hippel, C.L. Buck, Northern Arizona University / Department of Biological Sciences; P.K. Miller, Alaska Community Action on Toxics; D. Carpenter, University at Albany-State University of New York / Institute for Health and the Environment

Located west of the Alaska mainland in the Bering Sea, St. Lawrence Island is home to approximately 1,600 Siberian Yupik residents. The island also contains two formerly used defense sites (FUDS), one of which is located at Northeast Cape. Previous research reported local environments at the Northeast Cape FUDS having elevated concentrations of organochlorine pesticides, PCBs, and mercury (Hg). The current study is concerned with Hg contamination at the Northeast Cape. Hg is a toxic metal that acts as an endocrine disruptor in addition to causing neurological and reproductive harm in animals and humans. Due to its lipophilic nature, Hg bioaccumulates and biomagnifies through trophic food webs. Our current research focuses on the quantification of Hg concentrations in Dolly Varden (Salvelinus malma) trout living downstream of the Northeast Cape FUDS. The Dolly Varden was selected for both its relatively high trophic position as well as its cultural significance within the traditional diet of the Yupik residents. Dolly Varden samples were collected from the Suqitughneq (Suqi) River in 2013 and 2015, and stored at -80°C. Samples were sexed using previously described PCR techniques. Using a PerkinElmer FIMS 100 Flow Injector Hg system, Hg content of each sample was analyzed. Based on previous studies of sediments, we expect Hg concentrations in Dolly Varden living downstream of the Northeast Cape FUDS in the Suqi River to be significantly higher than those found upstream. The relevance of the current study is that residents of St. Lawrence Island face health disparities due in part to contaminant exposure. Our study will evaluate Hg concentrations in an important subsistence food, and also has relevance to contamination of higher trophic level wildlife.

RP015 Remote Estimation of DOC for Input into Metals Risk Assessment Models

S.D. Smith, Wilfrid Laurier University / Department of Chemistry and Biochemistry; J. McGeer, Wilfrid Laurier University / Biology; A. El Alem, S. Goubet, K. Chokmani, P. Campbell, University of Quebec / INRS Eau Terre Environnement; J. Cardille, McGill University / Department of Natural Resource Sciences and McGill School of Environment

It is well established that water chemistry can influence the toxic effects of metals; in particular, dissolved organic matter (DOM) can decrease the toxicity of copper, nickel, lead and zinc. This effect, DOM as a toxicity-modifying factor, can quantitatively be predicted using established biotic ligand models (BLMs). For this modelling, DOM is represented by the measurable quantity of dissolved organic carbon (DOC; i.e., mg C/L). Many governments recommend use of the BLM, and other related bioavailability approaches, for establishing site-specific water quality criteria, or for risk assessment, but many local jurisdictions lack the ability to consistently and accurately measure DOC. Remote sensing is an active research field that might be able to address this practical data gap, and help risk assessors and water managers to quantitatively take DOC into account when establishing metal risks for surface waters. The basis for remote sensing of DOC is that dissolved organic matter has colour (referred to as CDOM). It has not yet been demonstrated that remote sensing can accurately convert measurements of CDOM to a prediction of DOC in freshwater environments. As a proof of principle, we propose to study remote, un-impacted, lakes in Quebec using both drone- and Landsat-based methods. Preliminary results were satisfactory and have demonstrated that is possible to explain 90% of the CDOM variance. The estimates of CDOM will be converted to DOC estimates and ultimately, via BLM modelling, to metals risk estimates (i.e., effects concentrations). This risk estimate will be compared to observed concentrations in samples of these same site waters. The comparison will allow us to assess the feasibility, and confidence intervals, of remote sensing as a tool for metals risk assessment, including copper, zinc, lead and nickel. Funding provided by ICA and NSERC.

RP016 Sensitivity analysis of the biotic ligand model: Implications for potential application of remote sensing to estimate dissolved organic carbon

M. Nielsen, Wilfrid Laurier University / Department of Chemistry and Biochemistry; J. McGeer, Wilfrid Laurier University / Biology; S.D. Smith, Wilfrid Laurier University / Department of Chemistry and Biochemistry

The biotic ligand model (BLM) is a tool used to quantitatively evaluate how receiving water chemistry affects the bioavailability of metals. Sensitivity testing can be used to understand how the model outputs vary in response to systematic changes in water chemistry inputs. This will allow users of such models to understand how accurate their input parameters must be for a specified level of confidence in the output. Our focus is on dissolved organic carbon (DOC), which is often the most limiting data for application of BLM approaches to metals risk management. When using remote sensing as a tool to measure DOC, the question stands of how well does DOC need to be estimated in order to produce accurate water quality criteria outputs? This study inputs average water chemistries for both cold and warm water regions with 1%, 10%, 25% and 50% variations in the mean values for all parameters, ignoring correlations between dependent parameters. The variation in the model output criterion continuous concentration for copper as a function of DOC, and other model outputs, will allow estimation of how well DOC needs to be estimated in the context of remote sensing, to be useful for water quality and risk assessments. This study will be Phase I, as correlations will be taken into account in future research. Funding provided by ICA and NSERC.

RP017 Study on Health Effect of Antimony by Short-term Exposure in Rats

W. Gu, S. Tang, Chinese Center for Disease Control and Prevention

The objective of this study was to estimate the health risks caused by the short-term exposure of antimony orally in rats. Methods Sixty healthy Sprague-Dawley rats (male and female) were randomly divided into 6 groups. Rats were given orally antimony potassium tartrate every day with the concentration of 0.06, 0.35, 0.6, 6 and 60 mg/kg. The negative control group was administrated with deionized water. Rats were weighed weekly and sacrificed on the 14th day after exposure. Blood samples were taken from the abdominal aorta to detect blood biochemical indexes. The liver, kidney, spleen, thymus and thyroid glands were weighed and examined for pathology. Results Compared with negative control, the body weight of male rats in the group of 60 mg/kg was significantly decreased (P< 0.05). The liver-to-body ratio was elevated (P< 0.01) and the serum total cholesterol (TC) concentration was decreased (P< 0.01). There were significant differences (P< 0.05) between negative control and the group of 0.6 mg/kg in alkaline phosphatase (ALP), total protein (TP) and glucose (GLU). In the groups of 6 and 60 mg/kg, the concentration of serum T4 was decreased in the male rats (P< 0.05), and the concentration of serum FT4 was increased (P< 0.05), while the FT3 was decreased (P< 0.05) in female rats. Compared with the group of negative control and 0.6 mg/kg, the concentration of serum FT4 was decreased (P< 0.05) in the male and the FT3 was decreased (P< 0.05) in the female. Conclusion It can be caused metabolic changes, including abnormal glycolipid metabolism and thyroid hormone secretion by short-term oral exposure.
Effects of Abiotic Factors and Chemical Additives on the Toxicity of Environmental Contaminants to Aquatic Organisms

RP018 Effect of cutting pile discharges on the distribution and abundance of micro-benthos in soil and water samples
C. Ugochukwu, University of Nigeria, Nsukka / Biochemistry; I.N. Onwurah, University of Nigeria / Biochemistry

During oil drilling, cutting piles which are contaminated with inert emulsion drilling fluids are discharged to the surrounding environment, the sea and the sediment. Hence ecotoxicological tests in an aqueous media will not reflect the conditions found where the discharges were made. Usually presence of fluids will modify the physical structure of the sediment, which will affect the benthic community (the primary food chain). An analysis of sediments from onshore drilling well sites of SPDC W12/14 (active and abandoned) and an adjoining river (Apari) located at 5° 42′ 24″ N and 6° 47′ in Umuajoma farm settlement Oguta 2, Oguta local government areas of Imo state were made. W12/14 is located about 1.2km apart. The adjoining River where discharges were made is 3m water depth and about 500m away from the wellheads. Sediment samples were collected adjacent to the wellhead and at increasing distances of 10m apart. Sediment samples were collected using a diver. Samples were frozen and kept dark until delivered to lab for analysis. Result obtained showed both bacterial and fungal heterotrophic isolates from W12 (active) 10m from wellhead were the least in percentage hydrocarbon utilizers while W14 (abandoned) wellhead gave the highest hydrocarbon utilizers of 0.74% and 5.68% respectively. The results obtained from sediment analysis of the adjoining river where discharges were made showed that AP7 had the highest % hydrocarbon utilizers and AP2 the least % hydrocarbon utilizers of 16.86% and 0.86% respectively. These findings present strong evidence of ecotoxicological effects that cutting piles have on the flora and fauna in the ecosystem especially at the benthic zone.

RP019 Effects of Polycyclic Aromatic Hydrocarbons and Abiotic Stressors on Fundulus grandis Transcriptomics
E. Allmon, J. Serafin, M.S. Sepulveda, Purdue University / Department of Forestry and Natural Resources

Following the 2010 Deepwater Horizon oil spill, extensive research has been conducted on the toxicity of oil and polycyclic aromatic hydrocarbons (PAHs) in the aquatic environment. Many studies have identified the toxicological effects of PAHs in estuarine and marine fishes, however only recently has work begun to identify the combinatorial effect of PAHs and abiotic environmental factors such as hypoxia, salinity, and temperature. This study aims to characterize the combined effects of abiotic stressors and PAH exposure on the transcriptomes of developing Fundulus grandis larvae. F. grandis is a common estuarine species that is regularly exposed to fluctuations in water temperature, salinity, and dissolved oxygen levels, making it an ideal candidate for investigations into the effects of combined stressors in the estuarine environment. In this study, F. grandis larvae were exposed to varying environmental conditions (dissolved oxygen (DO) 2, 6 ppm; temperature 20, 30°C; and salinity 3, 30 ppt) as well as a low dose high energy water accommodated fraction (HEWAF) (ΣPAHs 15ppb). Whole larvae were sampled for RNA and transcriptional changes were quantified using RNA-Seq. Expression analysis revealed that multiple genes associated with cardiac and hepatic function were differentially expressed in larvae exposed to PAHs as well as those exposed to hypoxic conditions. Larvae exposed to PAHs also showed an upregulation in genes involved in xenobiotic metabolism. Results of this study will provide a holistic view of impacts of PAHs and common environmental stressors on early life stage estuarine species.

RP020 Enantioselective effects of 2, 2′, 3, 3′, 5′, 6 polychlorinated biphenyls (PCB-95) on GABAgentic and antioxidant transcriptome in zebrafish larvae
P. Ranasinghe, Clemson University / Environmental Toxicology; C.M. Lee, Clemson University / Engineering and Science Education Department

Nineteen ortho-substituted PCBs are chiral and several have been found enantioselectively enriched in ecosystems. The biological and toxicological characteristics of enantiomers of chiral PCBs may differ, but these enantioselective effects of PCBs have not been fully characterized. PCB-95 (2′, 3′, 5′, 6 polychlorinated biphenyls) is one such chiral PCB of current environmental relevance, that has been known for its neurotoxic effects. PCB-95 is most potent toward modifying ryanodine receptor (RYR) function and Ca²⁺ signaling, however, there could be several other mechanisms that pose neurotoxic effects. In this study, we seek those mechanisms by performing transcriptomic analysis of the GABAgentic profile and the antioxidant system to investigate the enantioselective toxic effects of PCB-95. There is no information available for the adverse effects of embryonic PCB-95 exposure on the GABAergic system and antioxidant system during early development. PCB-95 enantiomers were separated using HPLC and assigned (+) and (-). Gross morphological alterations, tissue up-take, neurotransmitter levels were analyzed along with different GABA-related genes such as GABA (A) receptors, GABA transporters (Gat-1, Gat-3 and V-gat) and glutamic acid decarboxylase (GAD-2). Further, we analyzed genes encoding for antioxidant proteins such as Nrf2, Cu/Zn-superoxide dismutase (Cu/Zn-SOD), manganese superoxide dismutase (Mn-SOD), catalase (CAT), and glutathione peroxidase (GPx). Results suggested that the toxic effects of (-) PCB-95 is more prominent than that of the (+) enantiomer and the racemates. This would also clarify the health risks associated with enantiosomeric enrichment of PCBs in the environment. Further, these data provide a framework for further analysis of stereoselectivity of PCB-95 toxicity on developing nervous system to determine the exact mechanism by which PCB-95 affect the neurogenesis and embryonic of an organism.

RP021 Impact of salinity and temperature on bioconcentration of permethrin in pyrethroid-resistant Hyalella azteca and the subsequent effects on fish
A. Derby, Southern Illinois University / Zoology; K.E. Huff Hartz, Southern Illinois University, Carbondale / Zoology; R.E. Conn, University of California, Davis / Anatomy, Physiology & Cell Biology; School of Veterinary Medicine; P.F. Landrum, Southern Illinois University; M.J. Lydy, Southern Illinois University, Carbondale / Zoology

Global climate change leads to increased variability of environmental parameters in aquatic ecosystems. Two such parameters, salinity and temperature, can have a profound effect on aquatic ecosystem health. Anthropogenic pollutants in aquatic ecosystems may act in conjunction with these environmental changes, compounding the effects on aquatic biota. Some anthropogenic pollutants, such as insecticides, have also caused genetic-level changes to some populations of aquatic biota. While these genetic changes lead to greater resistance to the toxicity, an increased potential for trophic transfer of insecticides via bioaccumulation by resistant populations also may occur. This research aims to determine the influence of the changes in temperature and salinity on bioconcentration of permethrin (a pyrethroid insecticide) in pyrethroid-resistant Hyalella azteca. Bioconcentration experiments conducted at three temperatures (18, 23, and 28°C) and three salinities (0.2, 1.0, and 6.0 ppt) in a 3x3 factorial design involved placing H. azteca in beakers all spiked at the same sublethal concentration of 14C-permethrin. H. azteca were removed from the test at six different time points (3, 6, 12, 16, 24, and 36 h) and analyzed for total permethrin and metabolic products in order to generate a toxicokinetic curve. The data suggest an increase in bioconcentration at higher temperatures and at higher salinities. Subsequent fish feeding experiments with 14C-permethrin-dosed H. azteca similarly showed higher bioaccumulation at higher salinities and temperatures. Taken together, this study provides critical information on how changing environmental conditions can result in higher tissue concentrations in
Advancing the OMICS into Regulatory Frameworks: Case-Studies and Perspectives

**RP022 A novel pipeline for functional extrapolation of toxicity effects across species**
*C. Rivetti, E. Butler, G. Hodges, S. Gutsell, J. Houghton, R. Kanapathywasam, P. Russell, A. White, B. Campos, Unilever / Safety and Environmental Assurance Centre SEAC*

There is a growing recognition that an improved functional understanding of both molecular targets and pathways in the context of the Adverse Outcome Pathway (AOP) framework will allow for a more informed extrapolation to unravel impacts across chemicals and species. Furthermore, growing interest in inferring toxicant impacts to higher levels of organization than individual species requires the development of new methods and models that allow covering the breadth of species that need to be considered across the many trophic levels. An increased understanding of cross-species conservation of pathways and toxicity effects would catalyze a tangible shift toward adopting Next-Generation Risk Assessment (NGRA) approaches. Genomes for a vast collection of different organisms are already publicly available, but there is still an overall lack of clear-cut functional annotation, often inferred from sequence-homology. It is also important to consider that even though upstream signalling processes are likely to be similar across species, downstream events may diverge, resulting in very different apical outcomes. A deeper understanding of the conservation of the physiological cascades of whole pathways across species is critical to assess conserved response patterns and associated (adverse) outcomes. In this perspective, protein families inferred on structural domains may offer a more relevant metric of relative functional conservation within a given pathway, than the individual gene level. The overall goal of this project is to facilitate the process of providing scientific evidence to the process of functional pathway re-construction, thus reducing the uncertainty inherent to cross-species extrapolation. Using available knowledge from different disciplines i.e. comparative biology, functional genomics and bioinformatics and chemistry, we created a new pipeline for functional extrapolation of toxicity effects across species to enable the identification of relevant pathway-conservation levels. We foresee that this approach will contribute in adding weight-of-evidence to support risk-based decisions using functional conservation of pathways across species and improving the confidence in how we can use data from multiple sources.

**RP024 EcoToxChip: A toxicogenomics tool for chemical prioritization and environmental management**
*N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; J. Head, McGill University / Natural Resource Sciences; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; J. Xta, McGill University / Institute of Parasitology; G. Hickey, McGill University / Natural Resource Sciences; S. Maguire, McGill University / Desautels Faculty of Management*

Here we provide an overview of our Large-Scale Applied Research Program (LSARP) grant from Genome Canada that aims to develop, test, validate, and commercialize quantitative PCR arrays (EcoToxChips) and a data evaluation tool (EcoToxXplorer.ca) for the characterization, prioritization, and management of environmental chemicals and complex mixtures of regulatory concern. In Project Phase 1, EcoToxChips are being developed for laboratory model species representing the most important vertebrate groups in ecological risk assessment (fish-fathead minnow; bird-Japanese quail; amphibian-Xenopus laevis). Model species (adult and early-life stage, ELS) are being exposed via standardized tests to 8 environmental chemicals representative of natural resource/environment sectors of Canadian concern and also ones that impact a wide biological space (EE2, chlorpyrifos, benzo[a]pyrene, lead, fluoxetine, selenomethionine, trenbolone, HBCD) (Activity 1). An integrative systems approach based on functional ‘omics (combined global transcriptomic and proteomic profiling, targeted metabolome) and physiological analyses across levels of biological organization is being applied to characterize relevant toxicity pathways including adverse outcome pathways, AOPs (Activity 2); from this, and other resources, species-specific EcoToxChips consisting of 384 environmentally-responsive genes of regulatory concern are being informed, built, tested, and optimized (Activity 3). EcoToxChip performance will be validated (and further optimized) through an inter-lab study with our collaborators (Activity 4). Under Activities 5-7, knowledge from Phase 1 is being translated to 3 native species (i.e., fish: rainbow trout; bird: double-crested cormorant; amphibian: Northern leopard frog). EcoToxXplorer.ca provides intuitive bioinformatics support and is modeled upon our successful cloud-based tools (metaboanalyst.ca). To position the team advantageously with regard to the commercialization and institutionalization of the deliverables, our GE3LS research will produce and leverage social science knowledge about the phenomenon of “institutional entrepreneurship.” The anticipated socioeconomic benefits associated with the adoption of our deliverables include, more focused animal testing, improved regulatory decision-making, and cost-efficiencies. Here we provide a 36 month update of our project (www.ecotoxchip.ca).
**RP025 EcoToxDB: A toxicogenomics knowledgebase to query, browse and interrogate chemical-gene-exposure networks**  

Q. Soufan, McGill University / Institute of Parasitology; J. Ewald, P. Liu, McGill University; E. Boulangier, McGill University / Natural Resource Sciences; A.J. Masse, University of Saskatchewan / Toxicology; J. Head, McGill University / Natural Resource Sciences; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; J. Xia, McGill University / Institute of Parasitology

The EcoToxChip project aims to develop, test, validate, and commercialize quantitative PCR arrays (EcoToxChips) and a data evaluation tool (EcoToxXplorer.ca) for the characterization, prioritization, and management of environmental chemicals and complex mixtures of regulatory concern. EcoToxDB is a knowledgebase that provides convenient access to all gene expression profiles generated using the EcoToxChip (as well as a range of other data such as metabolomics, proteomics, transcriptomics, chemical residue values, histology). It is a resource to query and browse results of exposure studies of several key model and ecological species of relevance to the Canadian and international regulatory community. Currently, EcoToxDB holds data from six species, eight chemicals, 47 exposure studies, 409 samples and annotations for thousands of genes. EcoToxDB will promote understanding of the effects of chemical hazards on ecological receptors of regulatory concern or interest. In EcoToxDB, users will be able to build chemical-gene-exposure networks and explore deeper scientific questions. Data can be projected onto a 3D space for interactive exploration. EcoToxDB will be hosted on a MongoDB server and will be accessible through an intuitive web interface. A set of application programmable interfaces (APIs) will also be developed for efficient loading of data into other related applications. Through an associated FTP site, protocol files, and raw and processed versions of EcoToxChip internal data will be available for download. EcoToxDB.ca will contain demonstrations, FAQs, tutorials, and other resources to best assist all levels of users. The database is designed to help researchers and scientists explore results of exposure studies on ecological species. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

**RP026 Effects of early life stage exposure of largemouth bass to a common Chesapeake Bay contaminant (atrazine) or a model estrogen (17α-ethinylestradiol)**  

Endocrine disrupting contaminants (EDCs) are of continuing concern in the Chesapeake Bay watershed (CBW). The incidence of testicular oocytes in black bass from CBW has been correlated with atrazine. Fish early life stages are of particular concern in agricultural areas, as a spring influx of pesticides coincides with spawning and early development. Our objectives were to expose newly hatched largemouth bass (LMB, Micropterus salmoides) fry to graded concentrations of atrazine or the model estrogen 17α-ethinylestradiol (EE2) during sexual determination and differentiation (from 7 to 80 days post-spawn), and monitor histological development and transcriptomic changes in gonad tissue. Concentrations of atrazine during the course of the exposure averaged 0.91 (± 0.06), 9.87 (± 0.68), and 105.09 (± 8.57) μg ATR/L, while concentrations of EE2 averaged 0.84 and 7.34 ng EE2/L. We monitored sex ratios, growth, and development of the gonads through histological examinations. We measured global gene expression in gonad tissue of males and females, in order to develop testable hypotheses for potential biochemical pathways and cellular mechanisms leading to altered gonad development and ultimately impairment of reproductive function. We observed a 100 % female sex ratio in LMB exposed to EE2 at 10 ng/L, presumably due to sex reversal of males. Overall, there was an absence of response to ATR in growth, sex ratio, and gonad morphology. Many genes were differentially expressed (DE) between sexes. Overall, males were more responsive to treatments than females. Few DE genes were common between ATR treated males and females. Most responsive genes in males were downregulated. Most responsive genes in females were up regulated, particularly male specific genes in females. In the 1 ng/L EE2-exposed fish, of those contigs differentially expressed in gonad (3811 in males, 2120 in females), 721 were identified in both sexes. There was a strong correlation of log fold changes between males and females in these 721 contigs (R² = 0.92), suggesting that some pathways responsive to EE2 exposure are not sex-specific. We found differential expression in male gonad in LMB exposed to EE2 at 1 ng/L of several genes involved in reproductive development and function, including star, cyp11a2, vasa, wnt5b, cypla, and samhd1. Expression of star, cyp11a2, and cypla were also responsive to atrazine exposure.

**RP027 Effects of PFBS and PFBA exposure on Lipids during the Development of Rainbow trout (Oncorhynchus mykiss)**  

J. Yang, Y. Gong, C. Wang, S. Su, Y. Xie, Z. Yang, J.C. Raine, University of Saskatchewan / Toxicology Centre; P.D. Jones, University of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences

Per-and poly-fluorinated chemicals(PFCs) are a concern in the 21st century due to their persistence in the environment. Perfluorobutane sulfonic acid (C4, PFBS) and perfluorobutanoic acid (PFBA) are among the most widely used short-chain perfluoralkyl sulfonic acids, which are applied in a variety of areas instead of the long-chain PFAS (Perfluorooalkylated substance). However, few studies focus on their potential effects on lipid metabolism in aquatic animals, since they play a vital role in the early development of fish. Lipids like cholesterol (TC), triglycerides (TG) and phosphatidylcholine (PC) are important for many biological functions including formation of cell membranes and synthesis of hormones, which could be disrupted by PFBA and PFBS. In this study, Early life stage of rainbow trout were exposed to the different concentrations of PFBS and PFBA, and samples were taken throughout development. We aim to find changes in functional lipids affected by PFBS and PFBA, which will alter the fat content of these cold water fish. Thermo obitrap LC-MS/MS was used to identify lipid profiles in these fish. Data consolidation, normalization, statistical analysis and databasing are also performed to get a more in-depth insight into the mechanisms of action of these chemicals. Our data could provide new information on lipid metabolism in trout and benefit future ecotoxicological assessment of PFBS and PFBA.

**RP028 Genome-wide analysis of cadmium-induced germline mutations over 1,123 generations**  

N. Keith, Lawrence Berkeley National Laboratory / Environmental Genomics and Systems Biology; C.E. Jackson, S. Glabolt, Indiana University / O’Neill School of Public and Environmental Affairs; K. Young, Indiana University, Bloomington / Department of Molecular and Cellular Biochemistry; M. Lynch, Arizona State University / Biosign Institute; J. Shaw, Indiana University / O’Neill School of Public and Environmental Affairs

Germline mutations provide the raw material for all evolutionary processes and contribute to the occurrence of spontaneous human disease. Yet despite interacting daily with an increasing number of chemicals that are potentially mutagenic, precise measurements of the rate that chemicals change the genome-wide rate and spectrum of germline mutation are lacking. A large-scale Daphnia pulex mutation-accumulation experiment was propagated in the presence and absence of an environmentally relevant cadmium concentration to quantify the influence of chemical stress on germline mutational processes. Cadmium exposure increased
the mutation rate in intergenic regions and decreased the exon mutation rate. The increased intergenic mutation rate under cadmium exposure was caused by an elevated rate of A:T → G:C mutations, while the decreased exon mutation rate is the result of a reduced C:G → G:C mutation rate in genes under cadmium exposure. Oxidative stress-associated G:C → T:A mutations are elevated by cadmium, but only in mutation clusters. We suggest the increased A:T → G:C rate in intergenic regions is caused by either the increased usage of error-prone DNA polymerase eta, or cadmium interference with the zinc-finger domain of Polymerase eta. Further, our results suggest the reduced generic C:G → G:C mutation rate under cadmium exposure is linked to cadmium reducing the prevalence of mutagenic 5-hydroxymethylcytosine positions. These results show that chronic, chemical exposure can drastically change the genome-wide rate and regional distribution of mutations. Our results demonstrate that a more concentrated effort is needed for understanding genome-wide, germline mutation patterns in the presence of chemical exposures in order to more accurately predict population outcomes and the occurrence of human disease.

RP029 gn thinking to inform the selection and organization of genes on the EcoToxChip

N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; J. Ewald, G. Pain, McGill University; Y. Jeon, J. Head, McGill University / Natural Resource Sciences; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; J. Xia, O. Soufan, McGill University / Institute of Parasitology; G. Hickey, McGill University / Natural Resource Sciences; S. Maguire, McGill University / Desautels Faculty of Management; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre

Our Large-Scale Applied Research Program (LSARP) grant from Genome Canada aims to develop, test, validate, and commercialize quantitative PCR arrays (EcoToxChips) and a data evaluation tool (EcoToxXplorer.ca) for the characterization, prioritization, and management of environmental chemicals and complex mixtures of regulatory concern. To help ensure that project deliverables are adopted by end-users, design thinking steps are being incorporated throughout the project. The methods underpinning design thinking include 6 steps: 1) Collect data to understand users; 2) Determine how to address users’ issues; 3) Generate product ideas; 4) Build product prototypes; 5) Test prototypes; and, 6) Make product. At last year’s SETAC NA meeting we outlined how “micro-level” features of the project deliverables were identified, and here we detail how the initial version of the EcoToxChip (i.e., version 1 of the Japanese quail EcoToxChip) was realized. The design of the EcoToxChip was driven by information we gathered over the past two years from key users and user groups, and articulated in last year’s presentation. From these interactions, key design elements of the EcoToxChip include the need for a range of QC wells, target genes identified by regulatory users, toxicology scholars, and bioinformatic approaches, a range of methods to organize the genes (e.g., gene sets, toxicity pathways), and case studies demonstrating EcoToxChip performance alongside other platforms. The initial version of the EcoToxChip contains 370 gene targets and 14 QC wells (5 housekeeping genes plus 9 technical controls). The 370 gene targets included 76 genes based on input from the regulatory community (i.e., from interviews, literature reviews, and conference presentations) and 212 genes from toxicology scholars within the project team (i.e., genes from the Avian ToxChip plus manual curation of CTD, Reactome, Gene Cards, Path Cards, Qiagen RT2 Profiler Array for Molecular Toxicology), with 19 genes overlapping between the two groups. The remaining genes were selected from a meta-analysis of RNAseq data generated within the project from hepatic tissue of early-life stage Japanese quail following exposure to 8 different chemicals. A range of factors were considered in a tiered approach (e.g., fold-change, p-value, abundance, impacted by multiple chemicals, presence of gene in modules defined by the project team) from which genes were identified and prioritized for inclusion on the EcoToxChip. In addition to detailed information on the specific genes and how they were organized into modules, we will report on the technical performance of the v1 Japanese quail EcoToxChip (i.e., inter- and intra-lab variation, EcoToxChip vs. RNA-seq results).

RP030 Household Garbage Bio-decomposition Influences the Abundance and Diversity of Antibiotic Resistome and Microbiome

Z. Liang, G. Li, Guangdong University of Technology / School of Environmental Science and Engineering; T. An, Guangdong University of Technology / Institute of Environmental Health and Pollution Control; Y. Zhang, Guangdong University of Technology / School of Environmental Science and Engineering

The development of antimicrobial resistance (AMR) bacteria is one of the most serious threats to global public health. Studies have revealed that, landfill, as the most common and essential strategy for the disposal of municipal solid waste, appear to contribute significantly to the acquisition of AMR by bacteria by horizontal DNA transfer, and gradually become a huge potential reservoir for breeding antibiotic resistance genes (ARGs). However, until now, no holistic assessment, including ARGs abundance and diversity, has been performed on household garbage system that contrasts decomposition processes and microbial communities. To better understand the impact, we studied the dynamics of ARGs and the bacterial community composition during household garbage decomposition in a bench-scale bioreactor. The result showed that household garbage (meat, vegetables and fruits) decomposition changed the ARGs diversity. Antibiotic deactivation and efflux pump were the two most dominant resistance mechanisms, followed by cellular protection. The total enrichment of ARGs in meat is the highest, followed by vegetables and fruits. The trends in variation for each antibiotic type were different among different samples. In a word, ARGs were detected with increased abundance and diversity, and distinct patterns, and were enriched during decomposition. The compositions of bacterial communities displayed distinct temporal variations during decomposing at the phylum level. ARGs patterns were significantly correlated with bacterial community structures, suggesting that the dynamic of ARGs was strongly affected by bacterial compositions during decomposing. This study documented elevated diversity and abundance, remarkable enrichment of ARGs, and significant correlation between ARGs structures and bacterial community compositions in household garbage decomposing. These results imply that refuse decomposition may lead to the spread of ARGs.

RP031 The genome of the cosmopolitan rotifer Brachionus plicatilis: Genome-wide expression of CYP450s in response to chlorpyrifos and 2-ethyl-phenanthrene

J. Park, J. Lee, Sungkyunkwan University

The marine monogonont rotifer Brachionus plicatilis is considered a suitable model organism for ecology, evolution, and ecotoxicology. In this study, we assembled an characterized the B. plicatilis genome. The total length of the assembled genome was 106.9 Mb and the number of final scaffolds was 716 with the N50 value of 1.15 Mb and a GC content of 26.75%. A total of 13,899 genes were annotated after manual curation. To demonstrate the use of whole genome data, we targeted one of the main detoxifying enzyme of phase I detoxification system and identified a total of 28 cytochrome P450s. Based on the phylogenetic analysis using the maximum likelihood, 28 B. plicatilis-CYPs were apparently separated into five different clades, namely, clan 2, 3, 4, mitochondrial, and 46. To better understand the CYPs-mediated xenobiotic detoxification, we measured the mRNA expression levels of the identified CYPs in response to chlorpyrifos and 2-ethyl-phenanthrene. In addition, xenobiotic-sensing nuclear receptor response element sequences were identified in the 5 kb upstream of promoter regions of 28 CYPs from the genome of B. plicatilis, indicating that these XNR are likely associated with detoxification potential in the rotifer. Overall, the assembled B. plicatilis genome presented here will
be a useful resource for a better understanding of the molecular ecotoxicology in the view of molecular mechanisms underlying toxicological responses, particularly on xenobiotic detoxification.

**RP032 Toxicogenomic Assessment of Complex Chemical Signatures in Double-Crested Cormorant Embryos from Varibly Contaminated Great Lakes Sites**

X. Pu, Nanjing University / Environment; D. Crump, J. O’Brien, Environment and Climate Change Canada / National Wildlife Research Centre; H.M. Chan, University of Ottawa / Department of Biology

Using omics approaches to monitor complex mixtures in the environment is challenging. The majority of these studies have focused on using well-characterized laboratory animals. However, there is a lack of studies using wild species that are naturally exposed to contaminated mixtures. Here, we examined the chemical residues (including 209 PCB and 8 PBDE congeners) and gene expression (47 genes using a ToxChip PCR array) in embryonic liver tissue of double-crested cormorants (DCCOs), a sentinel wild avian species that breeds extensively across North America. DCCO embryos were collected from 5 Great Lakes breeding colonies and one non-Great Lakes site. The objective was to assess the ability to predict complex chemical space by using transcriptomics responses measured in DCCOs. A gene regulatory network inference algorithm Context Likelihood of Relatedness (CLR) was used to infer/prioritize chemicals that may influence the expression of specific genes. For instance, the concentration of PCB-25 showed the highest relevance to dysregulation of the phase I metabolizing enzyme, CYP1A4. Furthermore, a partial least squares (PLS) regression model was applied to evaluate the performance of gene expression data for predicting chemical space. The best model used the expression of 20 genes to predict the concentration of several specific chemicals (e.g. PCB-25 and PCB-37). Overall, toxicogenomic evaluation in a wild avian species, the double-crested cormorant, may represent a novel approach for mixture assessment.

**Aquatic Toxicology, Ecology and Stress Response**

**RP033 Ex vivo Comprehensive Multiphase Nuclear Magnetic Resonance Spectroscopy of Intact Daphnia magna**

R. Ghosh Biswas, University of Toronto, Scarborough / Department of Chemistry; B. Fortier-McGill, University of Toronto / Department of Physical and Environmental Sciences; R. Soong, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; D. Schmidig, P. De Castro, S. Graf, Bruker BioSpin AG; S. Wegner, F. Busse, Bruker BioSpin GmbH; J. Struppe, M. Fey, Bruker Corporation; M.J. Simpson, University of Toronto / Department of Chemistry and Department of Physical and Environmental Sciences; A.J. Simpson, University of Toronto Scarborough / Department of Physical and Environmental Sciences

Daphnia magna (water fleas) are freshwater, keystone species and are model organisms for environmental toxicology studies. These organisms can provide key insight into the toxic-mode-of-action of environmental toxins. To fully comprehend the effects of these pollutants, the natural biological changes within the Daphnia must be understood first. Nuclear Magnetic Resonance (NMR) spectroscopy is a non-invasive analytical technique which allows for the study of whole organisms both ex vivo and in vivo. Natural biological samples contain many different phases, for example a living organism contains liquids (blood, fluids), gels (tissues) and solids (bone, shell). Unfortunately, NMR research typically tend to focus on one aspect of the sample (solution or solid state). This research uses a novel NMR technique, Comprehensive Multiphase NMR (CMP-NMR), to study different phases (solids, solutions and semisolids) in unaltered samples. This study illustrates multi-phase spectral editing techniques to follow ex vivo samples of Daphnia magna over various life stages and over different generations. The research demonstrates how spectral editing approaches in combination with multiphase NMR help uncover novel information on biological processes. In summary, ex vivo NMR proves to be a very powerful approach to study whole organisms in a comprehensive manner and should provide very complementary information to in vivo based research.

**RP034 Examining the impacts of superparamagnetic iron oxide nanoparticles on Daphnia magna with an integrated in/ex vivo nuclear magnetic resonance approach**

A. Jenne, University of Toronto / Environmental Chemistry; R. Soong, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; B. Wu, University of Toronto Scarborough / Department of Physical and Environmental Science; O. Gruschke, Bruker BioSpin GmbH; P. Monks, C. Moloney, University College Dublin / School of Chemistry; D. Gross, K. Zick, V. Nieman, Bruker BioSpin GmbH; D. Broughman, University College Dublin / School of Chemistry; A.J. Simpson, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

Superparamagnetic Iron Oxide Nanoparticles (SPIONs) are becoming environmental contaminants of considerable concern as their medical and industrial applications grow. SPIONs exhibit toxicity, especially in the aquatic environment, however the mechanism of toxicity, and the long-term impacts are not well understood. Daphnia magna (water fleas) are keystone species and model organisms for research. Due to their abundance in freshwater worldwide, and well understood life-cycle, they are one of the most common species used in toxicity testing. The goal of this research is to combine magnetic resonance imaging, relaxometry, and metabolomics (both in vivo and ex vivo) to provide a holistic and integrated understanding of SPION toxicity. SPIONs are commonly used in magnetic resonance imaging (MRI) as negative contrast agents, meaning they cause a localized darkening in the image. As such, MRI holds the potential to explain if the SPIONs compartmentalize within the organisms. However, MRI provides no information as to what chemical components within the organism bind with the SPIONs. As the SPIONs are paramagnetic they lead to faster relaxation with components in close proximity, and relaxation-chemical shift correlation can potentially identify the main components inside the organisms (protein, lipids, carbohydrates, etc.) that bind with them. Finally, metabolomics provides insight into how the organisms respond to exposure, which helps in the understanding of the toxic-mode-of-action of the nanoparticles. Here 1H-13C 2D nuclear magnetic resonance (NMR) spectroscopy is applied in vivo and ex vivo to identify metabolic fluxes during exposure. To increase the understanding of the toxic impacts of these nanoparticles, a range of SPIONs with different core and ligand sizes are studied, totaling nine samples. Results from imaging studies show darkening of all samples, with large variations in the relaxation values, indicating a higher rate of uptake with the largest SPION sizes. Preliminary results from the relaxometry studies show interactions with amino acids and proteins, likely due to the stress response of these organisms, but further elucidation of these results, combined with the metabolomics results providing insight on the toxic-mode-of-action are pending. To our knowledge this is the first time MRI, relaxometry, and metabolomics have been combined to provide a comprehensive overview of toxicity inside whole organisms.

**RP035 The determination of the optimal protocol for in vivo nuclear magnetic resonance studies of 13C enriched organisms for use in toxicity testing**

M. Bastawrous, M. Tabatabaei Anaraki, University of Toronto, Scarborough; R. Soong, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; W. Bermel, Bruker BioSpin GmbH; H. Heumann, Silantes GmbH; A.J. Simpson, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

The continual release of toxic chemicals into the environment provides an increased need for new analytical techniques that can identify why chemicals are toxic at a molecular level, and which ones cause detrimental biological impacts. The ultimate analytic solution is to “see inside” living organisms and extract molecular information directly using in vivo NMR.
Nuclear Magnetic Resonance (NMR) spectroscopy, which is the only modern tool with resolution that permits in-depth, non-destructive metabolic profiling. Owing to the sensitivity of 1H NMR, inverse detected multidimensional (2D) experiments are often ideal for in vivo studies, as such many modern NMR probes are optimized for this purpose. Despite its sensitivity, 1H detected NMR experiments can suffer from multiple drawbacks compared to 13C, such as reduced spectral width, faster relaxation, and complications from water requiring suppression, especially for in vivo samples. The increased sensitivity of NMR cryoprobe technology has greatly improved the capability of 13C detection which has great potential for metabolomic studies, offering a very interesting alternative for in vivo NMR studies of 13C enriched organisms. In this study we compare inverse (heteronuclear single quantum coherence or HSQC) and observe (two-dimensional heteronuclear 13C-1H NMR or HETCOR) experiments on inverse (triple resonance inverse probe or TCI) and observe (broadband observe probe or BBO) prodigy cryoprobes for collecting metabolic data on 13C enriched Daphnia magna. The key questions being: Which experiment identifies the most metabolites? Or are the two complementary and ideally run together? In in vivo research, data is continuously collected, as such cryoprobes cannot be changed during a study. Assuming both HSQC and HETCOR need to be run, is it best to run them on a TCI (optimal for 1H detected HSQC) or BBO (optimal for HETCOR but compromised for HSQC) probe? To answer these questions and determine an optimal protocol for in vivo studies, HSQC and HETCOR experiments are compared on TCI and BBO cryoprobes using the keystone species D. magna. The results will consider in detail the signal response of various metabolites in controlled and stressed conditions. This will assist in determining which experiment-probe conditions provide the most informative response trends within living organisms.

RP036 Exposure to glyphosate produces acute and transgenerational toxic effects in the cladoceran Daphnia exilis

M. Hernandez, Instituto Politecnico Nacional / Zoology; A. Rodriguez-Miguel, L. Martinez-Jeronimo, F. Martinez-Jeronimo, Escuela Nacional de Ciencias Biologicas, IPN / Laboratory of Experimental Hydrobiology

The use of agrochemicals has increased in the last decades in response to the higher food demands of a growing world population. Glyphosate is the herbicide most worldwide used; it is commercialized in more than 130 formulations that are applied to at least 100 different crops, including GMOs. The reported toxicity of glyphosate and its commercial formulations are mainly referred to acute effects, but little is known about glyphosate toxicity in freshwater biota across generations. The objective of this study was to determine the transgenerational effects produced by Faena(R), one of the most commercialized glyphosate formulations, in the cladoceran Daphnia exilis. Population growth, fecundity, metabolic biomarkers, and the size of progeny was measured. The acute toxicity of glyphosate in D. exilis was determined at 48 h; tested concentrations were 2, 3, 4, 5, 6 and 7 mg L-1 at 25°C, 16:08 h photoperiod, with no food supply during assays. In the chronic toxicity studies, D. exilis individuals were exposed to sub-lethal glyphosate concentrations equivalent to the LC0.1 (2.09); LC1 (2.49) and LC10 (3.15) (mg L-1), during 21 d at 25°C, 16:08 photoperiod, feeding with 8x105 cells mL-1 of the microalgae Pseudokirchneriella subcapitata (F1). Neonates of the third reproduction were used to prepare the F2 generation under the described experimental conditions for the same glyphosate concentrations. The determined median lethal concentration (LC50) was 4.22 mg L-1. Survival, accumulated progeny, and the number of clutches in F1 were significantly higher than values observed in F2. Age to first reproduction was significantly higher in F1 respect to F2 in the LC1 and LC10. The metabolic biomarkers in D. exilis exposed to glyphosate were determined only in F1 because herbicide inhibited the reproduction in F2. In F1 the carbohydrates content was decrease significantly in LC1 and LC10; nevertheless, proteins content was increase for the same concentrations. The lipids were not affected in any concentration of glyphosate. In general, the size of neonates (body and total lengths, and body width) was significantly decreased in F2 progeny. Glyphosate caused significant toxic effects in the second generation of D. exilis, indicating that because of transgenerational effects, the sensibility of individuals whose parents grown exposed to the toxicant, increased. Obtained results warn about accumulated effects in zooplankton populations exposed to chemical stressors.

RP037 Glyphosate (FAENA®) produced chronic toxic effects in the tropical cladoceran Ceriodaphnia rigaudi

Freshwater bodies are complex and sensitive systems which are stressed constantly by different pollutants. The use of pesticides produces negative impacts in non-target organisms, including aquatic biota. Glyphosate is the herbicide most worldwide used in agriculture, with no restrictions for the many of the commercial formulations; as a consequence, its occurrence in aquatic ecosystems is common. Different studies have demonstrated the toxic effects that glyphosate produce in hydrobiots. The toxicity of chemical stressors aimed to determine its ecological risk assessment; it is indispensable to establish their acute and chronic effects. The objective of this study was to evaluate the effects on reproduction and at the biochemical level produced in the freshwater cladoceran Ceriodaphnia rigaudi exposed to a glyphosate-based herbicide. Acute toxicity were determined (at 48 hours) obtaining the LC50 of 1.09 mg L-1. Demographic effects, and biochemical responses by chronic exposure at concentrations of 0.34, 0.44, 0.55, 0.62 and 0.72 mg L-1, were measured (complete life cycle). Glyphosate produced a delay of one day in the age at first reproduction at concentrations of 0.44, 0.55, 0.62 and 0.72 mg L-1, while total progeny decreased 35% in the higher concentration (0.72 mg L-1). The number of clutches was significantly reduced (p<0.05), and aboritions were recorded at the concentrations of 0.62 and 0.72 mg L-1. The concentration of macromolecules was in the order: lipids > proteins > carbohydrates. There was a significant increase (p<0.05) of lipids and proteins in the highest glyphosate concentrations (0.62 and 0.72 mg L-1), whereas carbohydrates decreased as the toxic concentration increased. The results obtained in this study demonstrate that glyphosate-based commercial formulations produce negative effects on non-target organisms during chronic exposures, warning about impairing consequences on natural aquatic ecosystems indirectly affected by glyphosate pollution.

RP038 Vallisneria americana Responses to Aquatic Glyphosate Exposure

M. Opincarne, University of Florida / School of Natural Resources and Environment

Glyphosate-based herbicides are heavily applied on land and freshwater bodies for control of broadleaf plants and grasses. Glyphosate molecules interrupt completion of the shikimate pathway by inhibiting 5-enolpyruvylshikimate-3-phosphate (ESPS) synthase, which prevents synthesis of three amino acids that are critical for plant growth and structural integrity. At sufficient exposures, amino acid concentrations are so diminished that the plant cannot grow and dies. All plant life, including seagrasses and aquatic plants, contain the shikimate pathway responsible for glyphosate’s functionality. We theorize that at low concentrations, non-target species including submerged aquatic vegetation respond to glyphosate exposure. Because of rapid hydrolysis in fresh water, lethality is not anticipated in submerged plants. However, we are interested in assessing whether sublethal exposure concentrations impact the fitness of submerged plants. In this study, we expose a native and ecologically significant Florida plant Vallisneria americana to a range of glyphosate concentrations in a laboratory setting. We will assess indicators of plant health that are known in other submerged non-target species to be affected by glyphosate, such as photosynthetic efficiency and biomass production. We will also take a novel approach to evaluating plant response by investigating shifts in phytochemical profiles such as lignins, flavonoids and alkaloids which require shikimate products for synthesis.
Because V. americana possesses glyphosate’s mode of action, we hypothesize that exposed plants will exhibit a dose-dependent decline in growth and photosynthetic capacity. We also anticipate that decreasing concentrations of shikimate-dependent amino acids will alter relative amounts of secondary compounds dependent upon these amino acids for their synthesis. As ecosystem engineers, seagrasses such as V. americana are critical in maintaining habitability of sensitive aquatic environments currently in decline. This experiment will provide insight into the potential role of aquatic glyphosate in V. americana decline. By looking at indicators of plant health as well as alterations in secondary metabolite profiles, we hope this study will illuminate whether glyphosate impairs the fitness and phytochemical defenses of submerged plant species.

RP039 Transgenerational effects in biomarkers of Daphnia curvirostris chronically exposed to glyphosate
L.L. González-Trujillo, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional / Department of Zoology; F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biológicas, IPN / Laboratory of Experimental Hydrobiology

The presence of pesticides in freshwater ecosystems produces toxic effects in aquatic biota and can also affect their future generations. The use of biomarkers for the evaluation of toxic pollutants in hydrobiota is an important approach to determine transgenerational effects at the sub-individual level. We aimed to determine if the chronic exposure to the herbicide glyphosate, as the active ingredient (AI) and as the commercial formulation (FAENA(R)), produces transgenerational effects in the cladoceran D. curvirostris, through the evaluation of the content of macromolecules and the oxidative stress response. The acute toxicity of AI and FAENA(R) was determined. After this, five sublethal concentrations (equivalent to the LC_{0.01}, LC_{0.1}, LC_{1}, LC_{5}, and LC_{20}) were chosen to determine in the second generation (F2) transgenerational effects during 21 days. Also, remnant effects in the F2 growing in a medium free of the herbicide were assessed (progeny in the recovery phase, F2R). The concentration of macromolecules (proteins, carbohydrates, and lipids), the analysis of antioxidant enzymes (superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GPx)), as well as the oxidative damage products (oxidation of lipids and proteins), were determined. The results indicate that neonates and adults of F1 exposed to FAENA(R) showed a significant reduction in macromolecules content; in the F2 a smaller decrease was documented, and in the F2R, no effects were observed. FAENA(R) induced oxidative stress on neonates of D. curvirostris in F1, F2, and F2R denoted as a reduction in the antioxidant response (SOD and CAT) and oxidative damage increase. No changes in the evaluated biomarkers were observed in F1, F2, and F2R exposed to glyphosate as AI, so the ingredients produces the toxicity of glyphosate in the commercial formulation (FAENA(R)). Reduction in effects observed in the F2 exposed to FAENA(R) can be explained as a developed resistance to the toxic ingredients in the commercial formulation. The increase in liperoxidation in F2R indicates that the total recovery of the progeny was not possible, this can be related to the inherited damages of the parents exposed to FAENA(R). Glyphosate as AI did not cause alterations in the biomarkers, but the commercial formulation induced oxidative stress in the cladoceran, so special attention should be put on the negative effects that the adjuvants produced; for this reason, they should also be regulated.

RP040 Toxicity of two pesticides to a tropical freshwater shrimp Xiphocaris elongata (Xiphocaris elongata)
W.X. Torres-Pérez, University of Puerto Rico, Rio Piedras / Department of Environmental Sciences; O. Pérez-Reyes, University of Puerto Rico, Rio Piedras / Department of Biology

In the tropical island of Puerto Rico, large quantities of different types of pesticides are used for agricultural activity and residential homes because they have a great effectiveness. Two pesticides commonly used in the island are glyphosate and malathion. These pesticides can exert neurotoxicity and developmental toxicity on aquatic organisms. For this reason, this study examined the toxicity of these two pesticides to tropical freshwater shrimp Xiphocaris elongata. The pesticides used were glyphosate, a herbicide applied to control grasses and field crops; and malathion, a persistent insecticide used against mosquitoes, leafhoppers and beetles. The results showed that malathion was most toxic to this freshwater shrimp with a 96-h LC50 of 7.74 μg/L (95% CI 7.63-7.85 μg/L). However, Xiphocaris elongata were less sensitive to glyphosate with a 96-h LC50 of 657.78 μg/L (95% CI 617.98-697.58 μg/L). The present study reveals that malathion may cause a significant impact on native freshwater shrimps in the island. Further studies are needed to establish the toxic effect of glyphosate and malathion to other aquatic organisms present in Puerto Rico.

RP041 Effects of Atrazine on the Function Biomarkers and Cyto-Architecture of the Liver in Juveniles of Clarias gariepinus (Burchell, 1822)
P.A. Opute, A.O. Udoko, I.P. Oboh, University of Benin / Department of Animal and Environmental Biology; E.F. Mbajorgu, University of the Witwatersrand / School of Anatomical Sciences / Faculty of Health Sciences

The liver is the primary organ for the metabolism and detoxification of drugs and environmental chemicals. Sub-lethal toxicity of environmentally significant levels of atrazine concentrations (40μg/L, 60μg/L, 80μg/L, and 100μg/L) on exposed African catfish (Clarias gariepinus) juveniles was assessed for 28 days in a quality controlled laboratory procedure. The objective of this research was to determine the effects of atrazine on liver function biomarkers including alanine aminotransferase (ALT), Aspartate aminotransferase (AST), Alkaline Phosphatase (ALP), Albumin (ALB), Total Protein (TP) and liver histopathology. The levels of plasma ALB, and TP in exposed specimens were observed to decrease with increasing concentrations of atrazine. However, the activities of ALT, AST and ALP showed significant (P < 0.05) increase with increase in sub-lethal concentrations of atrazine. To determine the negative health implications of atrazine exposure to Clarias gariepinus juveniles, a quantitative and qualitative histology-based health assessment protocol was used. The calculation of condition factors (CF) and hepatosomatic indices (HSI) were used to support the results of the qualitative and quantitative histological evaluation of liver tissue. Hepatic tissue assessment revealed marked histopathological alterations including structural changes (Necrotic/apoptotic liver tissue and poor hepatic cord structure) with effects in 39% of the liver tissues in the treatment groups; increase in melanomacrophage centers (29%); plasma alterations (vacuolation or fat inclusions 22%) of hepatocytes; hepatocyte nuclear alterations (97%); and necrosis of melanomacrophage centers (90%); and necrosis of liver tissue (27%). Results of CF and HSI showed significant decrease across treatment groups with increasing concentrations of atrazine in a dose-dependent pattern. Findings from this study suggest that atrazine interferes with liver function markers and disrupts cytoarchitectural components of the liver resulting in a noninfectious liver injury which may lead to repeated cycles of cell deaths and inflammation or eventual death of the exposed fish.

RP042 Analysis of photodegradation of benzobicyclon hydrolysate in the presence of relevant sediment and seawater ions
M. Knight, E.N. Vebrosky, Louisiana State University / Department of Environmental Sciences; L.M. Basirico, Accounting Services / Environmental Sciences School of the Coast and Environment; K. Armbrust, Louisiana State University / Environmental Sciences

Benzobicyclon (BZB) is a pro-herbicide recently approved for application on rice in California and undergoing research in anticipation of registration in southern states including Louisiana. BZB rapidly hydrolyzes in flooded fields to generate the active ingredient of the herbicide (BUTTE...), benzobicyclon hydrolysate (BH). Previous research has shown BH preferentially partitions into rice field water, while BZB is adsorbed in sediments. BH undergoes photolysis, and its half-life varies depending on the characteristics of the water. In distilled water, BH has a reported half-life of 78 hours, 38 hours in rice water, and 3.4 hours in 25
S-metolachlor are frequently paired with a “safener” which prevents the
Chemistry
S. Lanasa, Towson University; C.J. Salice, Towson University / Environmental Science & Studies Biology; A. East, Towson University / Environmental Sciences; J. Sivey, M. Niedzwiecki, Towson University / Chemistry

Chloroacetanilide is a group of herbicides with increasing use worldwide. They are used to control grass weeds that affect important crops such as corn, soybean and cotton. Acetochlor and S-metolachlor are the most common chloroacetanilide herbicides used. When applied, acetochlor and S-metolachlor are frequently paired with a “safener” which prevents the crop from being affected by the herbicide. Safeners are considered inert and, therefore, are not regulated or tested for toxicity. While the ecological toxicity of acetochlor and S-metolachlor have been well-studied safeners, however, have not. Runoff from agriculture fields has led to measurable concentrations of safeners in nearby freshwater systems. There is a lack of information needed to assess the potential risk safeners may pose to organisms in freshwater systems. The safeners we focused on where benoxacor (commonly paired with S-metolachlor), dichlormid and AD-67 (commonly paired with acetochlor). We conducted a series of 72-hour algae toxicity tests separately with the three safeners to find the EC50 (the effective concentration causing 50% growth inhibition) on a non-target algae, Raphidocelis subcapitata. AD-67 was the most toxic followed by benoxacor, and dichlormid showed toxicity only at high concentrations. ED50 values for all safeners tested were far above environmentally relevant levels. However, a difference in size of algae cells was observed during the toxicity tests. Images of algae were captured at the 72-hour timepoint and analyzed using ImageJ software to measure the total area of each cell. We found a size increase from the controls for each safener at concentrations lower than the EC50 value in all safeners tested, with the exception of benoxacor. Algal cell size was increased in all concentrations of AD-67, some of which are approaching environmental relevance. The changes seen in cell area suggest a potentially more sensitive endpoint than what is seen in standard toxicity tests. We are exploring the commonness and significance of the observed increases in algal cell size. Also, we are designing studies to determine if increases in algal cell size impacts Daphnia magna and algae dynamics. Results of these studies may lead to and improved understanding of the potential ecological effects of safeners.

RP043 Are “safeners” safe? Effects of unregulated inert safeners on population growth and size of non-target algae
S. Lanasa, Towson University; C.J. Salice, Towson University / Environmental Science & Studies Biology; A. East, Towson University / Environmental Sciences; J. Sivey, M. Niedzwiecki, Towson University / Chemistry

RP044 Mercury fluctuation in macroinvertebrate muscle in relation to the environmental variables in Buenaventura Bay, Colombian pacific
E. Gamboa, National University of Colombia / Sede Palmira; G. Duque, National University of Colombia / Facultad de Ingeniería y Administración / Departamento de Ingeniería; P. Cogua, University of Santiago de Cali

The objective of the present investigation was to contribute to the understanding of the dynamic processes of bioaccumulation of mercury macroinvertebrate species in a tropical estuary. Four field samplings were carried out throughout four seasons in 2015, in four zones, in Buenaventura Bay and the total mercury content (T-Hg) in sediments and macroinvertebrate muscle was measured (dry weight). A total of 17 species of macroinvertebrates were collected, and concentrations of T-Hg in muscle fluctuated from 0.01±0.02 µg/g to 0.31±0.19 µg/g. When the conditions of lower salinity predominated in the estuary, there were higher values of T-Hg in both sediments and muscle of the blue crab Callinectes arcuatus and mantis shrimp Squilla autacuta, suggesting that mercury has an anthropogenic origin and could enter the estuary by the contribution of rivers by runoff during the rainy season. Nevertheless, the bioaccumulation process was greater in marine conditions than in low levels of salinity.

RP045 Trophic and biogeochemical dynamics of mercury in two fishery lakes in the Northwest Territories
A. Yamaguchi, D. MacLatchy, A. Lister, Wilfrid Laurier University / Department of Biology; H. Swanson, University of Waterloo / Biology

Kakisa Lake and Tathlina Lake, located in the Dehcho Region of the Northwest Territories, support commercially and culturally significant fisheries for the local Ka’agee Hu First Nation. Presently, Walleye (Sander vitreus) in Tathlina Lake have mercury (Hg) concentrations that are above Health Canada’s commercial sale limit of 0.5 PPM. Elevated Hg concentrations in food fishes can pose neurological, developmental, and reproductive health risks to the people who consume these fishes, depending on consumption levels and vulnerability; vulnerability is highest in children, pregnant women, and the elderly. Mercury-related health risks are greater for indigenous Dehcho residents than for southerm and westernized populations because subsistence fishing contributes significantly to their diets. Separated by 23 km of land, Tathlina Lake and Kakisa Lake are directly connected by the Kakisa River, but vary widely in many physical and chemical properties. Additionally, Tathlina Lake’s food fishes generally have higher [Hg] than Kakisa Lake’s. Differences in physicochemical dynamics and their related ecological processes could contribute to differences in fish [Hg] between the two lakes. Initial data do not satisfactorily identify the root cause for the differences in fish [Hg] between lakes. The purpose of this study is to relate analyses of food web structure, fish growth rates, and lake physicochemistry to [Hg], and attempt to determine why fish [Hg] are different between the lake systems. I predict that a difference in productivity of the lakes may partially explain the different Hg burdens. I expect that chlorophyll a, as a proxy for algal biomass, will be higher in Kakisa Lake than in Tathlina Lake, resulting in a lower [Hg] per unit of algal biomass in Kakisa Lake than in Tathlina Lake. This would demonstrate a bloom dilution effect, which can be verified by comparing [Hg] along food webs between lakes. I further expect that growth dilution contributes to the [Hg] disparity, which I will verify with fish age and fork length data. I predict that fish growth rates will be faster in Kakisa Lake than in Tathlina Lake. Finally, I predict that the rates of Hg biomagnification between the two lakes will be different. Stable isotope analysis will provide the basis for constructing a model of the food webs in each lake, and I will match that trophic information with [Hg] to quantify biomagnification rates.

RP046 Influence of growth rate and food web position on inter-individual variation in fish mercury concentrations in lakes of northern Ontario, Canada
T. Johnston, Ministry of Natural Resources and Forestry / Science and Research Branch; M. Quesnel, Laurentian University / School of the Environment; P. Savage, G.L. Lescord, J. Gunn, Laurentian University / Boreal Ecology

Fish mercury concentrations vary at multiple scales across the landscape due to a variety of environmental and ecological factors. We compared the relative contributions of three factors - body size, growth dilution, and food web position - to observed inter-individual (within-population) variability in mercury concentrations using data from 44 populations of lake trout (Salvelinus namaycush), 120 populations of walleye (Sander vitreus), and 20 populations of burbot (Lota lota) in 17 Ontario lake systems. Mercurypopulations were chosen to span a range of environmental conditions, including lake productivity, trophic position, and body size. The results showed that growth dilution was a major contributor to variability in fish mercury concentrations, with smaller fish having lower mercury levels than larger fish. Food web position also had a significant effect, with higher trophic level fish having higher mercury concentrations than lower trophic level fish. Body size was also a significant factor, with larger fish having higher mercury concentrations than smaller fish. Overall, these results highlight the importance of considering multiple factors when assessing mercury in fish populations.
vitreus), and 55 populations of lake whitefish (Coregonus clupeaformis) from lakes across northern Ontario, Canada. Relationships between fish mercury concentrations and various combinations of body weight, growth rate, and C and N stable isotope ratios were fitted with linear models, and the models were compared and ranked using Akaike's Information Criterion (AICc). For all three species, single predictor models ranked from strongest to weakest predictor were weight, growth rate, trophic elevation (inferred from δ15N), and primary energy source (inferred from δ13C). Top-ranked models included weight, growth rate and δ15N for lake trout and walleye (piscivores), but only weight and growth rate for lake whitefish (benthivore). All of these models received very strong support, based on Akaike weights (0.98. 0.99, and 0.79, respectively). For all three species, mercury concentrations were positively related to weight, negatively related to growth rate, and positively related to trophic elevation. Our study demonstrates that variation in mercury concentrations among individuals in northern fish populations is most strongly related to body size, and that the remaining variability is better explained by growth dilution than by food web position.

RP047 Effect of nickel on growth and function of manganese-oxidizing benthic bacteria

R.M. Mendonca, D. Costello, Kent State University / Biological Sciences

Nickel (Ni) is a widespread pollutant in aquatic ecosystems that can impair diversity and ecological functions. In lotic systems, the cycling and toxicity of Ni are coupled to other elemental cycles that determine toxic metal speciation and sorption behavior, thus affecting Ni bioavailability. The mixture of competing oxidized and reduced ligands in natural sediments is largely driven by the redox metabolism of the sediment microbial community. Particularly, manganese (Mn) oxide formation and dissolution can be strongly influenced by microbial redox processes and influence Ni bioavailability to microbes and benthic invertebrates. Therefore, benthic microbes are key players in determining Ni fate and bioavailability, but they are concurrently susceptible to the toxic effect of Ni. Metal toxicity to microbes can lead to an energetic trade-off between metabolic and detoxification processes and result in decreased rates of redox reactions under high metal conditions, modifying the pool of solid-phase ligands. The sensitivity of benthic microbes to Ni toxicity and their potential influence on Ni bioavailability via metal redox cycling provides a unique interface with potential emergent feedbacks between toxicity and redox processes. This study aimed to determine the toxic effects of Ni on growth and function of Mn-oxidizing bacteria (MOB) isolated from sediments of urban and pristine streams. MOB isolates were inoculated on solid K media amended with 200 µM of nickel as Mn(II) and 10 µM, 100 µM, 1mM or 10mM of Ni. After a two-week incubation, pictures of the plates were taken and processed on ImageJ to obtain colony count, colony area (mm²), and presence/absence of Mn oxides. As Ni concentration increased, colonies became smaller and unable to produce manganese oxides. Average colony count was similar in 10 and 100 µM treatments (12.5± and 16±1 colonies, respectively), but decreased substantially at 1mM (2±1 colonies). No growth was observed at 10mM. Average colony area decreased by 61% and 81% from 10 to 100µM and 100µM to 1mM Ni treatments, respectively. The proportion of colonies oxidizing manganese relative to total colony count decreased by 7% from 10 to 100µM Ni. No manganese oxidation was observed in 1mM samples. Colony growth showed a more sensitive response to Ni, but the lower occurrence of Mn oxidation indicates that at sublethal Ni concentrations feedbacks can be expected and warrant further investigation.

RP048 Protective Effects of Ligands on Ni Toxicity to Purple Sea Urchin Embryos

S. Sherman, Wilfrid Laurier University / Biology; W. Chen, S.D. Smith, Wilfrid Laurier University / Department of Chemistry and Biochemistry; J. McGeer, Wilfrid Laurier University / Biology

Nickel (Ni) toxicity in seawater is of concern because of Ni mining and processing in coastal regions. Ni speciation is vital to understanding Ni toxicity. The goal of this study was to characterize the complexation of Ni by ligands in relation to toxicity. Purple sea urchin (S. purpuratus) embryological development was used as the toxicity endpoint. It was predicted that the binding affinity (logKd) of ligands would be inversely correlated to toxicity using total dissolved Ni concentrations [Ni(d)] but that on a free ion concentration [Ni2+] basis, toxicity would not vary. A two-phased approach was used; first, ligands with known logKd values (EDTA, NTA, glutamic acid, L-, tryptophan, histidine, and citric acid) were tested to establish a proof of principle and then second, natural waters were characterized for binding capacity and Ni toxicity. [Ni(d)] was measured by graphite furnace atomic absorption and [Ni2+] was estimated using aquatic geochemistry modelling software (Visual Minteq) and also quantified using an Ion Exchange Technique. The EC50 for [Ni(d)] in unmodified artificial seawater was 3.5uM (95%CI 3.0-4.5). Results showed that: 1. addition of ligands provided protection, up to 6.5-fold higher [Ni(d)] EC50 for EDTA; 2. samples of natural seawater from eastern North America showed a range of [Ni(d)] EC50 values from 3 to 7 mM; 3. as predicted, EC50’s based on [Ni2+] were less variable and there were no significant differences among EC50 values. The results of this research contribute to the development of biotic ligand-based prediction models for estimating Ni impacts in seawater. Funding was provided by Natural Sciences and Engineering Research Council of Canada (NSERC), VALE and NiPERA (Nickel Producers Environmental Research Association).

RP049 Metallic elements in zooplankton from the Mozambique Channel, Indian Ocean

J.D. van Aarwegen, North-West University / School of Biological Sciences / Unit for Environmental Science and Management; H. Kylin, Linköping University / Department of Thematic Studies Environmental Change; H. Mwevura, State University of Zanzibar / Natural Sciences; I. Mohamed-Tohir, National Fisheries / National Fisheries Department; A. Ada, Eduardo Mondlane University / Marine Biology and Oceanography; H. Bouwman, North-West University / Unit for Environmental Science and Management

Metals ascribed to pollution may increase their concentrations above the geological background and pose toxic challenges towards humans and biota. Zooplankton's role within the marine biogeochemical process is well known, particularly the redistribution of metallic elements through the water column, but little is known about their interaction with zooplankton. We determined concentrations of metals in zooplankton collected using a standard zooplankton net from the Agulhas II in 2017. Thirty-eight zooplankton samples were analysed using ICP-MS (EPA 3051A method) for 30 metallic elements along the coast of Mozambique, an understudied and economically important region within the Western Indian Ocean. Here, we will consider concentrations and ratio with calcium of eight metals (Cd, Cu, Hg, Mn, Ni, Pb, TI, Zn). Median concentrations for Cd in zooplankton were 0.28 mg/kg dm, for Cu 0.11 mg/kg dm, for Hg 0.25 mg/kg dm, for Mn 0.15 mg/kg dm, for Ni 0.23 mg/kg dm, for Pb 0.050 mg/kg dm, for TI 0.29 mg/kg dm, and for Zn 0.12 mg/kg dm, respectively. Of the eight elements, only Pb (p < 0.0001) concentrations showed a significant positive correlation with Ca, while Ni (p = 0.0136) and TI (p = 0.0056) showed significant negative correlations. An initial assessment indicated that the highest concentration found for Cd (80 mg/kg dm) along the Mozambique coast might be of concern.

RP050 The Impacts of pH on trace contaminant leaching and toxicity of coal ash in Planoribella duryi

C. Crowell, B. Odhiambo, University of Mary Washington / Earth and Environmental Sciences; L. Giancarlo, University of Mary Washington / Chemistry; T.E. Frankel, University of Mary Washington / Earth and Environmental Sciences

Coal fly ash is a major industrial waste that is primarily produced by coal-burning power plants. Ash contains multiple trace contaminants that have the potential to leach from the coal ash into waterways after rain events, causing undesirable effects on aquatic species in these ecosystems. Few laboratory studies have examined the relationship between acidified rainfall and the release of trace metals from coal ash and the impacts of
such rainfall on the toxicity of coal ash leachates on aquatic invertebrates. Thus, the goals of this study were to 1) evaluate the effect of varying pHs on the leaching of trace contaminants from coal ash and 2) examine the impacts of these leachates on the viability, development, and hatch rate of embryonic Planorberella duryi, a freshwater snail species commonly found in intermittent streams or shallow waters throughout North America. Briefly, 100g of coal fly ash obtained from a local coal ash repository was added to individual glass vessels containing 1L of synthetic water adjusted to pHs of 4.5, 5.0, 5.5, 6.0, 6.5, 7.0, or 7.5. After 48 hours, all leachates were vacuum filtered and an aliquot analyzed for sulfuric, arsenic, calcium, cadmium, chromium, cobalt, iron, mercury, magnesium, manganese, lead, selenium, and zinc using ICP-OES. Embryonic P. duryi clusters (< 2hrs old) were then exposed to each leachate or pH-adjusted synthetic water for 10 days using a 48hr static-replacement assay, and the number of viable individuals and hatchlings in each cluster assessed daily. To examine the impacts on growth, photographs of each embryo were obtained on days 5, 7, and 10 and differences in shell diameter and pigmentation assessed using ImageJ. While this project is currently ongoing, we expect to find increases in aqueous trace contaminant concentrations as a result of decreased pH in leachates as well as decreased viability, growth, and hatching success. This study will provide important information regarding the potential impacts of acidified rainfall on the mobilization of trace contaminants and toxicity of coal ash leachates on aquatic invertebrates.

**RP051 Accumulation of Heavy Metals in Fish Downstream from American Zinc Products and the Rogers Energy Complex on the Broad River, NC**

*C. Sandery, H. Woodburn, Appalachian State University / Biology; L. Rader, Appalachian State University; S.R. Tuberty, Appalachian State University / Biology*

The communities of Rutherford and Cleveland county, North Carolina depend on the Broad River for fishing and recreational opportunities. The caught fish are often consumed as a form of sustenance. American Zinc Products (AZP) is an industrial and hazardous waste recycling plant that is located on the Broad River. Approximately 6.5 miles downstream from AZP is the coal-fired energy facility Rogers Energy Complex (REC). Members of the community were concerned that the coal ash basins that are located on-site at the REC were leeching into the Broad River, contaminating the water and aquatic species. In this study water, sediment, and fish tissue samples were collected and analyzed for heavy metal concentrations; one tap water sample was also taken from a home located directly downstream from REC. The results revealed that many of the water samples exceeded safe levels of lead and zinc for aquatic life according to the NC Department of Environmental Quality criteria. The tap water sample nearly doubled the EPA’s action level for lead. In the fish tissue samples the mean concentrations of arsenic, cadmium, chromium, selenium, and copper did increase compared to the reference site. Levels of arsenic, cadmium, and selenium were compared to safe consumption advisories set by the EPA; these values describe safe monthly limits with a serving size of 8 oz.

**RP052 Effects of three Culture Systems on Histopathological and Biochemical Characteristics of Clarias gariepinus (Burchell 1822)**

*E. Okeke, International Students Environmental Coalition / Institute of Ecology and Environmental studies; O.T. Aladesanmi, Obafemi Awolowo University / Institute of Ecology and Environmental studies*

Fisheries occupy a unique position in the agricultural sector of the Nigerian economy. In terms of Gross Domestic Product (GDP), the fishery sub-sector has recorded the fastest growth rate in agriculture to the GDP of Nigeria. Fishery business is very lucrative in Nigeria, hence it has attracted a lot of people using different methods and culture systems. Fish has the tendency to accumulate pollutants in significant quantity consequently serving as a source of health risk to man and other predators. Therefore, this study assessed water quality of three (tank, earthen and concrete pond) different culture systems of Clarias Gariepinus commonly used in Nigeria, as well as the conditions of the cultured fishes. Water and fish samples were collected from the three different ponds. The water samples were collected at three points i.e. the inlet, the mid-point and the outlet of the ponds respectively. These were referred to as Points A, B and C respectively in this study. Physicochemical parameters (pH, temperature, turbidity, dissolved oxygen, BOD, COD, TDS, EC and major ions) were determined in the water samples. Samples for heavy metal (Pb, Cd, Zn, Fe, Cr) analysis were first digested before metal determination using PG 990 Atomic Absorption Spectrophotometer. Condition factor, Protein concentrations and antioxidant enzyme activities in the fish from the three ponds were also determined using standard protocols. The results shows that there were significant variations in the concentration of metals in the three culture systems. Pb (0.11±0.003) and Cd (0.13±0.0045) concentrations were highest in the tank ponds compared to earthen and concrete ponds. While the concentrations of Cr (0.18±0.003) and Fe (1.01±0.003) were found to be highest in earthen ponds than in tank and concrete ponds. In contrast, there were no significant difference in the oxygen parameters of the water sample. The presence of metals above permissible in the tank and earthen ponds could be due to the material used for the tank ponds which constantly add metals to the pond and also the contaminated water that serves the earthen ponds. Elevated metal concentrations were also present in the fish tissues. Enzyme activities showed direct correlation with increase in metal concentration. Photomicrographs of the fish tissues showed varying degenerative conditions from mild to severe. The study concludes that different culture systems influence the conditions of the water and the fish.

**RP053 Contaminant pulses associated with snowmelt in Northern Utah, USA**

*C. Fender, D. Kimberly, Westminster College / Biology*

Utah is dubbed as having the “greatest snow on earth” with average annual snowfall reaching 500 inches at many Northern Utah ski resorts. The Salt Lake valley, also located in this region, is notorious for poor air quality punctuated by frequent winter and summer inversions. Previous studies in other systems show that air pollutants can be integrated and stored in the snow pack and detected in snowmelt throughout spring and summer months. Data on these processes are lacking for the Salt Lake valley. With the Utah population projected to continue growing, it is likely to assume the amount of airborne pollutants will increase, thus an increase of toxicant presence in the snow pack. The purpose of this study is to better understand the fate and distribution of contaminants that could be integrated into snowpack and released into the environment via snowmelt. An array of samples were collected weekly from transects in Big Cottonwood Creek beginning in April, before mean daily temperatures were above freezing, and ending in September 2019. Collected media from each creek transect include, water, sediment, soil from within ten feet of creek bank, newly deposited snow if applicable, packed snow at least three feet below surface, and macroinvertebrates. Each compartment is analyzed for metals including Cadmium, Lead, Mercury, and Zinc as well as an assortment of PAHs. This year (2019) was a near record year with some ski resorts receiving over 700 inches of snow. Peak snowmelt is projected for the end of July. The increase in winter storms this season resulted in far fewer inversions. However, air pollution thatharbors combustion byproducts is still being created and potentially being distributed both locally and globally. While our chemical analysis is ongoing, it may not be indicative of historic trends of contaminant deposition in snowpack due to this years increase in precipitation.

**RP054 Adsorption of trace metals to Spartina alterniflora detritus in Galveston Bay salt marshes**

*C.L. Howard, A.L. Self, University of Houston Clear Lake / Department of Environmental Science*

Salt marshes are highly productive and biologically diverse habitats that are critical to estuarine ecological processes. Primary production is derived from emergent grasses, phytoplankton and benthic algae. Detritus from the marsh grasses provides an important source of nutrition for a
variety of transient and permanent marsh inhabitants, including many commercial fishery species in Galveston Bay. There are documented elevated levels of trace metals in Galveston Bay waters and sediment; studies have shown that detritus decaying on the sediment surface can become enriched with significant quantities of trace metals over time, which may be a significant dietary source of metals to benthic consumers. The objective of this research was to investigate the temporal adsorption of trace metals to Spartina alterniflora detritus during a 9-month decomposition period in Galveston Bay salt marshes, in order to provide new information on a potentially significant pathway for dietary uptake of trace metals in Galveston Bay. Transects were set up parallel to the shoreline at three marsh sites bordering West Galveston Bay (native reference, restored, and contaminated). Dead Spartina stems and sediment samples were collected from plots randomly placed along transects at each site. Leaves were removed from the stems, cut into 5-10 cm lengths, then dried and weighed in 2 g parcels and placed into 20 x 20 cm nylon mesh (3 mm) litterbags. Three litterbags were returned to each plot/transect/site from which the leaf material had been collected and secured to the marsh bottom. At intervals of 3, 6, and 9 months, litterbags were collected and returned to the lab, where the contents were rinsed with fresh water, dried, and weighed. The samples were acid-digested and analyzed for As, Cr, Cu, Ni, Pb and Zn by ICP-OES. Results indicate that the amount of time Spartina leaf detritus remains in the marsh correlates directly with the concentration of trace metals adsorbed and is likely to contribute to the trophic transfer of heavy metals in Galveston Bay.

RP057 A Closer Evaluation of Contaminant Distributions in Sediments of a Coastal Plain Stream Impacted by Industrial Runoff

C. Fulghum, Savannah River Ecology Laboratory; P.T. Stankus, D.E. Fletcher, University of Georgia / Savannah River Ecology Laboratory

As part of an on-going stream monitoring program, an effort was made to identify sources of contamination that could be causing pulse through a headwater coastal plain stream on the Savannah River Site (Aiken, SC) with a history of industrial disturbance. Past studies of bioavailable contaminants conducted on this tributary found elevated levels of several trace elements in biota, despite not being particularly elevated in stream sediments. Those results were unexpected, but possibly due to stream bottoms being severely scoured of organic matter and fine sediment by flashy storm flows from extensive impervious surfaces in the watershed. Thus, we sought to determine potential upstream contaminant sources and establish a baseline to assess potential impacts of a new facility under construction. The primary concerns for possible contamination hot spots included the construction site in the mid reaches of the stream, a series of sedimentation basins along the valley rim, and a previously used coal combustion waste basin located in the headwaters. Sample sites were selected longitudinally along the entire stream and focused on channel depositional areas, scour pools, and basins where contaminants were most likely to settle out. In total, 165 sediment samples were analyzed for 18 trace elements. Elevated levels of trace metal concentrations were higher in upstream basins than below the new construction site, despite outfalls in this midstream section, suggesting the upstream basins as the source of contamination found accumulating in biota. Mapping of the contaminant distributions will aid future assessments and guide potential restoration work aimed at mitigating stream damage from the excessive runoff.

RP058 Trace Elements in Exuviae of Emerging Damselflies

D.E. Fletcher, C.M. Fulghum, A. Lindell, D.B. Pitt, P.T. Stankus, University of Georgia / Savannah River Ecology Laboratory

Damsel fly adults and their aquatic immature stages are an important part of food webs and provide a link between aquatic and terrestrial components. The H-02 wetland system was constructed on the Department of Energy’s Savannah River Site, SC to treat building process effluents and stormwater runoff. Constructed wetlands play an important role in the SRS environmental plan to achieve both federal and state regulatory compliance for the discharge of effluent waters. The H-02 wetlands were built to regulate pH and remove trace metals, primarily Cu and Zn, from the effluent line before release to state waters. The system consists of a retention basin, two wetland treatment cells, an effluent pool, and a discharge stream. Our previous work established contaminants accumulating in aquatic biota throughout and below the wetland system. As an aquatic nymph emerges from the wetland, contaminants can be shed with their exuviae (nymph exoskeleton) or be incorporated into their body and enter the terrestrial food web as adults fly away. Consequently, to determine the amount of contaminants exported from the wetland versus left behind, we analyzed trace element concentrations in emerging damselflies and their shed exuviae. Damselflies were collected from three sites in the retention basin. Traps were designed to sample both near-shore and pelagic habitats within each section. We analyzed accumulation of 16 elements in over 250 samples distributed across 5 coenagrionid damselfly species belonging to 2 genera. Patterns of elements that are primarily shed in the exuviae
versus those incorporated in the emerging damsselfly and thus exported from the system were compared. Differences in trace element accumulation were assessed at both the generic and species taxonomic levels. Comparing basin sections assessed effect of spatial relationship to outfalls, whereas comparing pelagic versus shoreline established habitat influences.

RP059 The impact of selected trace elements on the redox status markers in freshwater fish (Cyprinus carpio)  
A. Kováčik, Slovak University of Agriculture in Nitra / Department of Animal Physiology; M. Tomka, E. Tyrda, Slovak University of Agriculture in Nitra; T. Jambor, Slovak University of Agriculture in Nitra / Department of Animal Physiology; P. Massanyi, Slovak University of Agriculture in Nitra

Toxic metals such as cadmium, lead, mercury, arsenic, or chromium are relatively well investigated. Their hazardous effect to metabolic and physiological system of all animals was confirmed. On the other hand trace elements such as aluminium (Al), Barium (Ba), lithium (Li), and molybdenum (Mo) are not completely investigated. The aim of this study was to assess possible relationships between redox status markers (glutathione-GSH, D-3-hydroxybutyrate-BHB, lipid peroxidation-MDA, protein carbonyls-PC, and uric acid-UA) and the content of Al, Ba, Li and Mo in carp blood serum. Blood samples (n = 38) were taken in spring (n = 19) and summer (n = 19) from aorta ventralis from each fish. The samples were allowed to coagulate at room temperature and centrifuged for 20 min at 3000 rpm. The concentration of Al, Ba, Li and Mo were determined using ICP-OES. GSH was evaluated by the Ellman method; Lipid peroxidation expressed through MDA production was measured with the help of the TBARS assay, modified for a 96-well plate and ELISA reader; BHB activity was measured using the Randox commercial kits. PC quantification was performed through the 2,4-dinitrophenylhydrazine (DNPH) method. BioLa Uric Acid commercial kit (Lachema, Czech Republic) and the spectrophotometer were used for the assay. Basic statistical analysis as well as Pearson’s correlations and ANOVA were performed using STATGRAPHICS Centurion ((C)StatPoint Technologies, Inc., USA). Factorial ANOVA showed us insignificant effect of season for elements content, however redox markers concentrations were affected (PC, MDA, UA - P<0.05), except GSH and BHB concentrations. Statistically significant correlation was found between the concentration of Li and PC (r=−0.54, P<0.05) in summer season. Similar tendency was observed between the concentration of Li and PC (r=−0.35, P<0.05) regardless of the season. Content of Al positively correlated with concentration of GSH (r=0.36; P<0.05) and UA (r=0.39; P<0.05). Weak and insignificant correlations were detected between trace elements and investigated redox markers in spring season. Our results demonstrated low effect of studied elements on the redox markers, however further studies are necessary to test eco-toxicology interactions between other biomarkers (haematology, serum chemistry) and other trace elements in natural conditions. This work was supported by the Slovak Research and Development Agency under the contract No. APVV-16-0289 and VEGA 1/0539/18.

RP060 The Effects of Anti-Sea Lice Therapeutants on Marine Benthic and Pelagic Species Under Varying Environmental Conditions  
F. Lin, C. Kennedy, G. Su, Simon Fraser University / Department of Biological Sciences

The aquaculture industry’s use of chemicals, including those used in disinfectants, anti-fouling paints, and feed additives has resulted in the contamination of local net pen areas. Of immediate concern are those compounds used in disease and parasite control, including anti-sea lice pesticides (Salmosan(R) and Paramove(R) 50) and drugs (SLICE(R) and Ivomec(R)). Acute (1-h/3-h exposure) bioassays (for the determination of toxicological parameters (LC50, EC50, NOAEC, LOAEC values) were conducted on natural assemblages of zooplankton, and specific pelagic larvae including Spot prawn (Pandalus platyceros) and herring (Clupea harengus pallasi) larvae. Exposures to either Salmosan(R) or Paramove(R) 50 in water were conducted under varying oxygen (10-100% O2 saturation) and temperature (7, 11, 16°C) regimes. In additional experiments, sediment dwelling amphipods and polychaete worms (Pacific species: Eohaustorius estuarius and Alitta virens) were subchronically (30-d) exposed to either SLICE(R), Ivomec(R), or a combination of the two in sediments under a range of oxygen concentrations and temperature as above to determine their lethal (LC50, EC50, NOAEC, LOAEC values) and sublethal (behaviour [e.g. orientation, paralysis, distance per unity t], feeding [e.g. reaction time, feeding motions, feeding response to food odors], oxygen consumption) toxicity. Threshold values for lethal and sublethal toxicity were determined for all chemicals and in each case, hypoxic conditions, and conditions of higher temperatures resulted in significant increases in chemical toxicity. This data specifically addresses information gaps needed for proper assessments of the environmental consequences of sea lice pesticide formulation use to be made.

RP061 In vivo toxicity of polyhexamethylene guanidine phosphate in zebrafish: A phenotype and genotypic assessment  
K. Eghan, J. Park, Korea Institute of Toxicology; S. Lee, Korea Institute of Toxicology (KIT) / Predictive Toxicology; W. Kim, Korea Institute of Toxicology (KIT) / Environmental Toxicology Research

Polyhexamethylene guanidine phosphate (PHMG-P) has a strong penetration in our households, particularly due to its resilient bactericidal properties. After a range of skin irritation tests, it has been considered safe and hence, applied in shampoos and lens cleaners. The use of PHMG-P in humidifiers lead to a tragic event in South Korea and epidemiological studies has linked the use of PHMG-P as a humidifier disinfectant to provoking pulmonary fibrosis. A different exposure route brings about an entire different mechanism and currently, little is known about the mechanisms by which PHMG-P exerts its toxic effects. To bridge this research gap, we applied an omics approach using RNA sequencing analysis as well as phenotypic assessments to determine the effects of PHMG-P on zebrafish. Exposure concentration was determined at 0.1, 0.2, 0.3, 0.4, 0.5, 1 and 2 µg/mL based on preliminary acute toxicity tests. Upon the administration of PHMG-P to zebrafish eggs ~3 hours after fertilization, the results of the test showed mortality at 96 hours for concentration of 2 µg/mL, and an LC50 value of 1.18 µg/mL at 96 hours. RNA sequencing analysis revealed that exposure to 0.4 µg/mL of PHMG-P for 96 hours was associated with upregulation of genes related to apoptosis, immune and inflammatory responses, and downregulated genes associated with oxidation-reduction, among other processes. The pathway analysis shows links to numerous pathways including cytokine-cytokine receptor interaction and ECM-receptor interaction. Real-time PCR and matched findings obtained in previous studies confirmed this. These findings on how PHMG-P exerts its toxic effects should help in alleviating future antagonistic effects. In addition, it will help comprehend PHMG-P-induced toxicity and its relation with pulmonary diseases.

RP062 Effect of pesticide TFM and its metabolites in fish mitochondria  
B. Huerta, Michigan State University / Fisheries & Wildlife

Sea lamprey (Petromyzon marinus) is a parasitic and invasive species in the Great Lakes. The chemical 3-trifluoromethyl-4-nitrophenol (TFM) is used to control the population because it is selectively toxic to sea lamprey. TFM toxicity is believed to be caused due to the impairment of mitochondrial ATP production through the uncoupling of oxidative phosphorylation. The specificity of TFM in sea lamprey has been attributed to a limited capacity to eliminate TFM through glucuronidation compared to other fish species. TFM also undergoes phase I biotransformation to reduced 3-trifluoromethyl-4-aminophenol (TFMa) and accumulates in sea lamprey liver. Our hypothesis was that TFMa present at higher concentrations in the sea lamprey inhibits mitochondrial oxidative phosphorylation, not only during ATP production but at all levels in the electron transfer chain, and this contributes to the specificity of TFM in this species. We characterized the toxicity of TFM, methyl-phenol and their amino metabolites in the mitochondrial metabolism of the heart of sea lamprey.
We measured mitochondrial oxygen consumption after exposure in order to determine the effect in the ATP production and in mitochondrial complexes I and II. We also determined the effect of TFM and metabolites on the mitochondrial membrane permeability by measuring the transmembrane potential after exposure. Mitochondrial bioenergetics were heavily affected when exposed to increasing concentrations of TFM, methylphenol, and amino methyl-phenol at the different protein complexes examined, which suggests that the mode of action of these compounds goes beyond the uncoupling of complex V (ATP-synthase) at the end of the electron transport chain but at an earlier stage. The transmembrane potential was greatly reduced by TFM and methyl-phenol, but it was not affected by the amino metabolites.

RP063 Effects of the gill microenvironment on toxicant speciation and uptake by fishes: A case study using the piscicide TFM
M.P. Wilkie, S.L. Hepditch, L. Tessler, O. Bizeanu, Wilfrid Laurier University / Biology

Invasive sea lamprey (Petromyzon marinus) populations are controlled using a piscicide, 3-trifluoromethyl-4-nitrophenol (TFM). Applied to infested streams, TFM targets larval lampreys, which have a low capacity to detoxify the agent. However, non-target adverse effects and mortality can occur during TFM applications, particularly following decreases in water pH. A weak acid, with a pKa of 6.07-6.38, total TFM (TFM_{tot}) exists as un-ionized TFM-OH or ionized TFM-O. As water pH decreases, TFM-OH, the bioavailable form of TFM_{tot}, increases leading to greater uptake and toxicity. Similarly, TFM toxicity is higher in low alkalinity waters, but the reasons are unclear. Our goal was to determine how water alkalinity and the chemistry of the gill microenvironment, defined as the expired water crossing the gills, influenced TFM uptake and TFM-OH bioavailability to lake sturgeon (Acipenser fulvescens) and rainbow trout (Oncorhyncus mykiss). Using radio-labelled TFM (^{14}C-TFM), we observed that TFM uptake by lake sturgeon was highest at pH 6.5 versus pH 9.0, confirming that uptake takes place by diffusion as un-ionized TFM-OH. Similarly, TFM uptake was greatest at low (<50 mg CaCO_3 L^{-1}) compared to moderate (~150 mg CaCO_3 L^{-1}) and high alkalinity (~250 mg CaCO_3 L^{-1}). As water pH was circumneutral (pH 7.8-8.2), differences in bulk water pH could not explain our findings. Instead, we hypothesized that greater acidification of the gill microenvironment resulted in higher TFM-OH bioavailability in low compared to higher alkalinity water. To test this hypothesis, trout were implanted with opercular catheters, allowing us to measure the pH of water expired across the gills (the microenvironment). At low alkalinity, expired water pH was 1.0-1.5 pH units lower than inspired (bulk) water pH, likely due to acid (H^+) excretion and CO_2 excretion across the gills. Notably, acidification was less at moderate alkalinity, and eliminated at high alkalinity. Thus, lower TFM uptake at higher alkalinitities was due to higher water buffering capacity, which reduces or prevents acidification of the expired gill water. Our results demonstrate that opercular catheters, which are easy to install and cause minimal stress to fish, allow accurate measures of water chemistry and toxicant bioavailability within the gill microenvironment. Using this approach, we also show that water-buffering capacity can profoundly affect toxicant bioavailability in the gill microenvironment.

RP064 Biochemical biomarkers in shrimp (Litopenaeus vannamei) exposed to chlorpyrifos
B.E. Jaramillo-Colorado, University of Cartagena / Chemistry Program; E. Duarte-Restrepo, University of Cartagena / Agrochemical Research Group / Chemistry Program; L. Duarte-Jaramillo, University of Cartagena / Agrochemical Research Group

Chlorpyrifos (O,O-diethyl-O-(3,5,6-trichloro-2-pyridyl)-phosphorothioate) residues were detected in sediments of Cartagena Bay. This pesticide comes from the Dique channel (Magdalena River) and spills of industries of the Mamonal sector in Cartagena, Colombia. Chlorpyrifos (CPF) is an organophosphorus pesticide (OP) extensively applied to control pests and agricultural practices, but they also adversely affect non-target fauna. It is the second largest selling OP and found to be more toxic to the marine organisms than organochlorine compounds. The effect of this OP on the shrimp (Litopenaeus vannamei) was evaluated. LC50 (96-hours) was determined. Lipid oxidation levels (LPO) and activities of catalase (CAT), glutathion peroxidase (GpX), glutathion-S-transferase (GST) were assessed on the muscle, hepatopancreas and gills from adults exposed to two sublethal CPF concentrations (0.7 and 1.3 μg/L) for four days. Furthermore, acetylcholinesterase (AchE) inhibition was determined in the brain. LC50 (96-hours) was 2.10 μg/L of CPF. Shrimp exposed to two sublethal CPF concentrations showed an increase of CAT activity in the three tissues, a decrease of AchE activities in the brain and an increase of GST activity in the hepatopancreas, while LPO increased in all tissues. These results show that L. vannamei could be used as biomarkers to monitor OP pesticides in aquatic environments.

RP065 Assessing the impacts of methoxychlor exposure on the viability, reproduction, and behavior of the seminole ramshorn snail (Planorbella duryi)
T.E. Frankel, University of Mary Washington / Earth and Environmental Sciences; M. Bohannon, University of Maryland / Environmental Science and Technology; J. Frankel, Howard University / Biology

In this study, the effects of short-term methoxychlor exposure on the viability, reproduction, and locomotor behavior of adult Seminole ramshorn snails (Planorbella duryi) was assessed. To examine impacts on viability and behavior, individual snails were exposed to a water control, vehicle control, 12.5, 50, 100, 250, 500, or 1000 μg/L of methoxychlor for 48hrs and differences in mortality and locomotor behavior were examined. To determine impacts on reproduction, pairs of snails were exposed to a vehicle control, 12.5, 50, 100, and 250 μg/L of methoxychlor for 9 days and the number of egg clutches and viable embryos laid quantified every 24hrs. To verify nominal vs. actual concentrations, water samples were collected and methoxychlor concentrations determined using gas chromatography. Complete mortality was observed in the 500 μg/L and 1,000 μg/L treatments after 48hrs and in the 250 μg/L treatment after 9 days. Significant decreases in the number of egg clutches were observed in all treatments, and the number of embryos laid decreased starting in the 25 μg/L treatment. Decreases in average speed, mobile speed, and total distance travelled as well as a significant increase in frozen events were also observed. Our results suggest that methoxychlor exposure causes detrimental effects on several non-lethal endpoints in an alternative model aquatic invertebrate species and that the analysis of locomotor behaviors serves as a reliable, sensitive endpoint for future ecotoxicology testing.

RP066 Effects of pesticides with different mechanism of toxicity in the freshwater prawn Macrobrachium borellii
S.M. Lavarias, K. Colpo, E. Ambrosio, Instituto de Limnología “Dr. Raúl A. Ringuelet” (CCT- La Plata CONICET –UNLP); S. Landro, Museo Argentino de Ciencias Naturales (CONICET); A. Rodrigues Capítulo, Instituto de Limnología “Dr. Raúl A. Ringuelet” (CCT- La Plata CONICET –UNLP) / Instituto de Limnología Dr Raúl A Ringuelet CCT La Plata CONICET UNLP; F. Arrighetti, Museo Argentino de Ciencias Naturales (CONICET)

Synthetic pyrethroids like cypermethrin (CYP) are extensively applied for control of agricultural pests and disease vectors. However due to its harmful consequences to non-target organisms, the bioinsecticides represents a benign and desirable alternative to the environment. Among them the biological insecticide produced from Bacillus thuringiensis israelensis (Bti) is mainly used for the control of mosquito vectors of diseases like dengue. Anyway, pest organisms have developed resistance mechanisms to such kind of insecticides so last generation pesticides, such as the tetramic acid spirotratrum (STM), have recently emerged. Due to the limited information available on the effect of these compounds on non-target species, the effect of CYP, Bti and STM on the freshwater prawn Macrobrachium borellii was analyzed. Initially, the LC50-96 h was determined in adult prawns (males and females in non-vitellogenic state), by serial dilutions of the three insecticides. A negative control without insecticides was included. Then, in order to determine metabolic disorders that could be
used as biomarkers of pollution, prawns were exposed to sublethal concentrations of CYP (0.006 and 0.02 μg/L), Bti (0.04 and 0.4 mg/L) and STM (0.5 and 1.7 mg/L) for 4 days. The levels of lipid peroxidation (LPO) and protein oxidation (OP), as well as the presence of histopathological changes were evaluated in the hepatopancreas. The LC50-96 h values were 0.8 and 8.2 mg/L for Bti and STM respectively, and 0.12 μg/L for CYP. All three insecticides significantly affected the LPO and OP levels in this organ (p < 0.05). Pesticides caused histopathological alterations in the hepatopancreas of the exposed prawns, such as atrophy in the epithelium of the digestive tubules, necrosis of the epithelial cells, and the infiltration of hemocytes into the connective tissue between the intertubular space. This study showed that *M. borellii* is less sensitive than other crustaceans to CYP. In addition they are the first results of sensitivity to *Bti* and STM in this taxonomic group. Considering that the hepatopancreas is the main organ for toxicant metabolism in crustaceans, these results indicate that oxidative status in *M. borellii* is very sensitive to these insecticides. Therefore, this prawn could be proposed as useful bioindicator to monitor freshwater environments that are exposed to these pollutants.

**RP067 A comparison of alternative 96-hr Hyalella azteca water exposure protocols for the sensitivity to the pyrethroid bifenthrin**

S.L. Clark, S. Vasquez, Pacific EcoRisk; S. Rees, T. Albertson, Caltest Analytical Laboratories; B.C. Jorgenson, Pacific EcoRisk

The Central Valley Regional Water Quality Control Board (California, USA) adopted a pyrethroid basin plan amendment and total maximum daily loading (TMDL) limits in 2018 requiring monitoring by publically owned treatment works, stormwater dischargers, and irrigated agriculture. As the goal of the monitoring is to determine the extent to which pyrethroids cause water column toxicity, water samples are analyzed for pyrethroids, organic carbon, and acute toxicity to *Hyalella azteca*in 96-hr bioassays. In order to appropriately determine if toxicity is due to pyrethroids, sufficiently sensitive methods must be applied and an environmentally relevant, yet cost effective, toxicity testing protocol must be used; it is imperative that the toxicity test design does not mask the toxicity of these extremely hydrophobic pesticides. There are currently two toxicity tests based on limited guidance in the 2002 EPA acute testing manual that are under consideration: the method applied for Surface Water Ambient Monitoring Program (SWAMP) studies and a method refined by the Southern California Coastal Water Research Program (SCCWRP) during a stormwater inter-calibration study. Both methods require static renewal testing with solution renewals at 48 hours. The SWAMP method includes the addition of food throughout the testing, whereas the SCCWRP method requires feeding 2 hrs before solution renewal. As demonstrated by others, substantial loss of pyrethroids to the walls of the bioassay test chamber is a significant concern. This loss, amplified by the 48-hour renewal test design could result in the SWAMP and SCCWRP protocols underestimate pyrethroid toxicity. Furthermore, the inclusion of food in the test chambers throughout testing (i.e., SWAMP method) could reduce the dissolved phase pyrethroids to which the organisms are exposed. To address this concern, a study was performed in which these two toxicity methods were compared to a modified SCCWRP protocol with daily solution renewals and feeding 2 hours prior to each renewal, with bifenthrin used as the toxicant. All testing was performed concurrently using the same bifenthrin stock solutions prepared daily. Stock solutions and representative samples collected during the testing were analyzed for bifenthrin using negative chemical ionization, GC/MS with selected ion monitoring (EPA 625.1M). The results of this testing will be presented, along with the ramifications for monitoring under the pyrethroid TMDL.

**RP069 Assessing the impacts of sulfoxaflor exposure on the viability, growth, behavior, and hematocrit of the seminole ramshorn snail (Planorbella duryi)**

T.E. Frankel, E. Hodges, University of Mary Washington / Earth and Environmental Sciences

Sulfoxaflor, a sulfoximine insecticide, has seen increased utilization as an effective tool against sap-feeding insect species that have developed resistances to other control agents. However, few studies have been conducted to examine the impacts of sulfoxaflor exposure on viability and non-lethal endpoints in freshwater aquatic invertebrates. As such, this study examined the effects of sulfoxaflor exposure on the viability, growth, locomotor behavior, and hematocrit of juvenile seminole ramshorn snails (*Planorbella duryi*). Individual juvenile snails (> 1 day post hatch) were exposed to a water control, vehicle control, 0.1, 1, 10, 100, and 1000 μg/L of sulfoxaflor for six weeks using a weekly static replacement exposure method. Mortality, defined as a lack of response to footpad contact, was assessed daily. To examine the impacts of sulfoxaflor on growth, a photograph of each snail was taken weekly and the shell height and width analyzed using ImageJ. A 15 minute video recording of each snail was obtained on weeks 3, 4, 5, and 6 and differences in locomotor behaviors assessed using automated behavioral analysis software. At the end of the exposure period, hemolymph from each individual was collected in heparin-treated glass capillary tubes, centrifuged, and packed cell volume determined using a microhematocrit capillary tube reader. While this study is still ongoing, we expect to observe significant decreases in growth, locomotor behaviors, and packed cell volumes in individuals exposed to sulfoxaflor in a dose-dependent manner. Findings from this study will help to elucidate the effects of sulfoxaflor contamination on aquatic invertebrates while also providing support for future studies to examine the presence and concentrations of sulfoxaflor in aquatic ecosystems.

**RP070 Lethal and sub-lethal effect of copper sulphate pentahydrate on two successive generations of Culex pipiens mosquito (Diptera: Culicidae)**

N. Amer, S.P. Lawler, University of California, Davis / Entomology and Nematology; R.E. Cannon, University of California, Davis / Anatomy, Physiology & Cell Biology / School of Veterinary Medicine

The *Culex pipiens* mosquito is an important public health vector of many diseases. It usually inhabits large ponds and sometimes is found in small water bodies. Copper may enter water when used as a biocide in antifouling paint formulations or from agricultural and urban uses. Copper sulfate is used as a fungicide, algicide and for root treatment, and is especially widely used in rice fields in California. We studied lethal and sub-lethal effects of copper sulfate pentahydrate on the immature stages of two successive generations of *Culex pipiens* using laboratory toxicity testing. Larval mortality rate increased with increased concentrations during both generations. During the 1st generation, mortality rates increased gradually from control to 100% at 1 mg/L. The 2nd generation showed a marked increase in mortality rates of the larval stage relative to generation one, especially at the higher concentrations of 0.25 and 0.5 mg/L. The larval LC50 level of the second generation was 40% lower than the first. Copper sulfate exposure delayed development in both generations, and pupation rate also decreased with increased concentrations in both generations. This study showed higher sensitivity of *Culex pipiens* to copper toxicity than other mosquito species. The higher sensitivity of the 2nd generation is a relatively novel finding because multi-generation studies are rare in comparison to short-term tests. More such studies are needed to determine if exposure of the parents to toxicants is usually detrimental to offspring.
RP071 Acute and chronic toxicity of three neonicotinoid alternatives to the amphipod Hyalella azteca

L. Brown, Environment and Climate Change Canada / ACRD; A.J. Bartlett, K. Intini; A. Hedges, J. Grabuski, Environment and Climate Change Canada / Water Science and Technology Directorate; F. Maisonneuve, S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate

Neonicotinoid pesticides are widely used across North America in agriculture, turf and ornamental applications. Although they are effective insecticides, their use has been associated with negative effects on non-target aquatic organisms and bans on some neonicotinoids have been implemented in Canada. As a result, the use of neonicotinoid alternatives has increased, although presently there is little information available on their toxicity to aquatic invertebrates. The objective of this study was to determine the acute and chronic toxicity of three neonicotinoid replacements, specifically flupyradifurone (butenolide), sulfoxaflor (sulfoximine) and chlorantraniliprole (ryanoid), to the freshwater amphipod, Hyalella azteca. Toxicity tests were conducted using a static-renewal, water-only method for a duration of 28 days. The endpoints chosen were survival and growth of the amphipods. Survival was assessed weekly and growth was assessed at the end of the experiment. Results for survival and growth for flupyradifurone, sulfoxaflor and chlorantraniliprole, respectively, were as follows: acute (7 d) LC50s were 26, 206 and 516 µg/L, chronic (28 d) LC50s were 20, 188 and 420 µg/L, and EC50s (28 d) were 16, 150 and 346 µg/L. Toxicity varied among compounds, with flupyradifurone being the most toxic and chlorantraniliprole being the least toxic. The reductions in survival and growth were similar between chronic and acute exposures for the three compounds tested. We compared our results to a recently conducted study on the toxicity of neonicotinoids to Hyalella and found that flupyradifurone was intermediate in toxicity, while sulfoxaflor and chlorantraniliprole were comparable to or less toxic than the least toxic neonicotinoid. Although there are few data on environmental concentrations of these neonicotinoid replacements, the information that does exist indicates the levels in surface waters are in the low µg/L range, lower than the effect concentrations observed in this study.

RP072 Imidacloprid modifies the mitotic kinetics and causes both aneugenic and clastogenic effects in the macrophyte Bidens laevis L.

G. Łukaszewicz, Universidad Nacional de Mar del Plata / Instituto de Investigaciones Marinas y Costeras; E. Ibarbura, Universidad Nacional de Mar del Plata / IMyC CONICET; D.S. Garanzini, Universidad Nacional de Mar del Plata / IMyC CONICET / Lab de Ecotoxicología Departamento de Ciencias Marinas; M. Menone, Universidad Nacional Mar del Plata / Lab de Ecotoxicología; S. Pflugmacher, Joint Laboratory of Applied Ecotoxicology, Environmental Safety Group, Korea Institute of Science and Technology Europe (KIST Europe) Forschungsgesellschaft mbH, Universität des Saarlandes

Imidacloprid (IMI) is a neonicotinoid insecticide widely used in agricultural activities all around the world. This compound is transported from croplands to surrounding freshwater ecosystems, producing adverse effects on non-target organisms. Because of the relevance of aquatic macrophytes in the above-mentioned environments and the lack of studies of potential effects of IMI on them, this work aimed to assess the mitotic process and potential genotoxicity in the aquatic macrophyte Bidens laevis L. Although the analysis of the Mitotic Index (MI) showed that IMI was not cytotoxic, the Cell Proliferation Kinetics (CPK) frequencies evidenced modifications in the kinetics of the mitotic process. Indeed, the anaphases ratio decreased at 10 and 100 µg/L IMI, while at 1000 µg/L an increase of prophases ratio and a decrease of metaphases ratio were observed. Regarding genotoxicity, IMI produced an increase of the abnormal metaphases frequency from 10 µg/L to 1000 µg/L as well as an increase in clastogenic anaphases-telophases frequency at 100 and 1000 µg/L. In addition, aneugenic anaphases-telophases and C-mitosis frequencies also increased at 1000 µg/L, confirming the effects on the mitotic spindle. Considering the genotoxic effects on B. laevis through two different mechanisms (aneugenic and clastogenic) and the wide spread use of IMI in agriculture, these mechanisms of toxicity on macrophytes should be considered among other recognized effects of this insecticide on aquatic biota.

RP073 Canadian Water Quality Guidelines for Aquatic Life Protection for Five Neonicotinoid Insecticides

Neonicotinoid insecticides (NNIs) are nicotine-based systemic compounds that are widely used in agriculture, either in field applications or as seed treatments, predominantly on wheat, corn, soybean, canola and horticultural crops. They are also used for killing insects in homes, controlling fleas on pets, and protecting trees from invasive insects such as the Emerald Ash borer. Studies show that they are toxic to non-target organisms, are mobile and may persist in the environment. NNIs are highly water soluble and may be present at concentrations that cause adverse impacts to aquatic life, specifically sensitive indicator species used in water quality determination. The use of NNIs has been controversial and research continues on the impacts of NNIs to the environment, particularly to non-target species. In Canada, five NNIs (acetamiprid, clothianidin, imidacloprid, thiacloprid, thiamethoxam) have been approved for various uses. The Canadian Pest Management Regulatory Agency (PMRA) has been re-evaluating three NNIs (imidacloprid, clothianidin, thiamethoxam) due to concerns with their impact on pollinators and aquatic life, resulting in restrictions on their use. PMRA is continuing to evaluate these three NNIs to determine if further actions are needed. Canadian Water Quality Guidelines (CWQGs) for the protection of aquatic life were derived for the five NNIs approved for use in Canada. CWQGs are nationally approved limits in the water column where no adverse toxic effects are expected to aquatic plants and animals. Both short-term benchmark concentrations and long-term exposure guidelines were developed. CWQGs are used to assess the quality of water, to identify areas where presence of chemicals may present a risk to aquatic life and to assess the success of risk mitigation activities. A set number of chronic toxicity studies are required to develop CWQGs using a species sensitivity distribution approach, and these were lacking at the start of this project. The Ontario Ministry of the Environment, Conservation and Parks commissioned additional toxicity data to develop CWQGs for four NNIs (acetamiprid, clothianidin, thiamethoxam and thiacloprid) and update the 2007 interim guideline for imidacloprid, as recent studies suggested it did not provide an appropriate level of protection.

RP075 Persistent organic pollutants in Hawaiian false killer whales: variance in relation to life history and social group

M.A. Kratafij, Michigan State University / Fisheries and Wildlife; G.M. Ylitela, NOAA / Environmental and Fisheries Sciences Division; R.W. Baird, S.D. Mahaffy, Cascadia Research Collective

False killer whales (Pseudorca crassidens) are long-lived, slow to mature, apex predators, and therefore susceptible to bioaccumulation of persistent organic pollutants (POPs). Hawaiian waters are home to three distinct populations/stocks: pelagic, Northwestern Hawaiian Islands (NWHI), and main Hawaiian Islands (MHI). Following a precipitous decline over recent decades, the MHI population was listed as “endangered” under the Endangered Species Act in 2012. This study assesses the risk of POP exposure to these populations by examining pollutant concentrations and patterns from blubber biopsy samples (n=56) related to life history characteristics (i.e., sex, age class, reproductive status). Samples (MHI n=45, NWHI n=8, pelagic n=3) were analyzed for polychlorinated biphenyls (PCBs), dichlorophenyltrichloroethanes (DDTs), polychlorinated diphenyl ethers (PBDEs), and some organochlorine pesticides. Pollutant
levels were generally similar among populations. For MHI individuals, 66.7 percent of all whales (all adult males, 50% of adult females, and 66.7% of juveniles/subadults) contained summed PCB concentrations greater than or equal to the suggested threshold for associated deleterious health effects in marine mammals. Based on long-term sighting histories, 8 of 24 MHI adult females have never been reported to give birth. These individuals are likely characterized by reproductive senescence associated with age, or impaired reproductive capabilities linked to high POP exposure. Juvenile/sub-adults had significantly higher concentrations of some contaminants than those measured in adults. Further, for individuals biopsied twice over 2-3 years, adults accrued more POPs while a subadult female lost some POPs (e.g., PCBs, DDTs). This loss is likely attributed to growth dilution, where metabolized contaminants are redistributed to other organs or within the bloodstream. Consequently, juveniles/sub-adults may be at greater risk to negative health effects (e.g., thyroid disruption, immunocompetence) as they undergo critical physiological development. Our results provide invaluable insight into the ongoing risk these contaminants pose to the MHI population’s viability, as well as consideration of risk for the NWHI and pelagic stocks. Additionally, MHI whales exhibit cohesive social organization that could make them more vulnerable to increasing anthropogenic threats; it is important to account for this vulnerability when assessing population-level concerns.

**RP076 Comparative toxicity of organic marine contaminants (PCBs, crude oil, corexit, B[a]P, PFOA) in gray whale skin cell cultures**

C. Wittmaack, J.D. Pierro, Texas Tech University / Environmental Toxicology; J.G. Surles, Texas Tech University / Department of Mathematics and Statistics; J. Jacobsen, V.E. Enterprises / Department of Biological Sciences; A. Lang, NMFS Southwest Fisheries Science Center, NOAA Fisheries / Southwest Fisheries Science Center; C. Godard-Codding, The Institute of Environmental and Human Health / Texas Tech University / Department of Environmental Toxicology

Gray whales (Eschrichtius robustus), unlike more pelagic species, migrate past and feed close to dense coastal human populations which increases their risk of exposure to organic marine contaminants. Polychlorinated biphenyls (PCBs) are persistent organic pollutants historically manufactured as industrial insulators. Crude oil is present in the marine environment via anthropogenic (oil spills and leaks) and natural (seeps on the sea floor) sources. Corexit is used as a dispersant during oil spills. PAHs are produced during the incomplete combustion of petroleum or wood whereas PFCs are components of flame retardants. PCBs, polycyclic aromatic hydrocarbons (PAHs) and per/poly-fluorinated compounds (PFCs) have been detected in cetacean (whale and dolphin) blubber. Cell culture is invaluable in toxicological research as it can be established minimally invasively from a single biopsy and allows for multiple investigations. This is critical for research on protected species such as the gray whale. Our goal is to understand whether these contaminants are cytotoxic to gray whale skin fibroblasts and whether these xenobiotics may be of concern for the species. We collected skin biopsies from three free ranging gray whales off the coast of California. Skin fibroblasts were cultured from the epidermis. Fibroblasts were maintained in DMEM/F12 media supplemented with 15% cosmic calf serum, 1% penicillin/streptomycin, 1% glutamax, and 0.1% sodium pyruvate. Cells were dosed with either PCB 126 in concentrations of 10uM, 1uM, 0.1uM, or 0.01uM or media accommodated fractions of crude oil and/or Corexit. Time points of exposure were 24h, 48h, 72h, and 96h. Cytotoxicity was investigated using MTT (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) and LDH (lactate dehydrogenase) assays. Viability was significantly reduced after exposure to PCB 126 at a concentration of 10uM at various exposure time points (p< 0.05). Preliminary results suggest that cellular viability was also reduced after exposure to Corexit at all time points. Additionally, results from an earlier portion of this study indicated that cellular viability was significantly reduced after exposure to either benzo[a]pyrene (B[a]P) or perfluorooctanoic acid (PFOA) at various concentrations and time points of exposure (p< 0.05). Results are allowing us to compare cytotoxicity between contaminants and identify those that are cytotoxic and/or cytotoxic at environmentally relevant concentrations. Further investigation is underway.

**RP077 Measurement of nine steroid hormones in fin whale blubber biopsies via LC-MS/MS**

D. Bernot, Autonomous University of Baja California Sur / Department of Marine Biology; L. Viloria-Gómez, Autonomous University of Baja California Sur; C. Wittmaack, N. Kumar, Texas Tech University / Environmental Toxicology; J. Urbán-Ramírez, Autonomous University of Baja California Sur / Department of Marine Biology; C. Godard-Codding, Texas Tech University / The Institute of Environmental and Human Health / Department of Environmental Toxicology

The fin whale Balanoptera physalus in the Gulf of California is considered resident and genetically isolated from other populations from the Pacific and Atlantic Oceans. Its low genetic variability, as well as the small number of individuals in the population (325; 95% IC: 248-427), it vulnerable to changes in its habitat, as well as disease. The measurement of steroid hormones in cetacean populations has proven to be useful in assessing the reproductive fitness of wild ranging populations, which helps evaluate the health of the population as well. There are very few studies about fin whale reproductive biology, which are key aspects to the population’s survival in the future. Therefore, the goal of this study was to measure ten steroid hormones via liquid chromatography mass spectrometry (LC-MS) in fin whale blubber biopsies obtained from free ranging individuals in the Gulf of California to determine a season of reproduction, as well as to assess stress in individuals in certain reproductive stages. Blubber biopsies were obtained from field work during 2015-2018 along the Gulf of California. Sex of the individuals will be investigated via PCR and electrophoresis analysis. Hormones were extracted using a liquid-liquid extraction method specifically designed for blubber and analyzed via a triple quadrupole LC-MS. Testosterone, progesterone, 17-estradiol, androstenedione, aldosterone, 17-hydroxyprogesterone, cortisol, cortisone and corticosterone were detected and quantified using 50 mg blubber samples. Extraction efficiencies ranged from 63-89% and RSD from 0.71-18%. Estrone was the only hormone consistently below our limit of detection. Genetic sexing analysis is underway, and we subsequently plan to investigate the influence of this life history parameter on hormone levels in this species.

**RP078 Reproductive and stress hormone analysis in small whale blubber samples using liquid chromatography mass spectrometry**

C. Wittmaack, Texas Tech University / Department of Environmental Toxicology; J. Urbán-Ramírez, Autonomous University of Baja California Sur / Departamento de Biología Marina; D. Bernot, UABCS / Departamento de Biología Marina; S. Martínez-Aguilar, Autonomous University of Baja California Sur / Departamento de Biología Marina; S. Subbiah, Texas Tech University / Department of Environmental Toxicology; N. Kumar, Texas Tech University / Environmental Toxicology; B. Halaska, P. Duignan, The Marine Mammal Center; C. Godard-Codding, The Institute of Environmental and Human Health / Texas Tech University / Department of Environmental Toxicology

The simultaneous analysis of multiple steroid hormones in cetaceans (whales, dolphins, and porpoises) provides valuable reproductive and fitness data useful in their conservation and management. Minimally invasive blubber biopsies can be collected from free ranging animals, including large whale species. A critical aspect of endangered and protected species research is the use of minimal tissue mass which allows for multiple investigations from biopsies. The goal of this project was to analyze a hormone panel to explore the endocrinology of gray (Eschrichtius robustus) and fin (Balaenoptera physalus) whales using small mass samples compatible with blubber biopsy collection. Blubber biopsies and samples were collected from free ranging and stranded gray (n=52) and fin (n=9) whales off the coast of California, Baja California, and from the Gulf of California. Androstenedione, aldosterone, cortisol, cortisone, hydroxyprogesterone,
RP079 Cytotoxic effects of HBCD on liver organ cultures of the fathead minnow (Pimephales promelas)

J. Bertucci, University of Saskatchewan / Toxicology Centre; S.H. Malala Irugal Bandaralage, University of Saskatchewan / Toxicology; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

Hexabromocyclododecane (HBCD) is a cycloaliphatic flame-retardant additive that is applied as a thermal insulator in extruded and high-impact polystyrene foams. HBCD is a ubiquitous organic contaminant with the characteristics of persistent organic pollutant due to its potential to bioaccumulate, long-range transport and toxicity. The aim of this work was to determine the in vitro cytotoxicity of HBCD in the fathead minnow (Pimephales promelas) using liver transplants and to investigate the molecular mechanisms for these effects. Toxicity of nine different concentrations of HCBD (0.00032, 0.0016, 0.008, 0.04, 0.2, 1, 5, 25 and 125 mg HBCD/L) were tested by using the LDH assay after 6 and 24 h of incubation. The expression of genes with a key role in the regulation of apoptosis, oxidative stress, cytoprotective responses to reactive oxygen species (ROS), and xenobiotic metabolism was also measured in liver explants after exposure to 0.00032, 0.0016, 0.008, 0.2, and 25 mg HBCD/L. After 6 h, a concentration-dependent increase in cytotoxicity was found between 0.008 and 1 mg/L, followed by a decrease between 1 and 25 mg/L. The cytotoxicity reaches 100% at a concentration of 125 mg/L. After 24 h, HBCD showed a biphasic response with a concentration-dependent decrease in cytotoxicity between 0.0016 and 1 mg/L that returned to baseline levels at 5 mg/L. Then, cytotoxicity increases at concentrations greater than 5 mg/L to reach a maximum value at 125 mg/L. Changes in the expression of genes related to apoptosis; apoptosis, oxidative stress, protection against ROS and xenobiotics, might suggest an explanation for the observed dynamics of HBCD cytotoxicity in liver organ cultures.

RP080 Relative Potency Factors of Brominated Dioxins Based on Japanese Medaka Early-Life Stage Toxicity Test

K. Nakayama, T.M. Nguyen, Ehime University / Center for Marine Environmental Studies; N. Fujioka, H. Tokusumi, Ehime University / Department of Biology; N. Uramaru, Nihon Pharmaceutical University / Faculty of Pharmaceutical Sciences; G. Suzuki, National Institute for Environmental Studies / Center for Material Cycles and Waste Management Research

Polybrominated dibeno-p-dioxins and dibenzofurans (PBDDFs) have been detected from biotic and abiotic matrices. Since PBDDFs are contaminated in brominated flame retardants as impurities, they can be released into environment via wastewater discharged from flame retardant fiber manufacturing or e-waste recycling processes. Brominated dioxins are thought to cause similar biological effects as chlorinated dioxins, however, information of their effects on aquatic organisms is limited. In the present study, we conducted early-life stage toxicity tests using Japanese medaka (Oryzias latipes) in order to derive toxic equivalency factors (TEFs) of PBDDFs. First, we exposed medaka embryos to 2,3,7,8-tetrachloro dibenzo-p-dioxin (TCDD) at different doses and durations to fix the experimental conditions. Then, using the fixed conditions, the toxic effects of 2,3,7,8-tetrabrominated dibenzofuran (tetrabDF), 2,3,7,8-tribrominated dibenzofuran (tribDF) as well as TCDD were evaluated, and TEFs of each brominated compound were calculated. TCDD-exposed fish showed typical symptoms called blue-sac disease, including yolk sac and pericardial edema, subcutaneous hemorrhages, and craniofacial malformations. EC50 for normal hatchling and LC50 at 21 or 28 days post-fertilization in TCDD exposure test were 249, 220, or 73.8 µM, respectively. TetrabDF exposure caused similar phenotypic effects to TCDD in medaka embryos and larvae, and its EC50 and LC50 values were 8720, 7500, or 4580 µM, respectively. On the other hand, tribDF induced none of the effects observed in the TCDD exposure test. Based on these results, TEF values of tetrabDF or tribDF ranged from 0.0171 to 0.0293 or < 0.000119, respectively. Previous in vitro studies demonstrated that tetraBDF had relatively high potency (REP: 0.10-0.97) causing TCDD-like effect, while triBDF had much less (REP: 0.00003-0.0013). These results agreed with our present study. TEF values obtained in the present study will be used for risk assessment and management of brominated dioxins in aquatic environment.

RP081 Chronic sub-lethal toxicity of two emerging isopropylated triarylphosphate (ITPs) isomers flame retardants in the amphipod Hyalella azteca

M. Giraud, L. Mercier, Environment and Climate Change Canada / Aquatic Contaminants Research Division; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; R. Robitaille, University of Toronto / Earth Sciences; M. Houde, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Since the phase-out of polybrominated diphenyl ethers (PBDEs), replacement mixtures containing different isopropylated triarylphosphates (ITPs) have been used increasingly as flame retardants as well as plasticizers in paints, textiles and in a large range of other commercial products and applications. Despite their widespread use, toxicity data on ITP mixtures are still very scarce, mainly because the relative composition of these commercial mixtures remained largely uncharacterized until very recently. In the last couple of years, individual ITPs contained in commercial flame retardant mixtures (e.g. Firemaster 550) were characterized; 2-isopropylphenyl diphenyl phosphate (2IPPDP) and bis-(2-isopropylphenyl) phenyl phosphate (B2IPPPP) were the most dominant isomers reported (27% and 11%, respectively). These ITPs have been reported in house dust, human urine, urban and rural air and in Arctic snow, indicating persistence and long-range transport potential of these chemicals. Despite their environmental presence, the toxicity of these two compounds in aquatic organisms remains to be elucidated. The goal of this study was to fill this gap by evaluating the effects of B2IPPPP and 2IPPDP in the freshwater amphipod Hyalella azteca. Organisms...
were exposed chronically (28-d) through sediments spiked with sub-lethal doses of each compound at 0, 10, 100 and 1000 µg/g. Transcriptional responses were measured using RNA-sequencing in organisms exposed to the highest dose in order to identify the molecular pathways impacted by each compound. Further dose-response analyses using qRT-PCR on candidate genes and biochemical measurements of suitable protein biomarkers will help better understand the modes of action of ITPs in freshwater organisms.

RP082 Physiological and molecular outcomes of dietary exposure to the flame retardant, BDE-99, in the Atlantic killifish (Fundulus heteroclitus)

N.A. McNabb, University of California, Davis; B.W. Clark, USEPA / Atlantic Ecology Division; I. Kirby, ORISE / USEPA / Atlantic Ecology Division; J. Bishop, ORISE / USEPA; D.M. Champlin, S. Jayaraman, D.E. Nacci, US Environmental Protection Agency / Atlantic Ecology Division; A. Whitehead, University of California, Davis / Environmental Toxicology

Polybrominated diphenyl ethers (PBDEs) are a class of flame retardants that were used widely in a variety of consumer products before being largely phased out in the early 2000s. However, they are persistent, bioaccumulative, and ubiquitous environmental pollutants. A prominent PBDE congener, BDE-99, is predicted to alter metabolic homeostasis through perturbation of peroxisome proliferator-activated receptor alpha (PPARα) signaling in fish. To better understand adverse outcomes from exposure to BDE-99 and their underlying mechanisms, we assessed the effects of dietary exposure to BDE-99 in the Atlantic killifish (Fundulus heteroclitus). Adult wild-caught killifish were fed diets amended with a range of concentrations of BDE-99 (0, 150, 375, or 750 ng/g fish ww/day) or clofibrate acid (known PPARα agonist; 80 µg/g fish ww/day) for 38 days. Fish length, weight, and fecundity were measured at three time points throughout the exposure period. On days 10 and 39, subsets of fish were sampled, and tissues (gonads, liver, abdominal fat, and brains) were weighed and archived for molecular and chemical analyses. Bioaccumulation was assessed to relate all endpoints to measured internal dose on a per individual basis. As expected for PPARα agonism, energetic reserves (fat and liver mass) were affected. At the termination of the exposure, reproduction was significantly impaired by all concentrations of BDE-99 compared to control. Genome-wide gene expression profiling (RNA-seq) is providing insight into the molecular pathways that are functionally involved in the observed growth, energetic, and reproductive impacts of BDE-99 dietary exposure. Ultimately, outcomes measured at the molecular, organ, and individual levels will be used to inform bioenergetic models to predict effects of BDE-99 on killifish populations. Ongoing transgenerational experiments are testing for impacts propagated across generations from these parental exposures.

RP083 2,2',4,4',5-Pentabromodiphenyl ether impairs the vision development of larval zebrafish

S. Wei, T. Xu, Tongji University / College of Environmental Science and Engineering

Polybrominated diphenyl ethers (PBDEs), though has been banned from using ten years ago, can be detected ubiquitously in different environmental medium and organisms, like surface water, outdoor and indoor dust, serum, breast milk and so on. Large numbers of laboratory and epidemiological studies have proved PBDEs possess reproductive, developmental, endocrine disrupting and neurobehavioral toxicities and exert such effects mainly by interfering with thyroid pathway and retinoic acid pathway. Considering that retinoic acid is especially important for eye development, PBDEs may pose great harm to the visual system of animals and human beings, yet few studies involved adverse effects on vision. This study focused on the negative effects that 2,2',4,4',5-penta-bromodiphenyl ether (BDE-99) brought to the vision development of larval zebrafish. Phototoxic and locomotor tests were used to identify the light sensitivity of larval zebrafish. The results showed embryos exposed to high dose were less likely to move to the illuminated areas and were less active when experiencing the transition from light to dark, indicating light sensitivity of larval zebrafish were impacted. Given that larvae at 5 days post fertilization serve functionally as an all-cone retina, genes expressing cone opsins were examined by qRT-PCR. After exposure to high dose BDE-99, almost all the expression levels of the tested genes were significantly downregulated, ranging from 0.44±0.08 to 0.64±0.05 fold, except one expressing opsin sensitive to middle wavelength was upregulated, implying that the vision development was severely impaired. Our results demonstrated that BDE-99 disrupted the vision development of larval zebrafish and the visual system could be a potential target of environmental pollutants, thus more attention should be paid to this new toxicological endpoint.

RP084 The naturally halogenated compounds and POPs compositions in squid differ between the Indian and South Atlantic oceans

Q. Wu, University of Hohenheim / Institute of Food Chemistry; H. Bouwman, B. Uren, North-West University / Environmental Science and Management; C. van der Lingen, Department of Agriculture, Forestry and Fisheries / Fisheries Management; V. Vetter, University of Hohenheim / Institute of Food Chemistry

Muscle tissue of Cape Hope squid (Loligo reynaudii) from three sites in the Indian and Atlantic oceans along the South African coast were analyzed for halogenated natural products (HNP)s and anthropogenic persistent organic pollutants (POPs). The most prevalent HNP (2,3,3',4,5'-heptachloro-1'-methyl-1,2'-bipyrrole; Q1), was quantifiable in all squid samples with mean concentrations of 100, 96 and 43 ng/g lipid mass, respectively, at the Indian Ocean (site A) and, two sites in the South Atlantic Ocean (sites B and C). Also, the bromine containing HNPs 1'-methyl-1,2'-bipyrrole, 2,4,6-tribromophenol (2,4,6-TBP, up to 28 ng/g lipid mass), polybrominated methoxy diphenyl ethers, MHC-1, TMPB and, other HNPs were also detected. HNP concentrations were generally more than one order of magnitude higher than POPs, consisting mostly of polychlorinated biphenyls (PCBs). PCB 153 was the most abundant PCB congener in Cape Hope squid from the Indian Ocean, and PCB 138 in samples from the South Atlantic Ocean. ANOVAs indicated significant (P < 0.05) differences between catch sites. Multivariate analyses discriminated between the sites. Halogenated natural products and, POPs could thus be further investigated as a stock discrimination tool. Of the POPs analyzed, only PCB 118 has a toxic equivalency factor, with toxic equivalents of 0.00037 (site A), 0.000030 (site B) and, 0.00019 (site C), respectively.

RP085 The sulfate metabolite of 3,3'-Dichlorobiphenyl (PCB-11) impairs Cyp1a activity and increases hepatic neutral lipids in zebrafish larvae (Danio rerio)

M. Roy, University of Massachusetts, Amherst / Environmental Health Sciences; P.R. Duche, University of Massachusetts, Amherst; K.C. Hornbuckle, University of Iowa / Civil and Environmental Engineering; A.R. Timme-Laragy, University of Massachusetts / Environmental Health Sciences

3,3'-Dichlorobiphenyl (PCB-11) is a lower-chlorinated PCB congener that is a byproduct of diarylde pigment manufacturing, and both PCB-11 and its metabolites have been detected in human samples. Our previous research in zebrafish (Danio rerio) demonstrates that static exposures to 20 µM PCB-11 starting at 1 day post fertilization (dfp) can stunt liver growth, and in co-exposures with other aryl hydrocarbon receptor (Ahr) agonists, PCB-11 can inhibit Cyp1a function to either prevent or exacerbate cardiovascular and craniofacial malformations, depending on the co-exposure. In this study, we tested whether two prevalent PCB-11 metabolites, OH-PCB-11 and PCB 138 in samples from the South Atlantic Ocean. ANOVAs indicated significant (P < 0.05) differences between catch sites. Multivariate analyses discriminated between the sites. Halogenated natural products and, POPs could thus be further investigated as a stock discrimination tool. Of the POPs analyzed, only PCB 118 has a toxic equivalency factor, with toxic equivalents of 0.00037 (site A), 0.000030 (site B) and, 0.00019 (site C), respectively.

RP085 The sulfate metabolite of 3,3'-Dichlorobiphenyl (PCB-11) impairs Cyp1a activity and increases hepatic neutral lipids in zebrafish larvae (Danio rerio)

M. Roy, University of Massachusetts, Amherst / Environmental Health Sciences; P.R. Duche, University of Massachusetts, Amherst; K.C. Hornbuckle, University of Iowa / Civil and Environmental Engineering; A.R. Timme-Laragy, University of Massachusetts / Environmental Health Sciences

3,3'-Dichlorobiphenyl (PCB-11) is a lower-chlorinated PCB congener that is a byproduct of diarylde pigment manufacturing, and both PCB-11 and its metabolites have been detected in human samples. Our previous research in zebrafish (Danio rerio) demonstrates that static exposures to 20 µM PCB-11 starting at 1 day post fertilization (dfp) can stunt liver growth, and in co-exposures with other aryl hydrocarbon receptor (Ahr) agonists, PCB-11 can inhibit Cyp1a function to either prevent or exacerbate cardiovascular and craniofacial malformations, depending on the co-exposure. In this study, we tested whether two prevalent PCB-11 metabolites, OH-PCB-11 and PCB-11-Sulfate drive these effects, as well as whether chronic single exposures to PCB-11 or the two metabolites result in increased hepatic neutral lipid accumulation. Wildtype AB embryos were statically exposed to 0.002-20 µM OH-PCB-11 or 0.2-20 µM PCB-11-Sulfate from 1-4 dfp using the live EROD bioassay to assess Cyp1a activity and morphological growth, and then co-exposed to these same concentrations with either of the Ahr agonists 5 nM.

SETAC North America 40th Annual Meeting | 505
RP086 Combined toxicities of tributyltin and polychlorinated biphenyls on the development and hatching of Japanese medaka (Oryzias latipes) embryos via in ovo noneinjection

Y. Oshima, Faculty of Agriculture / Kyushu University / Fisheries; X. Qiu, Jiangsu University; S. Kim, Faculty of Agriculture / Kyushu University; I. Kang, Kyushu University / Kyoso; T. Hano, Japan Fisheries Research Agency; Y. Shimasaki, Kyushu University / Faculty of Agriculture

Tributyltin (TBT) and polychlorinated biphenyls (PCBs) are typical organic pollutants that co-exist in the aquatic environment. Despite increasing awareness of their combined impacts, knowledge about their potential interactive effects remains limited. In this study, we investigated the effects of TBT-PCB mixtures on the survival, development, and hatching of embryos of Japanese medaka (Oryzias latipes). Our goal was to assess the interactive effects of TBT and PCBs on early-life-stage fish. We used in ovo noneinjection to simulate the maternal transfer process and to control exposure doses at 0, 7.5, 15, 30 ng/g-egg (for both toxins). A factorial design (4 A 4) corresponding to the above doses was used to define the formulation of mixtures. Results showed that injection of mixtures of TBT and PCBs into fertilized eggs caused significantly elevated rates of mortality, yolk-sac shrinkage, swim-up failure, and deformities of medaka embryos/larvae. TBT and PCBs interacted synergistically to induce the above developmental abnormalities. In contrast, exposure to only TBT increased the hatching times of embryos, whereas exposure to only PCBs decreased the hatching times. The dose ratios, dose levels, and interactive effect of TBT and PCBs in a mixture played significant roles in determining the final impact on time-to-hatching. Our results suggested that in ovo exposure to a mixture of TBT and PCBs may interact synergistically to induce developmental abnormalities in fishes.

RP087 Contaminants, Reproduction and Deformities in Snapping Turtles in the Hamilton Harbour Area of Concern (Canada)

K. Hughes, Broading Biological Consulting; C.A. Bishop, Environment and Climate Change Canada / Wildlife Research Division; S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; K. Intini; K. O’Hare, Environment and Climate Change Canada / WLSD; P.A. Martin, Environment Canada / Ecotoxicology and Wildlife Health Division

Contaminant burdens, reproduction and development were examined in the eggs of snapping turtles (Chelydra serpentina serpentina) within the Hamilton Harbour Area of Concern (AOC) from 1984 to 2016. Clutches of freshly-laid eggs were collected within the AOC, artificially incubated in the laboratory and assessed for hatching success and hatching deformities. Several legacy contaminants, including PCBs and mercury, and polychlorinated diphenyl ethers (PBDEs) were also measured in a subsample of eggs from these clutches. From 1986 to 1990, as mean percentages per clutch, hatching success ranged from 66.5-89.2% and deformities ranged from 1.9-21.4% whereas from 2012 to 2016 at two AOC locations, improvements were evident and hatching success ranged from 81.4%-94.7% and deformities ranged from 4.6%-16.1%. No significant differences were found for both of these endpoints between AOC locations and the Great Lakes reference site in three of four years when this could be assessed. During this period, contaminant burdens in eggs from the AOC also dropped significantly with sum PCB concentrations declining exponentially from, on average, 5.1 ppm in 1984 to 1.5 ppm in 2014. Such large declines in concentrations of sum PCBs and other organochlorines in eggs since the mid-1980s provide evidence that exposure to these compounds has decreased in snapping turtles foraging in the AOC. Current and historic cumulative total concentrations of sum PCBs, organochlorine pesticides and sum PBDEs indicate that eggs from the Hamilton Harbour AOC were among the most contaminated relative to other AOCs within the Canadian Great Lakes. Burdens in eggs were dominated by PCBs with p,p’-DDE being the second most abundant halogenated hydrocarbon. Several factors relating to both anthropogenic activities and physical attributes of the Harbour likely influenced spatial patterns of contaminants which is consistent with the history of contamination in this area. Mercury concentrations in eggs from Hamilton Harbour were relatively low compared to burdens at other Canadian Great Lakes AOCs. Currently, there is no evidence of adverse effects for the two reproduction and development endpoints examined in snapping turtles in the Hamilton Harbour AOC that can be attributed to local contamination within the AOC.

RP089 Polycyclic Aromatic Hydrocarbon in clarias gariepinus exposed to roofing sheet industrial effluents

E.J. Nweze, C.U. Ogbonna, I.N. Onwurah, University of Nigeria / Department of Biochemistry

This study aims to ascertain the presence and composition of polycyclic aromatic hydrocarbons in Clarias gariepinus exposed to roofing sheets industrial effluents. Matured Clarias gariepinus samples were collected from Ekwuru River in Emene Enugu Nigeria using simple fishing implements. Triplicate samples were collected from the point of discharge of effluents into the river, upstream and downstream all 10metres apart. Control fish samples were also collected from a privately owned fish pond. The samples were weighed, processed and prepared for Gas Chromatography analysis of PAH compounds present in the samples as well as their concentrations through the equipped Flame Ionization Detector (FID). It was observed that in all, a total of eleven (11) PAHs were present in the fish samples of which 10 of them were in the United States Environmental Protection Agency (USEPA 16PAH) list of toxic hydrocarbons to aquatic lives and mammals. Downstream samples showed the presence of only one (1) carcinogenic compound Benzo (a) pyrene as recognized by the International Agency for Research on Cancer. Anthracene was the most prevalent parent compound found in the test samples. The overall concentration of PAHs in the downstream fish sample was 0.1003Mg/ml while the upstream sample was 0.0977Mg/ml. The control fish sample contained five polycyclic aromatic hydrocarbons (although the concentrations were quite marginal), namely: acenaphthene (0.0008Mg/ml), fluorene (0.0004Mg/ml), anthracene (0.0374Mg/ml), xylene (0.0020Mg/ml) and benzo (g,h,i) perylene (0.0008Mg/ml). it can be observed that roofing sheet industrial effluents has a significant negative impact on the aquatic life of Ekwuru.

RP089 Differential gene expression responses after aryl hydrocarbon receptor (AhR) agonist exposure in resistant and reference Fundulus grandis populations

P. Brews, Baylor University / Environmental Science; E.M. Oziolor, University of California, Davis / Environmental Toxicology; C.W. Matson, Baylor University / Environmental Science

Gulf killifish (Fundulus grandis) populations from the Houston Ship Channel (HSC) have evolved resistance to the teratogenic effects of exposure to aryl hydrocarbon receptor (AhR) agonists including
polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs). This resistance is associated with reduced AhR induction after exposure as measured through CYP1A1 activity. In similarly resistant Atlantic killifish (F. heteroclitus) previous studies have found differences in expression of other cyp1 genes and components of the AhR signaling pathway after exposure. However, similar studies have not been conducted in F. grandis. The goal of this study was to use gene expression analysis to better characterize the differential responses of resistant and reference F. grandis embryos after exposure to several AhR agonists. Exposure compounds included PCB-126 and two PAHs (benzo[a]pyrene (BaP) and benzo[k]fluoranthene (BkF)). Expression responses after exposure differed between populations and between exposure compounds. In general, higher doses of PCB-126 were needed to elicit a response in resistant embryos than in reference embryos. There was also a difference in response timing between the two populations. Responses to PAH exposures were more similar between the populations and included downregulation of some genes that were upregulated by PCB-126 exposure. Several of these genes were also previously shown to be upregulated in F. heteroclitus after similar PAH exposures. Overall, the results show that the response of F. grandis embryos to AhR agonist exposure differs between populations and between PCBs and PAHs. These results will help further the understanding of the molecular processes that confer resistance in F. grandis.

**RP090 Polycyclic aromatic hydrocarbon levels of selected seafoods from crude oil exploration communities in Bayelsa State Nigeria**

J. Ifemgie, Chukwuemeka Odumegwu Ojukwu University / Biochemistry; C.K. Uhama, Enugu State University of Science and Technology / Biochemistry

This study was carried out to evaluate the polycyclic aromatic hydrocarbon (PAH) levels of seafoods from three selected crude oil exploration communities of Bayelsa State. The seafood samples (Catfish, periwinkles and water snails) were freshly collected from the study sites Azikolo, Amassoma and Yenagoa (control), transported to the laboratory and processed for analysis. Polycyclic aromatic hydrocarbon levels were determined in edible tissues of selected seafoods using Gas Chromatography-mass spectrophotometer. The result of the investigation revealed that the total mean concentrations of these PAHs in the three seafoods were highest in Azikolo (33.6 μg/kg), followed by Amassoma (23.46 μg/kg) and lowest in Yenagoa (3.96 μg/kg). Low Molecular Weight PAHs were generally predominant in seafoods from Azikolo, whereas High Molecular Weight PAHs were predominant in seafoods from Amassoma. Generally, catfish accumulated more PAHs with the total average concentration of 25.89 μg/kg, followed by periwinkles (20.63 μg/kg) and finally, water snails (12.70 μg/kg). However, the mean concentration of Biomarker PAHs (known as PAHs - Benzo[a]pyrene, Benzo[a]anthracene, Benzo(b)fluoranthene and Chrysene) of fish from Azikolo (13.53 μg/kg), periwinkles from both Azikolo (12.22 μg/kg) and Amassoma (26.09 μg/kg) were significantly higher (P< 0.05) compared with these samples from Yenagoa. The PAHs values of the samples from Azikolo and Amassoma exceeded the European Commission (EC) recommended limit of 12 μg/kg suggesting that sea foods remain a major endogenous source of PAHs among the people of the area.

**RP091 Regioselective Effects of Oxygenated Polycyclic Aromatic Hydrocarbons on Red Blood Cell Concentrations in Japanese Medaka Embryos**

P. Tanabe, C.A. Mitchell, V. Cheng, D.C. Volz, D. Schlenk, University of California, Riverside / Environmental Sciences

Previous studies have demonstrated that exposure to oxygenated polyaromatic hydrocarbons (oxyPAHs) at critical developmental time points can impair red blood cell (RBC) concentrations in a regioselective manner, with 2-hydroxychrysene being more potent than 6-hydroxychrysene. Japanese medaka embryos were exposed to 2 or 6-hydroxychrysene (10-70μM) or 50μM phenantherene (a positive control) from 2 hours post-fertilization (hpf) to 10 days post-fertilization (dpf). Following exposure, RBC concentrations were quantified by staining fixed embryos with o-dianisidine (a hemoglobin-specific dye), imaging stained embryos using brightfield microscopy, and analyzing images within ImageJ. Exposure of embryos to 50 and 60uM phenanthrene resulted in a significant decrease in hemoglobin concentrations compared to vehicle controls. Ongoing studies are comparing these results with oxy-PAHs. Future studies will evaluate the role of biotransformation in the regioselective toxicity of each metabolite. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).

**RP092 Oxidative stress produced by paracetamol, aluminum and their mixture in root meristematic cells of Allium cepa**

K. Ruiz-Larg, Escuela Nacional de Ciencias Biológicas, IPN / Laboratory of Aquatic Toxicology Department of Pharmacy; M. Galar-Martinez, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional; S. García-Medina, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional; E. Gasca-Pérez, Cátedra CONACYT IPN / Laboratory of Aquatic Toxicology Department of Pharmacy; S. Cano-Viveros, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology Department of Pharmacy; L.M. Gómez-Ólivan, National Autonomous University of Mexico / Farmacia Pharmaceutical products, as well as metals, are two of the groups that have been detected most frequently in surface and groundwater worldwide. One of the drugs that has been reported in water bodies is paracetamol, which is also one of the most widely used drugs in the world, and has an important role due to its intrinsic toxicity. On the other hand, aluminum is one of the most abundant elements in the earth’s crust; it is freed naturally in aquatic ecosystems as a result of erosion of rocks and soil, however, in recent years the environmental levels of this have increased due to various anthropogenic activities. The test of Allium cepa is a bioassay in plants recognized worldwide and it is considered as an efficient indicator to determine the toxic effects of the chemical compounds found in aquatic ecosystems. The objective of this project was to evaluate the oxidative stress induced by paracetamol, aluminum and their mixture in root meristematic cells of Allium cepa, because the contaminants are not found in the environment in isolation, but forming complex mixtures that modify the toxic response. For this, specimens of A. cepa of 25 to 30 mm diameter were used, cleaned and germinated in purified water under laboratory conditions for 72 h. The bulbs of A. cepa were exposed to paracetamol (0.003 ppm), aluminum (0.270 ppm) and the mixture of both at environmentally relevant concentrations during 2, 6, 12, 24, 48 and 72 h. Afterwards, the roots were cut, homogenized and oxidative stress was determined by evaluating the degree of lipoperoxidation, the content of hydroperoxides and oxidized proteins, as well as the activity of antioxidant enzymes superoxide dismutase, catalase and glutathione peroxidase. The results showed modifications in the activity of antioxidant enzymes as well as damage to lipids and proteins.

**RP093 Acute and chronic toxicity evaluation of nortriptyline in zebrafish (Danio rerio) adults using multiple endpoints**

A. Oliveira, M. Fascinelli, D. Moura, J.M. Pinto, A. Pic-Taylor, University of Brasilia / Department of Genetics and Morphology; J. Forte Mazzeu de Araújo, University of Brasilia / Faculty of Medicine; R. Rios Villacis, C. Grisolia, University of Brasilia / Department of Genetics and Morphology

In the last decade, several substances began to appear in quantifiable concentrations in different ecosystems, named as emerging pollutants. Psychiatric drugs are among the world’s leading prescription medicines for humans and their presence in aquatic environments has raised concerns about their potential harmful effects in non-target organisms. Nowadays, toxicological studies, mainly the chronic type, are still scarce for most of psychiatric substances. In this context, we evaluated the acute (4 days) and chronic effect (28 days) of the tricyclic antidepressant nortriptyline (NTP)
in zebrafish adults using several methodologies and cells/tissues: comet/ 
micronucleus tests for erythrocytes; biochemical test for head and muscle; 
histology for liver, gill and kidney; and gene expression microarray for 
brain. Acute toxicity was assessed at higher NTP concentrations (ranging 
from 0.5 to 2 mg/L), while the chronic analysis was conducted with low 
concentrations (0; 0.01; 0.001 mg/L). Acute exposure induced mortality 
(lethal concentration 50 of 1,1 mg/L) and decreased acetylcholinesterase 
activity in zebrafish heads, however, it was not genotoxic. On the other 
hand, chronic exposure did not generate genotoxic or histological dam-
age, as well as alterations in acetylcholinesterase activity. Nevertheless, 
the genomic analysis showed 184 and 66 differentially expressed genes 
between the controls and the groups exposed to 0.01 and 0.0001 mg/L of 
NTP, respectively. Genes related to oxidoreductase activity and neural regu-
lation were altered in the NTP concentration of 0,0001 mg/L. Moreover, 
genes associated with locomotion, immune system process and also oxire-
ductase activity were deregulated in the brains of animals exposed to 0,01 
mg/L of NTP. Our results showed drastic effects of NTP exposure only in 
the very high concentrations, which are not identified in the ecosystems. 
Nonetheless, the microarray data indicated that very low environmental 
concentrations of NTP may be toxic at long-term exposures.

**RP094 4-Epianhydrotetracycline development toxicity to zebrafish 
embryo-larval and transcriptome analysis**

*M. Wang, X. Chen, Tongji University / College of Environmental Science 
and Engineering; J. Zhao, Tongji University / State Key Laboratory of 
Pollution Control and Resource Reuse / College of Environmental Science 
and Engineering; L. Wu, Tongji University / College of Environmental 
Science and Technology*

Tetracycline is widespread in the environment due to the extensive using. 
It is very difficult to completely mineralize under field conditions, for 
instead, the majority of tetracycline is transformed into by-products.

4-Epianhydrotetracycline (4-EATC) is a primary by-product in tetra-
cycline degradation process and it may pose a potential environmental 
risk. Up to now, however, the toxicology information of 4-EATC is rare.

In this study, zebrafish embryo-larval had been employed to evaluated 
4-EATC developmental toxicity, including lethal and sub-lethal effects 
and different expression genes obtained by high-throughput transcript-
omic sequencing after 96h exposure. The result shown that 4-EATC 
significantly affects zebrafish embryo-larva stage development and in 
a dose-dependent manner. In lethal effect, the highest mortality occurred 
in 8 - 24 hours post fertilization, the 96h LC50 of 4-EATC to zebrafish 
embryo-larval was 29.13mg/L, this value is much lower than tetracycline 
in our previous research. In sub-lethal effects, the 96h hating rate and 48h 
heart rate of zebrafish embryo was decreased significant in higher concen-
tration 4-EATC treatment groups, furthermore, zebrafish embryo-larva 
abnormality had been observed even in the lowest concentration 4-EATC 
treatment group (1.25mg/L), the 96h EC50 of abnormality was 8.57mg/L, 
the most sensitive sub-lethal effect caused by 4-EATC was pericardial 
edema. Transcriptome determine result shown 430 different expression 
genesis caused by 4-EATC, and enrichment significant on 7 KEGG path-
way: cAMP signaling pathway, Tryptophan metabolism, Arachidonic acid 
metabolism, Mineral absorption, Proximal tubule bicarbonate reclamation, 
GABAergic synapse and Phototransduction, the highest enrichment 
ratio of KEGG pathway was Phototransduction. The overall result 
indicated that 4-EATC has stronger toxicity than tetracycline and could 
affect zebrafish embryo-larval development even in low concentration, 
Furthermore, 4-EATC could regulate gene expression and result in the 
toxic effect on organisms, but the underlying mechanisms needed further 
investigation.

**RP095 Evaluating Effects of Bioactive Contaminants Associated 
with Waste Water Treatment Plant Effluent Discharge to the South 
Platte River**

*D. Villenueve, USEPA; A. Cole, J.E. Cavallin, US Environmental 
Protection Agency / Mid-Continent Ecology Division; J. Behlhofer, 
USEPA / NEIC; B.R. Blackwell, US Environmental Protection Agency 
/ Mid-Continent Ecology Division; D. Ekman, US Environmental 
Protection Agency / National Exposure Research Laboratory; A. Jastrow, 
US Environmental Protection Agency / Region 5; J. Kinsey, USEPA; 
K.A. Keteles, US Environmental Protection Agency / NEIC; J. Parman, 
Metro Wastewater Reclamation District; D. Winkelman, Colorado State 
University / Fish, Wildlife, and Conservation Biology; D. Villenueve, 
USEPA / National Health and Environmental Effects Research 
Laboratory / Mid-Continent Ecology Division*

Previous studies have detected numerous organic contaminants - includ-
ing biocides and pharmaceuticals - in the South Platte River near Denver, 
CO, at concentrations that rank among the highest in the nation. Regarded 
as contaminants of emerging concern (CECs), some of these compounds 
can disturb biological pathways in exposed species. Bi-monthly sampling 
and analysis of surface water samples in 2018, documented increased 
centrations of multiple CECs downstream of a waste water treat-
ment plant (WWTP). In vitro bioassays conducted on the same samples 
detected estrogen receptor (ER; 2.9-88ng/L E2-EQ) and glucocorticoid 
receptor (GR; 17-117 ng/L Dex-EQ)-mediated activities downstream 
of the WWTP. Peroxisome proliferator activated receptor gamma 
(PPARγ)-mediated activities were also detected using a multifactor-
rial Attagene assay, but not a targeted PPARγ transcriptional activation 
assay. Additional bi-monthly water sampling in 2019 was used to further 
characterize the spatial and temporal distribution of GR and PPARγ-
related bioactivities along the river. In addition to bi-monthly monitoring, 
fathead minnows (Pimphales promelas) were exposed in situ for five days 
at six locations upstream and downstream of the waste water discharge (2018). In 2018, despite the ER-mediated biological activity detected in 
vitro, no significant differences in the expression of male hepatic vitel-
logenin were found between sites. Consistent with the general lack of 
detectable PPARγ-regulated activity, there were no significant effects 
on PPARγ-related gene expression in the adipose tissue of females. No 
native-related differences in GR-related gene expression were detected 
in females, despite GR-activity in the in vitro assays, suggesting either 
limited bioavailability or limited potency of GR-active contaminants, 
in vivo. Fathead minnows will be exposed in situ again in August 2019. 
Results will provide new insights into the significance of GR-and PPARγ 
active contaminants in this system. The contents of this abstract neither 
constitute nor reflect USEPA policy.

**RP096 A Comparison of the Growth and Photosynthetic Toxicity of 
Human Pharmaceuticals to the Chlorophytes, Raphidocelis subcapitata 
and Chlorella vulgaris**

*A. Aderemi, C. Hunter, O. Pahl, J. Roberts, Glasgow Caledonian 
University / School of Engineering and Built Environment*

The discharge of pharmaceuticals via wastewater into the environment 
remains a great concern due to the threat posed to the photosyn-
thetic organisms that are vital for the functioning and sustenance of 
the aquatic food web. In an effort to compare the photosynthetic 
and growth responses of green algae to priority human pharmaceuticals, 
*Raphidocelis subcapitata* and *Chlorella vulgaris* were exposed to 
idocaïne, ifosfamide, cyclophosphamide, erythromycin, clarithromycin, 
ciprofloxacin, amoxicillin and sulfaflomethoxazole for 96 h. Ifosfamide 
and cyclophosphamide were non-toxic to both endpoints whereas lido-
caine showed more acute and chronic toxicity towards growth (EC50, 
99-104 mg/L; NOEC < 25 mg/L) than photosynthesis (178-354 mg/L; 
NOEC, 100-200 mg/L) in both microalgae. Amoxicillin had no effects 
on microalgal growth but was chronically toxic to algal photosyn-
thesis. Interestingly, sulfaflomethoxazole exhibited similar toxicity towards 
growth and photosynthesis with the toxicity parameters (EC10, EC20 
and EC50) for growth in consonance with those of photosynthesis for
each of the microalgae. Ciprofloxacin was toxic to growth (EC₅₀, 16.4 mg/L) in *Raphidocelis* and showed a high risk quotient (RQ) value due to high PEC in hospital effluent. Erythromycin and clarithromycin posed the highest threat with RQ well above 1 in *Raphidocelis* biomass. Erythromycin was more acutely toxic to photosynthesis (EC₅₀, 24.6 µg/L) than growth (EC₅₀, 160 µg/L) of *Raphidocelis* while eliciting similar chronic responses using both endpoints. Clarithromycin (EC₅₀growth, 6.1 µg/L) and erythromycin were highly toxic to *R. subcapitata*, strongly inhibiting growth and photosynthesis in this study at environmentally relevant concentrations. Consequently, their release into the environment after normal therapeutic use should be of great concern due to their adverse effects on the phytoplankton community.

**RP097 Wild fish grow faster downstream of a municipal wastewater treatment plant (WWTP)**

S. Hayat, L. Bragg, H. Dhiyebi, University of Waterloo / Biology; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate; M.R. Servos, University of Waterloo / Biology

Municipal wastewater effluent (MWWE) is a major concern for aquatic organisms due to a variety of contaminants, including pharmaceuticals and personal care products (PPCPs), that have been linked to adverse effects. In the Grand River watershed, Ontario (Canada), rainbow darter (*Etheostoma caeruleum*) are a small-bodied fish species that have been used extensively to study impacts of MWWE exposure. Fish exposed to wastewater effluent are impacted across various levels of biological organization but the associated nutrient input on fish growth has not been explored at this location. Growth is an important indicator of fish health and is used by the Canadian Environmental Effects Monitoring (EEM) program to understand impacts of metal mining and pulp and paper effluent on fish health. To improve the quality of the final effluent, major infrastructure investments have been made at the Waterloo municipal wastewater treatment plant in 2017. This study aims to understand the impact of MWWE on growth of rainbow darter in the Grand River before and after upgrades using von Bertalanffy growth curves. Growth curves and parameters are compared to assess whether fish downstream of MWWE grow differentially from fish upstream. Preliminary results suggest fish grow faster downstream than upstream for both males and females. Understanding and quantifying these differences in growth attributed to wastewater effluent can allow for detection of subtle but important impacts. Use of these small bodied fish can be used as an endpoint for a regional monitoring program to provide another indicator of fish health and allow linkages between exposure and biological responses.

**RP098 Assessing the Toxicity of Atovaquone to Freshwater Invertebrates**

J. Bennett, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D.J. Milani, Environment and Climate Change Canada / Water Science and Technology Directorate; N. Stock, Trent University / Water Quality Centre; J. Salerno, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Unsworth, Environment and Climate Change Canada / Water Science and Technology Directorate; Y. Kiedla, S. Cook, Environment and Climate Change Canada / Aquatic Contaminants Research Division; T. Craftwell, Environment and Climate Change Canada / Water and Science Technology Directorate; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Atovaquone (C₂₃H₂₂ClO₄) is a pharmaceutical used as an anti-malarial drug and in anti-HIV cocktails. Little is known about the environmental fate of Atovaquone and whether it affects non-target organisms in waterbodies receiving municipal wastewater effluents. This study investigated the effect of Atovaquone to two freshwater invertebrates, *Chironomus riparius* (midge larvae), and *Elliptio dilatata* (freshwater mussel). Because no analytical methods were available to quantify Atovaquone in environmental samples, methods were developed to quantify Atovaquone in water and complex matrices (sediment and biota). Sediment samples were mixed with ethyl acetate, acetonitrile and formic acid and extracted using sonication; water samples were diluted with acetonitrile. All sample extracts were analyzed using liquid chromatography-tandem mass spectrometry (LC-MS/MS), using deuterium-labelled Atovaquone for quantitation. *C. riparius* was exposed to sediment-associated Atovaquone for 10 d per Environment Canada's EPS 1/RM/32 test method (Environment Canada, 1997) using a field-collected reference sediment spiked with Atovaquone. Two chironomid exposures were conducted (range finding and definitive). The definitive test included six (nominal) concentrations (0, 10, 100, 500, 1000, 2000 mg/kg) and a 2% acetone solvent control (SC). There were no significant differences in chironomid survival across treatments; however multiple comparison tests indicated that growth was significantly reduced at 2000 mg/kg compared to controls. Adult *E. dilatata* were exposed to aqueous solutions of Atovaquone for 14 d with exposure solution renewal every 24 hours. Because Atovaquone was largely insoluble in water the effectiveness of various solvents (dimethylsulfoxide (DMSO), acetone, methanol, ammonium hydroxide-methanol) were explored. The first mussel range finding toxicity test included six treatments (SC, 0, 200, 1000, 2000, 20000 µg/L) with DMSO (2%) as the solvent. Atovaquone was toxic to *E. dilatata* at concentrations of 1000 µg/L (nominal). Additional range finding exposures with mussels are underway as is analysis of Atovaquone in surface water and municipal wastewater effluents. The data generated in this study will contribute to the environmental risk assessment of this compound in the Canadian environment.

**RP099 Oxidative stress induced by metformin in liver and blood of Cyprinus carpio**

S. Cano-Viveros, Escuela Nacional de Ciencias Biológicas, IPN / Laboratory of Aquatic Toxicology / Department of Pharmacy; M. Galar-Martinez, Escuela Nacional de Ciencias Biológicas / Instituto Politécnico Nacional / Department of Toxicology; S. García-Medina, Escuela Nacional de Ciencias Biológicas / Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology Department of Pharmacy; E. Gasca-Pérez, Cátedra CONACYT IPN / Laboratory of Aquatic Toxicology Department of Pharmacy; K. Ruiz-Lara, Escuela Nacional de Ciencias Biológicas / Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology Department of Pharmacy; L. Gómez Olivián, Facultad de Química UAEMex / Laboratory of Environmental Toxicology

The widespread occurrence of emerging contaminants in water resources could lead to ecological risk and affect human and aquatic life even at small concentrations. Pharmaceuticals, such as metformin, enters the environment through different pathways and have been found in surface water, wastewater stream, and various environmental compartments. Metformin is a long term administered biguanide which has proven to be an effective and convenient pharmaceutical treatment of diabetes mellitus type II. The number of metformin prescription has increased over the years with the growing number of people diagnosed with diabetes, which has led to finding it, in various water bodies. *Cyprinus carpio* is a very important organism from an ecological and economic point of view. In Mexico, this species inhabits 80% of the freshwater bodies and is consumed by a large number of people. In the current study, *C. carpio* was exposed to 11.694 µg/L of metformin for 12, 24, 48, 72 and 96 hours, and oxidative stress (lipid peroxidation degree, oxidized and hydroperoxide content and antioxidant enzymes activity) was measured in liver and blood. Differences between the control and exposed groups were observed, finding increments in oxidized products and alteration of antioxidant enzymatic activity as a reflect of the damage induced by this contaminant.
RP100 Exposure of juvenile catfish (Clarias gariepinus) to acetaminophen induces dose-dependent and persistent disruption in gonadal development

L.J. Eceomwe, University of Benin / Dept of Animal and Environmental Biology; N.O. Erhumnwuese, I.I. Tong, University of Benin / Animal and Environmental Biology

Acetaminophen is the most commonly taken analgesic world-wide and as a result of the consumption, it has been detected at relatively high concentrations in both wastewater effluents and surface water. In this study, the effect of acetaminophen has been investigated by the toxicity assay using Clarias gariepinus. The acute (96 h) and chronic (28 days) toxicity assays have been performed using the catfish. The lethal concentrations of acetaminophen with 50% mortality (LC50) have been determined as Mean percentage mortality for the exposed juveniles of C. gariepinus for the different test concentrations (100, 300, 500, 700µg/L) were 0, 0, 29 and 100%, at 24 hours; 0, 19, 86 and 100%, at 48 hours, 0, 29, 90 and 100%, at 72 hours; and 0, 33, 95 and 100%, at 96 hours exposure. 100% mortality was observed in the highest concentration (700µg/L) of acetaminophen. Mean mortalities were significantly different (p<0.05) between the control and treatment concentrations with significantly (p<0.05) higher mortalities recorded in the highest concentration (700µg/L). The estimated LC50 values observed for 24, 48, 72 and 96 hours were 518.81, 424.98, 378.16 and 348.11 µg/L respectively. The effect of acetaminophen on the reproductive responses in the fish has been studied from the expression level of four biomarkers (Gonad pathology, Vtg, testosterone and estradiol) after 28 days exposure to the varying concentrations. The results show that Fish exposed to acetaminophen exhibited high vitellogenin induction, intersex and female-biased sex-ratio. Acetaminophen reduced testosterone levels in all exposed groups and increased estradiol levels at higher concentration. An anti-androgenic effect was observed since a decrease in testosterone levels of exposed fish and an increase in levels of estradiol was found in the higher concentrations. This evidence supports the hypothesis that acetaminophen is involved in the observed endocrine disruption effects.

RP101 Tributyltin Affects Retinoid X Receptor-Induced Lipid Metabolism in the Marine Rotifer Brachionus koreanus

M. Lee, Sungkyunkwan University; F. Castro, CIMAR - University of Porto; J. Lee, Sungkyunkwan University

To examine the effects of tributyltin (TBT), a model obesogen, on lipid metabolism in the marine rotifer Brachionus koreanus, we carried out life-cycle studies and determined the in vitro and in silico interactions of retinoid X receptor (RXR) with TBT, the transcriptional levels of RXL and lipid metabolism-related genes, and the fatty acid content. The lethal concentration 10% (LC10) was determined to be 5.12 µg/L TBT, and negative effects on ecologically relevant endpoints (e.g., decreased lifespan and fecundity) were detected at 5 µg/L TBT. Based on these findings, subsequent experiments were conducted below 1 µg/L TBT, which did not show any negative effects on ecologically relevant endpoints in B. koreanus. Nile red staining analysis showed that, after exposure to 1 µg/L TBT, B. koreanus stored neutral lipids and had significantly increased transcriptional levels of RXR and lipid metabolism-related genes compared to the control. However, the content of total fatty acids did not significantly change at any exposure level. In the single fatty acids profile, a significant increase in saturated fatty acids (SFAs) 14:0 and 20:0 was observed, but the contents of omega-3 and omega-6 fatty acids significantly decreased. Also, a transactivation assay of TBT with RXR showed that TBT is an agonist of Bk-RXR with a similar fold-induction to the positive control. Together, these results demonstrate that TBT-modulated RXR signaling leads to increased transcriptional levels of lipid metabolism-related genes and the synthesis of SFAs but decreases the content of polyunsaturated fatty acids (PFAs). Our findings support a wider taxonomic scope of lipid perturbation due to xenobiotic exposure that occurs via NRs in aquatic animals.

RP102 The Unresolved Dose-Response Challenge: Causal Linkage Between Exposure and Site of Toxic Action

L.S. McCarty, L.S. McCarty Scientific Research & Consulting; C. Borgert, Applied Pharmacology & Toxicology, Inc.

Aquatic toxicology assumes a constant exposure-organism-target dose relationship such that exposure is a suitable surrogate for target dose. However, previous work indicates exposure-based testing data can deviate 10 to 1000-fold from critical body residue (CBR) dose metrics due to the influence of toxicity modifying factors. Since both toxicity target sites and concentrations are largely unknown, a simple fish-based exposure model was modified to include a hydrophobic target based on neutral narcosis (~5 mmol/kg at 5% lipid content), which enabled examination of dose-surrogate relationships and toxic causality. A fixed organism size (CiT) was subdivided into hydrophilic (CiW, water) and total hydrophobic (CiTH, lipid) phases; the latter composed of non-target (CiNT) and target (CiTH) volumes. The target site is assumed constant for 50% mortality. Thus, the influence of total body lipid content and body size on exposure water, CBR, and target dose metrics can be parsed for steady-state toxicity and the number of molecules in the target and other phases can be quantified. Default is a 0.3 g fish at 5% lipid. Setting the toxicity target to 0.001 of the lipid phase, 1.0 density assumed, the volumes of the hydrophilic, nontarget hydrophobic, and target hydrophobic phases are 2.85*10^7, 1.49*10^8, and 1.50*10^11 m3, respectively. Assuming that nontarget lipid is independent of the water and target phases, changing the non-target phase by 0.2 and 4 times, produces toxicologically-equivalent fish of 0.288 and 0.345 g and ~1.04 and 17.4 % body lipid, respectively. Although various model results can be calculated, the target dose is a tiny proportion of the total fish concentration. It can vary widely, including setting it to zero, and the difference on the whole-body estimate is below the detection limit of the number of significant digits available. Problems related to this signal-to-noise issue (CiHT vs CiT), especially for experimental validation, are reviewed.

RP103 Toxicity of tributyltin and triclosan in tributyltin-binding protein 2 knocked-out medaka, Oryzias latipes

Y. Oshima, Faculty of Agriculture / Kyushu University / Fisheries; T. Takamura, S. Enok, Y. Kato-Unokia, Y. Nagano, Faculty of Agriculture / Kyushu University; M. Kinoshita, Kyoto University / Faculty of Agriculture; T. Kitano, Kumamoto University / Department of Biological Sciences; I. Kang, Kyushu University / Kyuso; Y. Shimasaki, Kyushu University / Faculty of Agriculture; X. Qiu, Jiangsu University

A concentration of free-form drug form blood is critical to exert its toxicity. Binding protein in blood, i.e., acid alpha acid glycoprotein (AGP) or albumin bind with drug and might play an important role in detoxification of them. However, few studies were performed on this topic. Tributyltin-binding protein type 2 (TBT-bp2) is the homolog of AGP which bind to small hydrophobic molecules and suspect to play an important role in transportation, detoxification, and excretion of xenobiotic compounds. In this study, we established a homo strain of TBT-bp2 knockout (KO) (-/-) medaka, Oryzias latipes, using CRISPR/Cas9 system in F2 generation, to analyze the function of TBT-bp2, tributyltin and triclosan (TCS) was exposed to TBT-bp2 KO (-/-) medaka for 94 hours in a semi-static system and evaluate their toxicity on survival and alternation of behavior. Using mRNA-seq, no expression of TBT-bp2 was confirmed in the liver of TBT-bp2 KO (-/-) medaka. Compared with wild type medaka, the survival, swimming speed and number of vocal sound were decreased in the TBT-bp2 KO (-/-) medaka exposed to TBT or TCS (p<0.05). These results indicated that TBT-bp2 play important roles in detoxification of TBT and triclosan. mRNA-seq and GO analysis shows that TBT-bps might be linked with cyp450 and complement systems. TBT-bps is proposed as a detoxification system for xenobiotic compounds.
The AOP (adverse outcome pathway) approach offers an attractive framework for developing a mechanistically-based alternative testing methods. Well-defined AOPs can simplify the identification of assays affecting key events, which have high analytical value for an adverse outcome (AO) of interest. Aromatase (Cyp19a1) is a steroidogenic enzyme that plays a role in converting aromatizable androgens into bioactive estrogens. However, to date, most studies link the molecular initiating event (MIE) of aromatase interruption by chemicals subject to the AO of reproductive impairment are closely related with female fish. Thus, current study aimed to unravel the mechanism of chemical aromatase-induced endocrine disruption by illustrating the MIE perturbations responsible for the observed effects in male zebrafish (Danio rerio). In this study, we evaluated changes in estradiol (E2), vitellogenin (Vtg) and testosterone (T) caused by four different chemicals, Atrazine (ATZ), Di-hydro testosterone (DHT), Metformin (MET) and Prochloraz (PRO) to construct an aromatase activity (ARO) screening test. Three days post-fertilized larvae stage of zebrafish was exposed for 4 days (200 larvae/each crystal disk beaker) and 3 different concentrations for each chemical (ATZ: 10^-5 M - 10^-7 M, DHT, MET and PRO; 10^-6 M - 10^-8 M) was applied. Meanwhile, adult fish exposure (~7 mo) was exposed to the different chemicals (ATZ 10^-5 M; DHT, MET, MET and PRO were 10^-6 M respectively) for 21 days. We predict that the aromatase inducer chemicals will affect reproduction mechanisms and the levels of some enzymes/proteins including aromatase, estradiol (E2) and vitellogenin (VTG). Expected results could help to construct the conceptual model (AOP development) leading from aromatase interruption by chemicals to reproductive impairment in environment, which is the most progressive aromatase related AOPs developed so far.

RP105 Morphometric Effects of Individually Tested Various Weathered and Pure Microplastics on Sac Fry Zebrafish

G.M. Moreno, Rutgers University / Biochemistry, Microbiology; K. Cooper, Rutgers University / School of Environmental and Biological Sciences / Microbiology and Biochemistry

Microplastics (5mm to1nm) and plasticizers are ubiquitous in waterways, beaches, sediments and biota across the world. It is estimated that since the emergence of plastic in the 1950s, ~18 trillion pounds of plastic have been produced. Ingestion of microplastics by various marine species and accumulation of plasticizers has been documented and is of growing concern. Additionally, microplastics act as a carrier for the transport of persistent organic pollutants and biota, increasing the hazard to aquatic species. Microplastics vary in composition based on their monomeric component and the specific plasticizer, i.e. chemical additives that increase the plasticity, rigidity or other qualities of plastics. The toxic effects associated with the components that comprise the polymerized microplastics are not yet well characterized. The results presented here examine gross morphological variations in sac fry zebrafish as a result of exposure to weathered microplastics and pure plastic polymers. Embryos were exposed from 3 hours post fertilization (hpf) to 96 hpf with samples of weathered microplastics from estuaries in Newark Bay, NJ, as well as commercially available pure plastics at concentrations of 1 µg/mL or 10 µg/mL. The Newark Bay microplastics were analyzed via pyrolysis GC-MS to determine composition. Pyrolysis GC-MS determined that the three samples were composed primarily of polyethylene (PE), polypropylene (PP) and polyvinyl chloride (PVC). Morphometric data were statistically analyzed, significant changes were noted between the controls and the treated groups in the embryonic zebrafish samples for the Newark Bay, Fenton treated, weathered samples. The commercial microplastics tested included: PE (LD low, MD medium and HD high density), poly styrene (PS), polyvinylchloride (PVC), sodium polyacrylate (SPA), polypropylene (PP), polyethylene terephthalate (PET), polyurethane (PU), and poly-methyl methacrylate (PMMA) polyethylene(co-vinylacetate) (PEVA), and polystyrene(co-acrylonitrile) (PSAN). Significant changes were seen in total body length in Newark Bay as well as pure microplastic treatment groups. Significant changes were seen in pericardial sack size in Newark Bay as well as pure microplastic treatment groups. Some significant changes were seen in interocular distance in the pure microplastic treatment groups.

RP106 The influence of polyethylene nanoplastics on the toxicity of methoxychlor on D. magna

T. Duong, B. Odhiambo, M. Hoffman, T.E. Frankel, University of Mary Washington / Earth and Environmental Sciences

Nanoplastics (NPs), defined as plastic particles < 0.1 mm, have become an emerging concern in aquatic environments due to their multiple pathways of entry into rivers and streams. NPs may originate from the manufacturing of beads for personal care products as well as from the fragmentation of larger plastic items. Due to their small size they are easily ingested by aquatic organisms, resulting in detrimental health effects such as digestive tract obstructions, feeding debilitation, and overall energy depletion. Due to their high surface area and physicochemical attributes, NPs have also been shown to sorb and mobilize organic pollutants such as pharmaceuticals and pesticides, suggesting that interactions between these two types of pollutants may result in an altered biological response compared to the effects of each individual contaminant. This study assessed the potential synergistic or antagonistic effects of polyethylene nanoparticles and the organochlorine pesticide methoxychlor on the viability and mobility of Daphnia magna. Adult D. magna were exposed to either 1) virgin 10-20um polyethylene pellets (0, 12.5, 25, 50, or 100 mg/L), 2) methoxychlor (0, 1.0, 2.5, 5.0, or 10 µg/L), or 3) various combinations of the same pellet and methoxychlor concentrations for 48 hours. Juveniles (< 24hrs old) were exposed to the same treatments for 7 days using a static exposure method. Mortality and paralysis were assessed per 24 hours of exposure for both exposure assays. To assess mobility, exposed individuals were recorded in a light-controlled behavioral chamber for 3 minutes. Recordings were analyzed using ToxTrac to quantify average mobile speed, acceleration, and distance traveled by each individual. Mobility was assessed after 24 hours of exposure for the 48 hour assay and after 7 days of exposure for the 7 day assay. While this project is currently ongoing, we expect to find a significant difference in mobility parameters and mortality rates when exposed to the combination of polyethylene pellets and methoxychlor compared to the effects from each contaminant alone. Thus far, few studies have examined the ability of NPs to influence the toxicity of organochlorine pesticides and other chemical pollutants in aquatic invertebrates. Additionally, this is the first study to assess the impacts of NPs on locomotor behavior in D. magna, using automated analyses. As such, this study will help elucidate the span of which plastic pollution may impact aquatic systems and its relationship with pesticide contamination.

RP107 Suborganismal responses of the aquatic midge Chironomus riparius to polyethylene microplastics

A.M. González, National Distance Education University / Mathematical Physics and Fluids; C.J. Silva, University of Aveiro / Biology Department & CESAM; G. Gravato, University of Lisbon / Department of Biology & CESAM; A.P. Silva, Campus Universitário de Santiago / Biology: D. Campos, University of Aveiro / Biology Department and CESAM; J. Pestana, CESAM & University of Aveiro / Biology; J. Martinez-Guitarte, National Distance Education University / Fisica Matematica y de Fluidos

Microplastics (synthetic polymers with less than 5 mm) are now ubiquitous and persistent in freshwater ecosystems. Once in freshwaters, microplastic particles undergo fragmentation, biofouling and sedimentation processes reaching high concentrations in sediments where they can be ingested by sediment-dwelling invertebrates. Deleterious effects of microplastics have been described at organismal level (e.g. growth,
development). Notwithstanding, molecular, biochemical, cellular and physiological alterations can be used as early warning indication of sub-lethal effects providing information regarding the mechanisms of action of microplastics. This study aimed to assess and describe the potential effects of microplastics in the aquatic midge Chironomus riparius using biochemical responses and gene-expression tools. Fourth instar C. riparius larvae were exposed for 48 h to a gradient of concentrations (from 0.025 to 20 g kg\(^{-1}\)) of different size (up to 48 mm) polyethylene (PE) microplastics. Assessed biochemical endpoints included oxidative stress and damage responses (enzymatic and non-enzymatic responses, lipid peroxidation), and energy reserves and consumption (electron transport system activity) while the gene expression evaluation (Real Time PCR analysis) was developed using an array designed with 42 genes related to essential routes in invertebrates such as endocrine system, detoxification response, stress response, immune response, DNA repair and apoptosis. Results showed that short-term exposure to environmental relevant concentrations of PE microplastics impaired energy reserves, altered energy consumption, and triggered responses related to oxidative damage and genes involved in different routes have modified their mRNA level, being able to generate important alteration in their development and response against stress situations. Such results agree with the previously reported responses at organismal level and highlight the potential adverse effects of microplastics for freshwater benthic communities considering the ecological role of C. riparius within these habitats.

**RP108 Microplastic Content in Oysters (Crassostrea virginica) from Charleston Harbor, South Carolina (USA)**

B. Blosser. College of Charleston / Biology; R.R. Leads, University of North Texas / Biological Sciences & Advanced Environmental Research Institute; P. Kingsley-Smith, South Carolina Department of Natural Resources / Marine Resources Research Institute; J.E. Weinstein, The Citadel / Department of Biology

Microplastics (< 5 mm) are ubiquitous in coastal waters and abundances as high as thousands of particles/m\(^2\) are present on shorelines worldwide. A previous survey of Charleston Harbor, South Carolina (USA) reported an average of 414 ± 77 microplastic particles/m\(^2\) in intertidal sediments (Gray et al. 2018). The objective of the present study was to characterize the abundance and distribution of microplastics in oysters (Crassostrea virginica) collected from those state-managed, commercially harvested intertidal oyster grounds contributing substantially to annual landings statewide. To achieve this objective, three locations were selected within the Folly River based on historic shellfish harvest landings, and three sites within each location were sampled. Oysters, sediment, and surface water samples were collected at each site. In the laboratory, for each oyster sampled, both gills were dissected from the other oyster tissues, and both were subsequently digested using 10% KOH solution. Microplastic particles from all three sample types were characterized based on shape, size, and color, and a subset of samples were analyzed using micro-Raman spectroscopy to identify polymer type. The ultimate utility of these results will be in providing the rationale for estimating human exposure levels to microplastics following the consumption of oysters.

**RP109 Assessing the trophic ecology and movement of walleye using stable isotopes in the southern Grand River, Ontario**

H. Quinn-Austin, University of Waterloo / Biology; T. MacDougall, Ontario Ministry of Natural Resources and Forestry / Lake Erie Management Unit; H. Dhiyebi, University of Waterloo; R.C. Rooney, M.R. Servos, University of Waterloo / Biology

Lake Erie supports the largest commercial and recreational walleye fishery of the Great Lakes, which contributes greatly to the Ontario economy annually. Walleye are also a valuable ecosystem component that require a diverse mesotrophic environment to maintain stable populations. The walleye population of the southern Grand River in eastern Lake Erie is degraded due to the compounding impacts of habitat and water quality degradation and restricted access to spawning grounds by a low-head dam, making the Grand River a priority management area for walleye restoration. To investigate factors influencing the year class success of the southern Grand River walleye population, this study used stable isotope analyses of nitrogen and carbon to test for spatial changes in the trophic ecology and condition factor of young-of-the-year (YOY) walleye among river segments of varying habitat quality. Sampling for YOY walleye was conducted during the growing season of 2018 and 2019. Significant variation in trophic position and carbon source were observed between the lotic upper river segment, the degraded Dunnville Dam reservoir, and the lake-effect zone at the river mouth. YOY walleye condition was significantly greater at the river mouth compared to upstream sites. Moving forward, this study will link our understanding of YOY walleye to mature walleye spawning activity using acoustic telemetry data, which can be used to determine the movement patterns and spawning habitat of mature walleye in the southern Grand River. This project will aid in advancing biomonitoring and management practices that protect and enhance both the health of the southern Grand River and the Lake Erie walleye fishery.

**RP110 Tracing Origin of Pollution Using Isotope Fingerprints**

Protecting our environment from contamination is a global challenge, one that requires international focus and collaboration for our air, water and land resources. The natural and synthetic materials in our air, water and on our land have a fingerprint, a unique chemical signature that allows them to be identified and differentiated from one another. Consequently, we are able to interrogate samples, chemically, to determine where they came from, allowing measures to be developed and executed to reduce and remove environmental pollution. In this presentation we explain how stable isotope fingerprints of carbon, nitrogen, sulphur, oxygen and hydrogen are used to identify the origin of air, soil and water pollution, in the context of investigations focused on understanding pollution source and pollution events. Data are shown that illustrate how isotope fingerprints offer conclusive answers on questions associated with where pollution came from: this is known as the understanding the point source of the pollution. Specifically, we focus on air pollution as measured on filter papers and on nitrates measured from soils and waterways, and illustrate, how isotope fingerprints can differentiate pollution source. In addition, an overview of the interpretation of isotope fingerprints and the technology used is also provided. Specifically, we focus on Isotope Ratio Mass Spectrometry (IRMS), a technique used to visualize the isotope fingerprints within pollutants.

**RP111 Do you see what I see? Tracing indirect effects using stable isotope and elemental analysis**

J.P. Zubrod, D. Englert, S. Lüderwald, B. Furß, A. Pollitt, R. Schulz, University of Koblenz-Landau / iES, Institute for Environmental Sciences; M. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Department of Aquatic Sciences and Assessment

Alterations in trophic interactions or food web structure are hard to detect using traditional approaches. Stable isotope signatures and elemental composition, both providing information on the assimilated food source, appear as promising tools. To test for their suitability in an ecotoxicological context, in a first experiment, the omnivorous amphipod Gammarus fossarum was given the choice to feed either on black alder leaves or prey on mayfly larvae (Baetis sp.). This trophic interaction was assessed under exposure towards the neonicotinoid thiacloprid (0.75 µg/L). We used a multi-factorial design (thiacloprid x leaves) to assess the effect of all factors - individually and in combination. Consumption of leaves and Baetis were monitored for two weeks and stable isotope signatures and elemental composition were determined for both resources as well as the consumer (i.e., G. fossarum) at the end of the experiment. In a second experiment, we tested if chemical stress could affect stable isotope signatures by exposing gammarids towards thiacloprid (0, 0.75, or 6 µg/L) for up to six weeks while providing them with a single food source (i.e., leaves or Baetis). In the first experiment, exposure towards thiacloprid affected the food choice of G. fossarum: a higher consumption...
of **Baetis** was observed, while this was not reflected by gammarids’ elemental composition. However, the nitrogen content of **Gammarus** was increased by thiacloprid when only fed **Baetis**. Elemental analysis thus seems unsuitable to trace changes in dietary interactions due to chemical stress. In contrast, stable isotope signatures well reflected the increased predation success and no differences in signatures were observed between exposed and unexposed animals when only one food source was offered. Moreover, the second experiment revealed that even after six weeks of exposure towards 6 µg/L, a concentration significantly reducing gammarids’ physiological fitness and increasing their mortality rates, stable isotope signatures differed only minimally (< 0.5 %) when compared to the control. Although further experiments with different test systems (i.e., combinations of consumers and resources as well as contaminants) seem necessary to draw final conclusions, our data suggest that stable isotope analysis is indeed a promising tool to trace indirect effects of chemical stressors in affected food webs.

**RP112 Is labelling aquatic food webs with stable isotopes not so harmless after all?**

**J.P. Zubrod, M. Konschak, S. Lüderwald, R. Schulz, University of Koblenz-Landau; M. Bandschuh, Institute for Environmental Sciences University of Koblenz-Landau; Department of Aquatic Sciences and Assessment**

Heavy stable isotopes (such as 15N) are commonly used to trace the flow of energy, nutrients, and matter in food webs while assuming that their enrichment does not affect the physiology of consumers. However, recent evidence (Andriukonis & Gorokhova, 2017, Scientific Reports) implies that algal growth was negatively correlated with 15N concentration in medium, while at an intermediate level of labelling (3.5 at%) growth lag phase was shortest (effect size [ES] ~10%). To test if this phenomenon is universal in aquatic food webs, which would question the use of 15N as an indicator for labelling to be rather unfavorable. This observation is supported by leaf litter decomposition being lowest for this treatment during the second experiment. Generally, the experiment followed OECD 211 but with 6 animals cultured in 150 mL medium with a replication of five. In the second experiment, we assessed if heterotrophic microorganisms show similar effects as observed for algae. Black alder leaf material was subjected to colonization and decomposition by a natural microbial community (particularly fungi and bacteria) for 12 days with medium containing increasing 15N concentrations (n=15). During the first experiment, reproduction of **D. magna** was not affected (ES 0.5%). However and contrary to literature, survival was reduced by 10% compared to the control at 3.5 at%, indicating this level of labelling to be rather unfavorable. This observation is supported by leaf decomposition being lowest for this treatment during the second experiment (ES >10%), though differing non-significantly to the control (i.e., 0.37 at%). Currently, we are analyzing preserved samples of both experiments (e.g., physiological condition of **D. magna** and microorganisms) to verify the identified trends (i.e., detrimental implications in the survival of a primary consumer and the functioning of microbial decomposers at 3.5 at%). As our data and the literature, nonetheless, indicate that relevant heavy stable isotope concentrations (i.e., up to 35 at%) do not affect biological and ecological responses considerably, labelling with 15N still seems well-suited to trace the flow of energy, nutrients, and matter in aquatic food webs.

**RP113 Factors influencing variation in Hexagenia rigida sensitivity**

**N. Mason, Alma College / Environmental Studies; A.D. Harwood, Alma College / Environmental Studies / Biology**

The burrowing mayfly (**Hexagenia** spp.) is an important member of freshwater benthic ecosystems, therefore, methods have been in development for their use as a test species in both sediment and water-only exposures. However, **Hexagenia** toxicity data can have more variation than other species (e.g. **Hyalella azteca**). One potential explanation for this variation could be lack of standardization in raising animals for testing. For example, there is no standard age or hatch time, only size. Therefore, the objective of the current study was to evaluate the effects of hatch date, age, and size on the sensitivity of **Hexagenia rigida** to stress. **H. rigida** were separated into early hatchers (first 3 days of hatching) and a mix across hatching days. At 8 and 12 weeks post-hatch, nymphs were separated by size (5-8 mg or 15-20 mg) and exposed to a stressor, either NaCl or lack of artificial burrow for 96 h. Lack of artificial burrows did not cause significant mortality in any treatment. This indicates that it may not serve as an effective means of evaluating stress in these organisms. Hatch date and age did not significantly affect **H. rigida** NaCl sensitivity. However larger nymphs were less sensitive to NaCl at 8 weeks, which is consistent with previous research. Differences between sizes were not significant at 12 weeks. While other chemical stressors should be evaluated, this may indicate that the effects of size may diminish with age. If variations in age do not impact toxicity, this allows for comparisons among studies with different rearing methodologies and flexibility in raising mayflies for toxicity studies.

**RP114 Comparing the sensitivity of the burrowing mayflies Hexagenia limbata and Hexagenia rigida to toxicants at three different life stages**

**A. Hedges, Environment and Climate Change Canada / Water Science and Technology Directorate; L. Brown, Environment and Climate Change Canada / ACRD; A.J. Bartlett, Environment and Climate Change Canada / Water Science and Technology Directorate**

Use of the mayfly genus **Hexagenia** in toxicity testing has undergone several cycles of prominence marked by frequent use in research, as well as periods of relative scarcity, and there is currently increased interest in exploring the use of **Hexagenia** as a model organism. Original research into these species, driven by the near extirpation of **Hexagenia** from the western basin of Lake Erie in the 1950s, highlighted the benefits of using mayflies as indicators of ecosystem health as they thrive in mesotrophic bodies of water. Historically, the two species of burrowing mayfly **Hexagenia limbata** and **Hexagenia rigida** were indistinguishable as they often co-occur in the environment, are morphologically similar, and exhibit similar life cycles. Recent advancements have allowed the two species of **Hexagenia** to be reliably identified, and thus the relative toxicity of contaminants to each species can be evaluated. The aim of our research was to determine if any differences in sensitivities exist between the two species, as well as to develop methods for testing potentially more sensitive life stages and endpoints. Toxicants were chosen that encompass varying modes of action and are well documented in the toxicity literature to ensure the development of robust methods. Compounds included a salt (potassium chloride), a metal (copper chloride), and an organic contaminant (the neonicotinoid insecticide imidacloprid). The life stages of interest in this study were developing eggs, hatchlings (< 24 h old), and nymphs that were several weeks old (5-8 mg wet weight). Tests involving developing **Hexagenia** eggs were conducted in 12-well plates for a 14 d duration to determine time to hatch, total percent hatched, and percent hatching. Hatching tests were also conducted in 12-well plates to assess survival, but for a 7 d duration. Nymph tests were 96-h water-only exposures conducted in 600 mL beakers to measure survival and growth. Testing is ongoing; however, preliminary results indicate only minor differences between the two mayfly species, and that exposure to a contaminant as nymphs that are several weeks old results in the greatest toxicity while exposure as eggs results in the least toxicity. The assessment of differences in contaminant toxicity between **Hexagenia limbata** and **Hexagenia rigida** and the development of methods involving more sensitive life stages and endpoints will allow for better assessments of risk and increased environmental relevance.
RP115 Shedding light on the toxicity of benzotriazole ultraviolet stabilizers and a benzothiazole to aquatic invertebrates

Benzotriazoles (BZTs) and benzothiazoles (BZThs) are high production volume industrial chemicals that are primarily used as ultraviolet stabilizing additives and vulcanization accelerators for rubber, respectively. These compounds are environmentally persistent, have the potential to bioaccumulate, and have been detected in environmental samples; however, the available toxicity information for aquatic invertebrates is scarce. Therefore, our objective was to conduct spiked-sediment exposures to assess the toxicity of three BZTs and one BZTh to *Hyalella azteca*, *Hexagenia spp.*, *Tubifex tubifex*, and *Daphnia magna*. Test compounds were UV234 (phenol, 2-(2H-benzotriazol-2-yl)-4,6-bis(1-methyl-1-phenylethyl); CAS RN 70321-86-7), UV326 (phenol, 2-(5-chloro-2H-benzotriazol-2-yl)-6-(1,1-dimethylpropyl)-4-methyl; CAS RN 3896-11-5), UV329 (phenol, 2-(2H-benzotriazol-2-yl)-4-(1,1,3,3-tetramethylbutyl); CAS RN 3147-75-9), and MBTS (2-mercaptobenzothiazole disulfide; CAS RN 120-78-5). Maximum nominal sediment concentrations tested were 100 and 1000 mg/kg (dry weight) for BZTs (UV234, UV326, and UV329) and BZTh (MBTS), respectively. Depending on the species, tests were 21-42 d in duration, and survival, growth, and reproduction were examined. Chemical analysis of water and sediment is ongoing; therefore, results are currently based on nominal sediment concentrations. Survival of *Hyalella*, *Hexagenia*, *Tubifex*, and *Daphnia* was not significantly different between controls and treatments for any of the four compounds tested. Growth of *Hyalella* and *Daphnia* was also not affected; however, growth of *Hexagenia* was significantly reduced compared to controls at 1-100 mg/kg UV234 and 1000 mg/kg MBTS. Cocoon production of *Tubifex* was unaffected by BZTs, as was cocoon hatch success with the exception of 1 mg/kg UV326, which was significantly lower than controls. Juvenile production of *Tubifex* was significantly reduced compared to controls at 10 and 100 mg/kg UV329. Cocoon production, cocoon hatch success, and juvenile production in *Tubifex* were all significantly lower than controls at 1000 mg/kg MBTS. *Daphnia* reproduction was unaffected by BZTs, but increased significantly compared to controls at 1000 mg/kg MBTS. The results of this study will be compared to environmental concentrations, and will support environmental risk assessments to determine the impacts of these compounds on aquatic organisms.

RP116 Validation of Pulsed Exposure Toxicity Methods at San Diego Regional Naval Bases
M. Colvin, SPAWAR Systems Center, Pacific / Energy and Environmental Sustainability; G. Rosen, NIWC Pacific / Energy and Environmental Sustainability; N. Hayman, NIWC Pacific (Naval Information Warfare Center Pacific) / Energy and Environmental Sustainability; K. Kowal, San Diego State University Research Foundation; J. VanVoorhis, Wood Environment Infrastructure Solutions, Inc. / Toxicology; C. Stranksy, Wood / Environment Infrastructure Solutions, Inc.

Episodic discharges such as stormwater require environmentally-relevant, scientifically-defensible, and conservative toxicity test designs to assess potential for receiving water impacts. Permittees in highly industrialized areas are increasingly required to conduct 96-h (or longer) toxicity tests on stormwater collected at end-of-pipe associated with events that are generally less than 24-h. This project is currently evaluating alternative toxicity test designs for episodic exposures that would require minimal modification to standard methods, yet increase realism towards protection of beneficial uses from episodic discharges. The feasibility of using site-specific rainfall runoff duration is being evaluated, and additional measures associated with time-varying discharges, to derive more environmentally relevant toxicity exposure regimes for stormwater compliance. The pulsed exposure methodology was validated to ensure that it is indeed representative and protective of actual site conditions during dynamic runoff events. This was performed through end-of-pipe monitoring of stormwater/episodic discharge samples along with concurrent in situ toxicity testing at select locations. SEA Rings served as the platform for exposing the same species selected for the laboratory exposures, and house passive sampling devices and water quality loggers (e.g. salinity, temperature, dissolved oxygen) for characterization of the stormwater runoff and assessment of potential confounding factors. In situ validation of the pulsed exposure method was performed at San Diego Regional Naval Bases during two storm events. Three SEA Rings were deployed at the two targeted sites: 1 within the first meter of the surface, 1 at about 2-3 meters, and 1 at the sediment surface. For laboratory exposures, receiving water samples were collected prior to the storm to be used as renewal water for the respective stormwater samples. Receiving water was also collected right in the midst of the storm while stormwater samples were collected for side-by-side testing. All samples were tested using the mysid (*Americamysis bahia*) acute survival test as well as the more sensitive chronic sea urchin (*Stronglylocentrotus purpuratus*) embryo-larval development test. All samples had the treatments of 6, 12, and 24 hr pulsed exposures and also were tested using the standardized 96 hr static-renewal exposure. All samples/exposures were tested in a dilution series of 25, 50 and 100%. Following pulsed exposures, organisms were transferred to uncontaminated seawater for the remainder of the 96-h exposure period. This ESTCP & NESDI funded project was introduced at SETAC in 2017 and this presentation will summarize results to date and future plans to assess proposed WET test modifications within NPDES requirements for episodic discharges.

RP117 Derivations Studies for an Environmentally Relevant Approach for Stormwater Toxicity Testing Compliance Monitoring
M. Colvin, Naval Information Warfare Center Pacific / Energy and Environmental Sustainability; K. Kowal, San Diego State University Research Foundation; N. Hayman, G. Rosen, NIWC Pacific / Energy and Environmental Sustainability; J. VanVoorhis, Wood Environment Infrastructure Solutions, Inc. / Toxicology; C. Stranksy, Wood / Environment Infrastructure Solutions Inc

Episodic discharges such as stormwater require environmentally-relevant, scientifically-defensible, and conservative toxicity test designs to assess potential for receiving water impacts. Permittees in highly industrialized areas are increasingly required to conduct 96-h (or longer) toxicity tests on stormwater collected at end-of-pipe associated with events that are generally less than 24-h. This project is currently evaluating alternative toxicity test designs for episodic exposures that would require minimal modification to standard methods, yet increase realism towards protection of beneficial uses from episodic discharges. The feasibility of using site-specific rainfall runoff duration is being evaluated, and additional measures associated with time-varying discharges, to derive more environmentally relevant toxicity exposure regimes for stormwater compliance. Tests were performed under standard static (96-h continuous) exposure and pulsed exposures (time varying toxicant exposure). Following pulsed exposures, organisms were transferred to uncontaminated seawater for the remainder of the 96-h exposure period. To date, results with these species and endpoints suggest pulsed exposure median effective and median lethal concentrations for copper and zinc are up to two orders of magnitude greater (i.e. less sensitive) than current recommended continuous approaches for these test methods. Preliminary results associated with this work include chronic toxicity tests with purple sea urchin (*Stronglylocentrotus purpuratus*) embryos and acute toxicity tests with mysid shrimp (*Americamysis bahia*), the freshwater flea (*Ceriodaphnia dubia*) and a freshwater amphipod (*Hyalella azteca*). Additional considerations assessed included: (1) timing of the onset of a pulse; (2) evaluation of different life stages of proposed test organisms; and (3) the potential for latent effects following a pulsed exposure. This ESTCP & NESDI funded project was introduced at SETAC in 2017.
and this presentation will summarize results to date and future plans to assess proposed WET test modifications within NPDES requirements for episodic discharges.

**RP118 Effects of different lighting source of light emitting diode and fluorescent light for growth inhibition tests with cyanobacteria and diatom**

Currently, algae growth inhibition tests are commonly performed using a growth chamber with a fluorescent lamp (FL) as the light source because the test guidelines require continuous lighting with uniform fluorescent illumination. However, FL is one of the mercury-added products that the Minamata Convention (adopted in 2013) requires to reduce or prohibit to produce, in-port and export them because mercury is harmful to humans and environmental organisms. On the other hand a light emitting diode (LED) does not contain mercury which provides the photosynthetically effective wavelength range of 400–700 nm and an adequate light intensity for algae growth. In the near future, LED will be used as a light source instead of FL in algae growth inhibition test.

At SETAC North America 39th Annual Meeting, we showed the results of our investigation whether LED can be used as a substitute for FL for green alga (*Pseudokirchneriella subcapitata*) study. The results of the *Pseudokirchneriella subcapitata* growth inhibition tests using LED was the same as the test using FL. However, we have not investigated on other algae, cyanobacteria, diatom, marine algae and lemmna yet and these algae require different wavelengths respectively. Hence, in this study we investigated whether LED can be used as a substitute for FL for cyanobacteria (*Anabaena variabilis*) and diatom (*Navicula pelliculosa*) tests by using LED and FL with different wavelengths respectively. These algae growth inhibition tests were conducted according to OECD TG 201. We performed tests on each of the five chemicals using either LED or FL at the same time.

Sodium chloride, cadmium chloride, potassium dichromate, 3,5-dichlorophenol and pentachlorophenol were used for the tests because these chemicals have different mode of actions and are assigned as reference substances in the test guidelines. In this meeting, we will show the test results of *Anabaena variabilis* and *Navicula pelliculosa*.

**RP119 Building an Aquatic Research Facility (Wet lab): Challenges to achieve and maintain good water quality in support of aquatic toxicology studies**

A. Mehlenbacher, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Operating an aquatic facility (wetlab) that is able to provide high water quality for use with aquatic organisms in toxicology, ecological, and behavioral studies, is challenging. Although not all wetlabs are built the same, there are common challenges that managers of these facilities face. These include complex issues dealing with dechlorination processes, filtration systems, water chemistry readings/results, recirculation vs flow through systems, temperature maintenance, animal care practices and husbandry (under the guidance of the Canadian Council for Animal Care (CCAC)), new species challenges, species decontamination procedures, and the costs to maintain these facilities. In the Aquatic Life Research Facility (ALRF), operated by Environment and Climate Change Canada in Burlington, Ontario, several of the noted challenges have been resolved or refined in order to ensure a high water quality standard required for toxicity testing and other ecological research. Water samples were taken before and after changes to the water treatment system, and in each instance, water quality improved after modifications were implemented. Changes that were applied include improvements to the dechlorination process, reduction of supersaturation, implementation of a refined controls system, addition of back-up systems and regular maintenance of the piping system. These modifications along with the constant re-evaluation of processes have all been applied with the goal to obtain the highest water quality needed to ensure the upmost care and welfare of animals housed and tested in the facility. Aquatic research facilities are found across several government, university, hospital and private institutions.

With diligent monitoring of water quality, refining methods and systems, collaborating with experts from other facilities, and working with local Animal Care Committees, these challenges can be overcome, resulting in healthy animals and good, repeatable, scientific results.

**RP120 Toxicity evaluations of chemicals in seawater using the hyalid amphipod, Ptilohyale barbicornis**

S. Uno, Kagoshima University / Faculty of Fisheries; K. Hayakawa, T. Mikami, Kagoshima University; E. Kokushi, Kagoshima University / Faculty of Fisheries

Until now, many kinds of aquatic organisms have been used to evaluate the toxicities and risks of chemicals in water systems. However, most of those are freshwater biota, and the tests with seawater organisms are limited. In new condition, the risk assessment of chemicals even in seawater are almost conducted with freshwater biota. However, in fact, the physiological functions are much different between those organisms, and their sensitivity for the individual chemicals is possibly too different between seawater and freshwater organisms. Therefore, the independent evaluations for seawater biota are required recently. The hyalid amphipod, *Ptilohyale barbicornis*, inhabits in seawater and brackish water area, and likes to stay in the gaps of mussel community. Their keeping and breeding are easy even in the laboratory, and we expect to use this invertebrate in the toxicity tests of chemicals as an index organism in seawater area.

In fact, freshwater amphipod such as *Hyalella Azteca* has been using the toxicity tests of chemicals frequently, and the application for *P. barbicornis* in the tests is similar with *H. Azteca* except for using seawater. In the present study, we conducted the acute toxicity tests with *P. barbicornis* because of the evaluations of a few chemicals such as dichlorophenols, chlorpyrifos in seawater, and others and compared their sensitivities were compared with other test organisms. *P. barbicornis* tends to be carnivorous, and frequently feeds on each other, when they are kept a limited space. Therefore, we prepared the small glass cuvette for keeping the individual amphipod, and exposed each chemical to individual amphipod in a vessel. The results of toxicity tests suggest that the sensitivities to chemicals are almost similar to other invertebrates such as Daphnia.

**RP121 Determination of optimal cultural conditions for Pomacea paludosa-a considerable species for aquatic toxicology research**

P. Hitch, Loyola University Chicago; T. Hoang, Loyola University, Chicago / Institute of Environment and Sustainability

A number of studies have been conducted with Pomacea paludosa to understand its life cycle, including growth, development, reproduction, and the ecological importance of its presence in the natural ecosystem, as well as its sensitivity to environmental contaminants. This sensitivity allows them to be used in toxicology research. To be considered a model organism for aquatic toxicology research and testing, a laboratory culture method should be developed. This study sought to determine favorable conditions, such as water quality for growth and breeding of the snail within a laboratory setting by culturing the snails in three different qualities of water, classified as soft water (hardness of 40-48 mg/L as CaCO₃), hard water (hardness of 160-180 mg/L as CaCO₃), and very hard water (hardness of 280-320 mg/L as CaCO₃). The experiments were conducted in 10 gallon aquariums and under static renewal conditions at a temperature of 30°C in the Loyola Ecotoxicology and Risk Assessment Laboratory. Survival, growth, reproduction, and mineral content were the measured endpoints of the study. The results shows that snails cultured in hard water grew larger and experienced a lower mortality rate within an amount of time than snails cultured in soft and very hard waters. Concentrations of Ca, Mg, and Na in the soft tissue of very hard water cultural snails were highest while these concentrations in the shell of the very hard water cultural snails were lowest. These results suggest that although snails need minerals (e.g., Ca) for shell development and growth, exceeding minerals in water doesn’t seem to support biological function of the snail. While this study reveals that hard water might be optimal for snails to grow, another study should be conducted to determine whether a static or flow-through culture is optimal for the snails to grow and reproduce.
**RP122 Evaluation of Microcystin-LR effects to juvenile fathead minnows**

Cyanobacterial blooms are increasing in frequency and intensity and are linked to increased eutrophication from urbanization, agriculture and industrial nutrient enrichment. Microcystin is one of the most common classes of algal toxins found in waters of the United States. The objective of this study was to evaluate the toxicity of Microcystin-LR (MC-LR) to the fathead minnow *Pimephales promelas* (FHM). Three 14-d bioassays were conducted with high concentrations of MC-LR ranging from 100 µg/L to 240 µg/L. In our initial bioassay, an inverse toxicity response was observed between Days 5 and 11 with 100% mortality in all test concentrations by Day 11. To investigate possible mechanism for this response, the second bioassay varied the feeding rate of the brine shrimp. However, survival of FHM in our second bioassay ranged from 85-100% in all MC-LR in all concentrations across both feeding rates, and survival of FHM in the third bioassay, set up to mimic our first bioassay, ranged from 95-100% across all 5 concentrations. To evaluate if exposures to MC-LR in the third bioassay, which was prepared with a fresh feeding solution, stressed the FHM, we evaluated brine shrimp survival, thus potentially affecting the uptake of MC-LR through the FHM diets, we exposed brine shrimp for 5-hrs at MC-LR concentrations in the third bioassay. Survival of brine shrimp in the MC-LR 25 and 50 µg/L treatments were significantly higher compared to the control. Concentrations of algal toxins measured with enzyme-linked immunosorbent assays (ELISA) generally were within 40 to 64% of the nominal MC-LR concentration across all three bioassays, demonstrating that differences in survival among tests were not caused by differences in waterborne MCLR concentrations. Ongoing analyses will further document MCLR exposure by determining bioaccumulation of MCLR in fish tissue and evaluate potential sublethal effects of MCLR on fish growth and swimming behavior.

**RP123 Tile Drainage and Anthropogenic Land Use Contribute to Harmful Algal Blooms and Microbiota Shifts in Inland Water Bodies**

L. Mrdjen, Ramboll; S. Fennessy, J. Slonczewski, Kenyon College; J. Lee, The Ohio State University College of Public Health

Freshwater harmful algal blooms (HABs), driven by nutrient inputs from anthropogenic sources, pose unique risks to human and ecological health worldwide. A major nutrient contributor is agricultural land use, specifically tile drainage systems, including tile drainage discharge. Small lakes and ponds are at elevated risk for HAB appearance, as they are uniquely sensitive to nutrient input. HABs introduce exposure risk to microcystin (MC), hepatotoxic and potentially carcinogenic cyanotoxins. To investigate the impact of anthropogenic land use on small lakes and ponds, 24 sites in central Ohio were sampled over a 3-month period in late summer of 2015. MC concentration, microbial community structure, and water chemistry were analyzed. Land use intensity, including tile drainage systems, was the driver of clustering in principle component analysis, ultimately contributing to nutrient deposition, a driver of HABs. Relative abundance of HAB-forming genera was correlated with elevated concentrations of nitrate and soluble reactive phosphate. One location (FC) showed MC concentrations exceeding 875 µg/L and large community shifts in ciliates (Oligohymenophorea) associated with hypoxic conditions. The prokaryotic community at FC was dominated by Planktothrix sp. These results demonstrate the impact of HABs in small lakes and ponds, and that prevailing issues extend beyond cyanotoxins, such as cascading impacts on other trophic levels.

**RP124 Cyanobacteria and microcysts alter zooplankton community structure: a case study in Lake Zumpango, Mexico**

C. Zamora Barrios, Posgrado en Ciencias del Mar y Limnología, UNAM; N. Sarma, UNAM Mexico City Campus Iztacala / UICSE; S. Sarma, Facultad de Estudios Superiores Iztacala, UNAM / Laboratorio de Zoología Acuática II, Unidad de Morfología y Función

Environmental factors play an important role in structuring aquatic ecosystems. Global warming causes expansion and permanence of cyanobacteria, often toxic strains, which alter the abundances of zooplankton community structure, especially in eutrophic reservoirs. Lake Zumpango formed the northern zone of one the most important reservoir of the great lake of Mexico’s valley during the 1500’s. Nowadays the Lake is filled with partially treated waste water from Mexico City causing an excessive increase of phosphates and nitrates (0.7-3.4 and 0.9-28.8 mg L-1, respectively) promoting a persistent bloom composed mainly of high densities of cyanobacteria such as Planktothrix sp., Microcystis sp., Cylindrospermopsis sp. and Dolichospermum sp. causing alterations of zooplankton abundances and diversity favoring tolerant organisms or with adaptations to minimize the deleterious effects associated with microcystin concentrations. We measured monthly, over one year, physico-chemical variables and microcystin fractions (particulated and diluted) with the Envirologix ELISA Kits. Zooplankton samples were collected monthly by filtering 80 L from superficial water with a 40 µm mesh size. We recorded 20 rotifer and 7 microcrustacean species where Keratella cochlearis (<1200 ind L-1) and Acanthocyclops americanus copepoids (>300 ind L-1) had the highest densities. Highest abundance of Microcystis aeruginosina and microcystin concentrations were found in October and December (34.13, 27.17 µg L-1) which correlated with the lowest observed value of Shannon-Wiener diversity index (1.3 Bits ind-1). Multifactorial analyses showed that some dominant microphagous rotifer species were positively related with the presence of cyanobacteria and their secondary metabolites which related to findings from laboratory tests. The relations obtained have been discussed with emphasis on the importance of regular monitoring of water bodies in Mexico to test the ecological impacts of cyanobacterial blooms.

**RP125 Biochemical effects in the green microalgae Chlorella vulgaris during the bioremoval of the azo dye Direct Blue 15**

P.d. Antuna-González, Escuela Nacional de Ciencias Biologicas, IPN / Experimental Biology; M. Hernández, Instituto Politecnico Nacional / Zoology; F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biologicas, IPN / Laboratory of Experimental Hydrobiology

Each year, 800,000 tons of dyes are produced; from this amount, 30% are discharged into water bodies as industrial effluents. Synthetic dyes obtained from benzidine are carcinogenic, mutagenic, and have genotoxic potential so they can affect the aquatic biota. The bioremoval of colorants using microalgae is an alternative method to avoid water pollution. The objective of this study was to evaluate the capability of Chlorella vulgaris to bioremove the Direct Blue 15 (DB15) dye employing different concentrations by Day 11. To investigate possible mechanism for this response, the second bioassay varied the feeding rate of the brine shrimp. However, survival of FHM in our second bioassay ranged from 85-100% in all MC-LR in all concentrations across both feeding rates, and survival of FHM in the third bioassay, set up to mimic our first bioassay, ranged from 95-100% across all 5 concentrations. To evaluate if exposures to MC-LR in the third bioassay, which was prepared with a fresh feeding solution, stressed the FHM, we evaluated brine shrimp survival, thus potentially affecting the uptake of MC-LR through the FHM diets, we exposed brine shrimp for 5 hrs at MC-LR concentrations in the third bioassay. Survival of brine shrimp in the MC-LR 25 and 50 µg/L treatments were significantly higher compared to the control. Concentrations of algal toxins measured with enzyme-linked immunosorbent assays (ELISA) generally were within 40 to 64% of the nominal MC-LR concentration across all three bioassays, demonstrating that differences in survival among tests were not caused by differences in waterborne MCLR concentrations. Ongoing analyses will further document MCLR exposure by determining bioaccumulation of MCLR in fish tissue and evaluate potential sublethal effects of MCLR on fish growth and swimming behavior.

**RP126 Biochemical effects in the green microalgae Chlorella vulgaris during the bioremoval of the azo dye Direct Blue 15**

P.d. Antuna-González, Escuela Nacional de Ciencias Biologicas, IPN / Experimental Biology; M. Hernández, Instituto Politecnico Nacional / Zoology; F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biologicas, IPN / Laboratory of Experimental Hydrobiology

Each year, 800,000 tons of dyes are produced; from this amount, 30% are discharged into water bodies as industrial effluents. Synthetic dyes obtained from benzidine are carcinogenic, mutagenic, and have genotoxic potential so they can affect the aquatic biota. The bioremoval of colorants using microalgae is an alternative method to avoid water pollution. The objective of this study was to evaluate the capability of Chlorella vulgaris to bioremove the Direct Blue 15 (DB15) dye employing different concentrations by Day 11. To investigate possible mechanism for this response, the second bioassay varied the feeding rate of the brine shrimp. However, survival of FHM in our second bioassay ranged from 85-100% in all MC-LR in all concentrations across both feeding rates, and survival of FHM in the third bioassay, set up to mimic our first bioassay, ranged from 95-100% across all 5 concentrations. To evaluate if exposures to MC-LR in the third bioassay, which was prepared with a fresh feeding solution, stressed the FHM, we evaluated brine shrimp survival, thus potentially affecting the uptake of MC-LR through the FHM diets, we exposed brine shrimp for 5 hrs at MC-LR concentrations in the third bioassay. Survival of brine shrimp in the MC-LR 25 and 50 µg/L treatments were significantly higher compared to the control. Concentrations of algal toxins measured with enzyme-linked immunosorbent assays (ELISA) generally were within 40 to 64% of the nominal MC-LR concentration across all three bioassays, demonstrating that differences in survival among tests were not caused by differences in waterborne MCLR concentrations. Ongoing analyses will further document MCLR exposure by determining bioaccumulation of MCLR in fish tissue and evaluate potential sublethal effects of MCLR on fish growth and swimming behavior.
time of bioremoval. The inoculum has a variable effect on the elimination process, depending on the time and xenobiotic concentration. The concentration of photosynthetic pigments increased significantly in dye concentrations greater than 15.92 mg L\(^{-1}\). Likewise, there was a rise in protein concentration per cell in the greatest concentration of DB15. An increase in lipid concentration in the inoculum of 6x10\(^6\) cells mL\(^{-1}\) and a decrease in 3x10\(^6\) cells mL\(^{-1}\) were observed. Dye concentration, time, and the number of cells are factors that influenced the capability of C. vulgaris to bioremove DB15; nevertheless, the photosynthetic pigments and macromolecules content were affected in response to the xenobiotic. C. vulgaris can be useful to remove DB15, but toxic effects could be expected.

**RP126 Effects of urbanization on water quality and instream biota in Northern Utah, USA**

C. Fender, D. Kimberly, Westminster College / Biology

It is widely acknowledged that urbanization can degrade water quality of inland waterways. Increased acidification, sedimentation, and habitat fragmentation are some stressors from urbanization that can directly affect the health of instream biota. Over the past decade, Utah has consistently ranked as one of the fastest growing states in the nation. Moreover, the vast majority of Utah’s population (>80%) resides within a densely packed 100-mile corridor. This has led to an increase in development near sensitive habitats, such as alpine streams. This study sought to better understand the impacts of urbanization on City Creek and Emigration Creek, which are very close to Salt Lake City. During the summer of 2018, we surveyed macroinvertebrates every river mile from headwaters to mouth in each stream. The majority of sampling was done using hester-dendy plates, which is an artificial substrate that promotes invertebrate colonization. In addition to collecting and distributing plates on a monthly basis, dissolved oxygen and temperature were also collected. As a proxy for urbanization, we quantified the percent impervious surfaces within a quarter mile radius of each transect. Results from this study suggest that macroinvertebrate diversity decreased along a gradient from the forested headwaters to more urbanized landscapes downstream. Additionally, upstream transects were characterized by greater family diversity and a greater proportion of sensitive families, such as Sphaeriidae and Lepidostomatidae. Conversely, transects among urbanized areas were less diverse and characterized more by tolerant organisms. This data supports many other studies that show shifts in macroinvertebrate communities from rural, forested sources to more impacted sections close to urban centers. If development in Utah continues to spread into upper reaches of these sensitive habitats, we can expect greater impact on total stream health in the future.

**RP127 Rapid Bioassay Screening of Effluent Discharges from a Mobile Offshore Drilling Unit to the Marine Environment**

A study was performed to evaluate the potential biological impacts from 6 types of miscellaneous discharges from a remote arctic oil and gas mobile offshore drilling unit (MODO). Samples were initially evaluated for toxicity using a rapid (< 1 h) initial screening test (echinoderm [Dendraster excentricus] fertilization test), and if toxicity was found, further testing was conducted using 3 chronic whole effluent toxicity (WET) tests. For an initial toxicity screening test to be an effective tool, the test should be adequately sensitive, and results should include a low incidence of false positives. The EC25 results from WET tests were reviewed as indicators of either observed toxic effects or false positives from the screening test. Screening of effluent samples for toxicity prior to rigorous sampling and investigation, particularly in challenging logistical situations such as this study, can be an effective method of reducing unnecessary effort, cost, and testing of vertebrate species, while continuing to safeguard aquatic ecosystems. This study established the usefulness of the echinoderm fertilization test for effluents discharged into marine waters. Additional tests for marine and freshwater discharges need vetting and there seems to be potential for expanded application within the regulatory framework. California and Gulf of Mexico general permits for offshore oil and gas exploration and point source extraction (CAG280000 & GMG290000, respectively) both require a 7-day chronic fish survival and growth test. An appropriate screening assay, such as the echinoderm fertilization test, could be used to reduce the testing of vertebrate species tested as mandated by these permits.

**RP128 Interactions Between Oil Exposure and Immune Function Relevant for Pacific Herring Population Collapse**

J. Gill, UC DAVIS College of Biological Sciences / Department of Environmental Toxicology; T. Linbo, NOAA Fisheries / Northwest Fisheries Science Center; P. Hershberger, US Geological Survey / Western Fisheries Research Center; J. Incardona, NOAA / Fisheries; A. Whitehead, University of California, Davis / Environmental Toxicology

The population of Pacific herring (Clupea pallasi) in Prince William Sound (PWS) collapsed in the early 1990’s, following record high biomass levels. Cause(s) of the decline remain uncertain; however, surveillances indicate that the decline occurred concomitantly with epizootics of infectious and parasitic diseases. The contribution of the 1989 oil spill to this collapse remains controversial. Here, we test two general hypotheses to evaluate possible connections between the 1989 oil spill and the observed disease epizootics, including: 1) oil exposure caused genotype-selective mortality, where surviving genotypes had compromised immune function that facilitated disease outbreaks (evolutionary impact); 2) oil exposure during early life impaired the development of the immune system such that adults were more susceptible to disease (developmental impact). To test hypothesis 2, we exposed herring embryos to oil during embryogenesis, reared the larval survivors through metamorphosis to juveniles, and exposed metamorphosed juveniles to an endemic pathogen. This experiment included groups from three different populations, including PWS and two other populations that never experienced an oil spill or pathogen-induced collapse, to address hypothesis 1. For sub-lethal oil exposures, we measured dose-response impacts on heart rate and genome-wide gene expression in developing embryos. For pathogen exposures we measured mortality, infection rates, and genome-wide gene expression in post-metamorphosis juveniles. These responses were contrasted between populations. Additionally, new genomics resources were developed, including a reference genome and reference transcriptome for Pacific herring. We present data showing population similarities and differences in their sensitivity to oil and pathogen. Transcriptomics data provide mechanistic insight into the effects of very low oil exposures throughout sequential stages of embryogenesis. These data provide insight into the potential interactions between contaminant exposure and disease that may be relevant for Pacific herring and other wild species.

**RP129 Assessing the Impact of Crude Oil Exposure on the Bioturbation Rate of the Ghost Shrimp Lepidophthalmus louisianensis**

A. Kascak, P.L. Klerks, University of Louisiana, Lafayette / Department of Biology

The ghost shrimp, Lepidophthalmus louisianensis, is an infaunal bioturbator that lives along the northern coast of the Gulf of Mexico (GoM). Ghost shrimp are often present in high numbers and move large amounts of sediment - thereby causing numerous biotic and abiotic changes to the local ecosystem. The GoM is also home to a robust fossil fuel industry, resulting in accidental releases of oil into the environment. It is therefore important to assess the effect of oil on ghost shrimp bioturbation. We are doing this using microcosm experiments and quantifying two bioturbation measures. The first is the rate at which sediment particles at the sediment surface are getting buried (“burial rate”). This rate is measured using a luminophore trace technique utilizing fluorescently coated inert particles initially placed on the sediment surface. The burial rate will be quantified using a biodiffusion/
bioadvection model that accounts for the ghost shrimp’s upward con-
voyer form of bioturbation. This will be assessed for both a surface and
subsurface oil exposure. The second bioturbation measure is the rate at
which subsurface sediment is expelled from a burrow (“expulsion rate”).
This rate is assessed with a sediment trap placed over the burrow open-
ing, catching expelled sediment, in an experiment in which oil is placed
on the sediment surface. All experiments include three oil treatments: an
oil-free control, a light, and a light to medium oiling (oiling terms
based on criteria used during assessments of the Deepwater Horizon
refinement in REEs industry steadily grow, inducing amounts of REEs
alone of extracted samples from environmental and biological matrices,
it is difficult to accurately determine the bioavailability of REEs and
then reflect their cell-based effects as well as subsequent toxicity risks.
Therefore, understanding the species, degrees of REEs contamination and
pollution characteristics regarding of entirely environmental matrix and
biological samples in study sites and successfully culturing the primary
cells from critical tissues in aquatic organisms of ecological niche, the
field exposure were performed to analyze the subcellular distributions of
REEs and adverse effects of chemicals combined with cell-based in vitro
assays and in situ tests. Further, the dynamic exchanges, translocation
and mobilization of typical REEs were then clarified among the “vari-
os particles, water and cells in exposed organisms” interfaces of matrix.
Moreover, coupled with chemical analysis to quantify the mitochon-
dria components within culture wells of primary cells and molecular
approaches to assess the expression of responsive genes in field exposure,
the mechanisms of associated toxicity were elaborated and the interactive
relationships were then obtained between REEs bioavailability and in situ
stress. Simultaneously, the high throughput assays of cell-based evalu-
ation and in situ monitoring are proposing to be established considering
the consistency of framework as protocols among cell culture, field tests,
exposure effects and high throughput in situ identification. Overall, the
outcomes support full-scale evaluations of environmental prevention and
ecological retrieval and thus provide robust tool to scientifically mine
and refine of REEs, further improving accuracy towards future ecological
re-establishment as powerful tools and more comprehensive pollution
monitoring assessments and relevantly high throughput in situ identifica-
tions in complex scenarios (This research was supported by a grant from
the Jiangxi University of Science and Technology for promoting high-tier
scientists (No.3401223393)).

RP130 Long Term Exposure to Bleached- Kraft Pulp Mill Effluent at
Jackfish Bay, ON
S. Williams, K.R. Munkittrick, Wilfrid Laurier University / Biology;
M.E. McMaster, Environment and Climate Change Canada / Water
and Science Technology Directorate / Aquatic Contaminants Research
Division
Jackfish Bay, on the north shore of Lake Superior (48°50’N, 86°58’W),
was identified as an Area of Concern (AOC) in 1987 due to changes in
its chemical and biological integrity associated with the volume of
effluent discharged from a pulp mill in Terrace Bay, ON. Studies from the
late 1980’s have documented impacts to white sucker (Catostomus
commersoni) populations exposed to the mill effluent including: reduced
reproductive fitness, delayed sexual maturation, and altered levels of
circulating sex steroid hormones. The purpose of this study was to 1)
examine whole-organism and histological impacts in white sucker popula-
tions following chronic exposure to bleached-Kraft mill effluent (BKME)
at Jackfish Bay, ON and 2) compare the results of this study to previous
studies. Gill nets were set during the gonadal recrudescence period (August
2018) to collect suckers from the exposure site (Jackfish Bay) and the
reference site (Mountain Bay). During the pre-spawning period (May
2019), white sucker were collected from Sawmill Creek (Jackfish Bay)
and Little Gravel River (Mountain Bay) using hoop nets. In both sampling
sessions, 20 individuals (10 males, 10 females) were collected and the
following whole-organism parameters were measured: liver somatic index
(LSI), gonad somatic index (GSI), condition factor (k), mass (g), body
length (cm), age (years), fat and tubercle index. Histological parameters
included blood smears, proximal intestine, anterior kidney, spleen, gonad
and stomach. Collections from the gonadal recrudescence period showed
that fish at Jackfish bay were longer (males) and heavier (both sexes),
with a larger LSI (both sexes) and smaller GSI (males) and had a larger
fat index (males) and more tubercles (males). Collections from the pre-
spawning period also showed that males at Jackfish Bay were heavier,
longer a larger GSI and no difference in male LSI. Females at Jackfish
Bay had larger LSI but no significant difference in female length, weight
and GSI. Histological analysis showed no significant difference in
melanomacrophage activity in spleen and anterior kidney between sites in
either sex and further analysis on the remaining tissue is underway. These
findings indicate that the health of white sucker inhabiting Jackfish Bay
are adversely affected at the whole-organism level. The mill is expected to
switch process types (from BKME to dissolving pulp) in the near future
and as such, my study will serve as a baseline for which future studies
will compare.

RP131 Bioavailability of typical anthropogenic REEs and high
throughput identification of in situ effects based on cell-based
in vitro assays
Z. Wang, Jiangxi University of Science and Technology
With the rapid development of innovative technology and extensive usage
of rare earth elements (REEs) in agricultural fertilizers, the mining and
refinement in REEs industry steadily grow, inducing amounts of REEs
and their chemical compounds have been discharged into aquatic environ-
ments, and focusing on relevant exposure risk of environmental health.
While, traditional methods are mostly based on the chemical analysis

RP132 The Protective Effects of Carbon: Why are carbon sources
effective at reducing toxicity of a common fungicide?
M. Barry, A.M. Isabella, A. East, Towson University / Environmental
Sciences; C.J. Salice, Towson University / Environmental Science &
Studies Biology
Test species like Daphnia magna are used to assess ecological effects
of chemicals in freshwater systems. The strobilurin fungicide, pyraclos-
tribin, is highly toxic to D. magna, however, toxicity is ameliorated in a
carbon-amended (fed) environment compared to a carbon-free (unfed)
environment. These results suggest that the presence of carbon provides
a bioenergetic advantage to daphnia that increases resistance to pyra-
clostrobin. Alternatively, pyraclostrobin may become less bioavailable as
it sorbs to the carbon. To better understand the role that carbon plays in
ameliorating toxicity of pyraclostrobin, D. magna were exposed to pyra-
clostrobin and several sources of carbon: algae, snail waste, lettuce and
control (no carbon). However, if pyraclostrobin levels
were exposed to pyraclostrobin. Alternatively, pyraclostrobin may become less bioavailable as
it sorbs to the carbon. To better understand the role that carbon plays in
ameliorating toxicity of pyraclostrobin, D. magna were exposed to pyra-
clostrobin and several sources of carbon: algae, snail waste, lettuce and
control (no carbon). However, if pyraclostrobin levels
were exposed to pyraclostrobin. Alternatively, pyraclostrobin may become less bioavailable as
it sorbs to the carbon. To better understand the role that carbon plays in
ameliorating toxicity of pyraclostrobin, D. magna were exposed to pyra-
clostrobin and several sources of carbon: algae, snail waste, lettuce and
control (no carbon). However, if pyraclostrobin levels
were exposed to pyraclostrobin. Alternatively, pyraclostrobin may become less bioavailable as
it sorbs to the carbon. To better understand the role that carbon plays in
ameliorating toxicity of pyraclostrobin, D. magna were exposed to pyra-
clostrobin and several sources of carbon: algae, snail waste, lettuce and
control (no carbon). However, if pyraclostrobin levels
were exposed to pyraclostrobin. Alternatively, pyraclostrobin may become less bioavailable as
it sorbs to the carbon. To better understand the role that carbon plays in
ameliorating toxicity of pyraclostrobin, D. magna were exposed to pyra-
clostrobin and several sources of carbon: algae, snail waste, lettuce and
control (no carbon). However, if pyraclostrobin levels
were exposed to pyraclostrobin. Alternatively, pyraclostrobin may become less bioavailable as
it sorbs to the carbon. To better understand the role that carbon plays in
ameliorating toxicity of pyraclostrobin, D. magna were exposed to pyra-
clostrobin and several sources of carbon: algae, snail waste, lettuce and
clostrobin. Alternatively, pyraclostrobin may become less bioavailable as
the lettuce. We hypothesized that if excess assimilated energy
is allocated to metabolic processes (e.g. resisting the stress of pyraclos-
tribin exposure), then the daphnia fed algae would be most resistant to
pyraclostrobin in several sources of carbon: algae, snail waste, lettuce and
clostrobin. Alternatively, pyraclostrobin may become less bioavailable as
the lettuce. We hypothesized that if excess assimilated energy
is allocated to metabolic processes (e.g. resisting the stress of pyraclos-
tribin exposure), then the daphnia fed algae would be most resistant to
pyraclostrobin in several sources of carbon: algae, snail waste, lettuce and
clostrobin. Alternatively, pyraclostrobin may become less bioavailable as
the lettuce. We hypothesized that if excess assimilated energy
is allocated to metabolic processes (e.g. resisting the stress of pyraclos-
tribin exposure), then the daphnia fed algae would be most resistant to
pyraclostrobin in several sources of carbon: algae, snail waste, lettuce and
clostrobin. Alternatively, pyraclostrobin may become less bioavailable as
the lettuce. We hypothesized that if excess assimilated energy
is allocated to metabolic processes (e.g. resisting the stress of pyraclos-
tribin exposure), then the daphnia fed algae would be most resistant to
pyraclostrobin in several sources of carbon: algae, snail waste, lettuce and
lettuce treatment and our treatment with no carbon. Studies like this can be used to better understand the role that resource environments play regarding toxicity, which can help to refine risk estimates for D. magna.

RP133 DFO’s National Contaminants Advisory Group: Highlights on research investigating the biological effects of contaminants in aquatic environments
C. Dubetz, Government of Canada; T. Pretorius, J. Leblanc, Government of Canada / Fisheries and Oceans Canada
As a science-based federal government department, Fisheries and Oceans Canada (DFO) requires scientific evidence to facilitate the sound management of Canada’s fisheries and to advance sustainable aquatic ecosystems while fostering economic prosperity across maritime sectors and fisheries. The National Contaminants Advisory Group (NCAG) provides scientific information and advice to DFO on priority issues related to the biological effects of contaminants on aquatic species. The main functions of the group are to facilitate research projects through external researchers, to synthesize results and to develop science advice in support of DFO decision-making. Current priority research themes are: (1) oil and gas, (2) pesticides, (3) aquaculture and (4) contaminants and issues of emerging concern. The NCAG has funded a variety of multi-year research projects at Canadian universities and not-for-profit research institutions. A summary of NCAG supported research projects and their highlights is presented.

RP134 The study of acute and delayed toxicity of ethylenediamine in aquatic animals for environmental risk assessment
S. Park, S. Kim, Korea Institute of Toxicology (KIT) / Gyeongnam Department of Environmental Toxicology and Chemistry; Y. Dong-Hyuk, Korea Institute of Korea (KIT) / Global Environmental Regulation and Compliance Center
Ethylenediamine (EDA) is a widely used for chemical synthesis process. The occurrence of this to the water environment can result in a corrosive and toxic mist, and cause serious damage to health. However, its toxicity data were not sufficient to evaluate the environmental risk assessment. This study investigated acute and delayed toxicity effects of EDA on aquatic ecosystem after chemical accident in water environment. Chironomus (Glyptotendipes tokunagai) and two fish species (Zacco platypus and Aphycypris chinensis) were used for semi-static and closed semi-static acute toxicity test. The result showed that Pale chub (Z. platypus) was particularly sensitive to EDA with a NOEC of 40 mg/L and chronic EC20:EC5 ratios and chronic EC20:EC5 ratios were averaged at the species level for each chemical and regressed along species mean acute values and species mean chronic values, respectively, to determine if within-species variation in sensitivity was influenced by species sensitivity. With an increased emphasis placed on the use of C-R models to develop point estimates to inform aquatic life criteria derivation and risk assessment, this work may provide insight into how the same C-R models can also be used to further consider variation in sensitivity within individual species and taxa.

RP135 Determination of biomarkers in the oyster Crassostrea virginica (Gmelin, 1791) of the Gulf of Mexico
M. Del Carmen Guzman Martinez, P. Ramirez Romero, Metropolitan Autonomous University / Hidrobiologia
This is a monitoring study to observe the effects of oil pollution. Using biomarkers The oyster Crassostrea virginica was chosen as a bioindicator organism. The aim of the present work was to evaluate the DNA damage, the lysosomal stability and the determination of the activity of the enzyme acetyl cholinesterase (AChE) in the oyster Crassostrea virginica organisms were collected from five lagoons of the Gulf of Mexico. For the comet analysis, the method of Singh (1988) was used with some modifications. For the determination of the lysosomal stability, observations were made at 15, 30, 60, 90 and 180 minutes. For the determination of acetylcholinesterase were divided into two groups, the first group was obtained the digestive gland was homogenized and the activity of AChE was determined. The other group was kept in depuration for a period no longer than three months. For the comet analysis all the cells of all the study sites had damage. For the lysosomal stability, significant differences were detected in the retention time of the organisms of the different localities analyzed. Regarding the AChE activity, there were significant differences in the localities of Pueblo Viejo and Tamiahua, which shows an alteration in these organisms since the lower the activity, the greater the contamination present in the environment. The biomarkers chosen were an excellent tool to know the effect of contaminants on organisms.

RP136 Acute toxicity Testing Using Catfish And Tilapia
B. Gbadamosi, University of Lagos, Akoka, Lagos, Nigeria / Zoology
The toxicological evaluation of commercial liquid soap - a domestic cleaning agent, was carried out against Africa Catfish - Clarias Gariepinus and Nile Tilapia - Oreochromis Niloticus. The catfish had a mean weight of 6.10g and a standard length of 4.8-6.0cm. The Nile tilapia had a weight of 5.4-11.0kg and a standard length of 5.3-7.0cm. After a series of range finding tests, the catfish were exposed to lethal concentrations of 0.01ml/L, 0.02ml/L, 0.04ml/L, 0.06ml/L and 0.08ML/l. While the Nile Tilapia was exposed to lethal concentrations of 0.001ml/L, 0.002ml/L, 0.004ml/L, 0.060ml/L and 0.008ml/L. On the basis of 96 hours, the LC50 of liquid soap on the Africa Catfish was found to be 0.029 and the lethal concentration on the Tilapia was found to be 0.032. When the fishes were exposed, we observed erratic swimming, respiratory disturbance, loss of equilibrium, lethargies and ultimately death. The mortality of these fishes on exposure to the liquid soap indicates that an indiscriminate discharge of this effluent to the surrounding should be highly discouraged.

RP137 What Influences Within-Species Variation in Sensitivity to Chemical Exposures?
C. Dubetz, Government of Canada; T. Pretorius, J. Leblanc, Government of Canada / Fisheries and Oceans Canada
Concentration-response (C-R) curves are commonly assessed to quantify point estimates (e.g., LC50) to inform sensitivity across species and taxa; however, their use to assess within-species variation in sensitivity receives less attention. For example, the USEPA 1985 Guidelines for deriving aquatic life water quality criteria focuses heavily on the use of point estimates (e.g., LC50 values) to construct acute species sensitivity distributions on a chemical-by-chemical basis but considers a universal factor of 0.5 sufficiently representative of the variation between LC50 and LC10 values for all taxa and chemicals. The goal of our work was to determine if within-species variation in sensitivity to a pollutant is influenced by 1) pollutant type and 2) species sensitivity itself. We obtained all available raw data from studies used to derive the USEPA acute and chronic cadmium and ammonia aquatic life criteria. Raw data were fit to C-R curves using R software to calculate curve-specific acute LC50:LC5 ratios and chronic EC20:EC5 ratios that served as surrogate measures of within-species variation in sensitivity. Acute LC50:LC5 ratios and chronic EC20:EC5 ratios were species represented in both the cadmium and ammonia datasets were compared to determine if within-species variation in sensitivity is influenced by chemical type. Acute LC50:LC5 ratios and chronic EC20:EC5 ratios were averaged at the species level for each chemical and regressed along species mean acute values and species mean chronic values, respectively, to determine if within-species variation in sensitivity was influenced by species sensitivity. With an increased emphasis placed on the use of C-R models to develop point estimates to inform aquatic life criteria derivation and risk assessment, this work may provide insight into how the same C-R models can also be used to further consider variation in sensitivity within individual species and taxa.
RP139 Effects of chronic 17β-estradiol exposure on the marine polychaete Capitella teleta
A. Murillo, J. Otoo-Appiah, J. Wilson, McMaster University / Biology
Capitella teleta is a marine lophotrochozoan used as an indicator species for pollution due to its high growth rate in contaminated sediments. An in vitro reporter assay has previously shown that the C. teleta estrogen receptor is ligand activated by estradiol (EC50 = 9.2 nM). However, in vivo biological effects of estrogen have not been investigated. This study investigated the biological effects of chronic exposure to 17β-estradiol (E2) in C. teleta over different life stages to explore potential roles in development and reproduction. C. teleta were exposed to control conditions, 0.1% vehicle control, and two doses of E2 (0.367 nM and 36.7 nM). Exposures began at pre-metamorphosis (5 days postemergence or dpe) or sexual maturity (70 dpe). Prior to exposure, animals were reared in control conditions. Survival, sex ratio, and body volume were monitored weekly from 35 dpe until they reached sexual maturity. At maturity, paired worms (1 male and 1 female) remained isolated in control conditions, and were checked for survival, time to first brood tube appearance and number of larvae per brood tube formed. These data will help elucidate the role that estradiol may play in endocrine signaling in development and reproduction of C. teleta.

RP140 Could human activities be affecting Munida gregaria larval distribution along the Beagle Channel, Tierra del Fuego, Argentina?
L. Xaus, Wilfrid Laurier University / Biology; M.L. Presta, F.L. Captamin, CONICET / Institute of Biodiversity and Experimental and Applied Biology
Munida gregaria - the squat lobster - has been subject of numerous studies during the past 20 years. In the last decade their density has increased dramatically, becoming one of the most abundant decapod species in the Southwestern Atlantic Ocean. By feeding upon algae, detritus and sediment and particulate organic matter and being prey of many top predators, this species represents a trophic shortcut in the marine food web. The squat lobster exhibits phenotypic plasticity that allows it to exploit resources in both the neritic and benthic environments. Here, we analysed the spatio-temporal variations in M. gregaria larvae by means of samples collected seasonally at the coastal and external zones of Ushuaia Bay (inner Beagle Channel), the former one being highly impacted by urban discharges. Also, we provide baseline data regarding the abundance of M. gregaria larvae along the Beagle Channel, including the inner and outer sectors, during the springtime of 2014 and 2015. Results from 2012 showed the highest zoae abundances during late winter (September) (8.46 ind.m3) coinciding with maximum values of salinity and chlorophyll-a. Mean abundance of larvae was similar between the coastal and external zones of the bay; except in late winter, when larvae were more abundant at the external zone. In regards to the spatial distribution of M. gregaria larvae along the Beagle Channel, highest larval abundances were found at the outer sector during both years, with values being significantly higher in 2014 (max: 143.16 ind/L) than in 2015 (max: 3.96 ind/L). Previous experimental studies in Ushuaia Bay have reported that, crustacean larvae can suffer inhibition in the moulting process and anomalies in the swimming behaviour caused by petroleum hydrocarbons and heavy metals, two contaminant present in the coastal zone of this bay. Considering that there is little knowledge on the sensitivity of M. gregaria larval stages to aquatic contaminants, we recommend further experimental and field studies about the potential effects of human activities on this species in order to better understand the spatial patterns observed in this study.

RP141 Application of Phase I TIE Techniques in the Identification of Wood Extractives Toxicity in a Saw Mill Effluent
A.M. Briden, B.C. Jorgenson, Pacific EcoRisk
The cause of unknown chronic toxicity to Selenastrum capricornutum (now Raphidocelis subcapitata) in a sawmill effluent was investigated and elucidated through the execution of a toxicity identification evaluation (TIE) targeting wood extractives such as tannin and lignin associated with log deck runoff. Removal of color through the application of anion exchange chromatography completely eliminated growth inhibition. Removal of color was similarly correlated with the removal of tannin and lignin. A simple relationship between growth inhibition and absorbance of light in the visible spectrum was developed to assist in field tuning of log deck runoff management practices and the passive treatment of wood extractives.

RP142 Effects of DNA methylation associated with EE2 induction of estrogen receptor alpha expression in fathead minnows (Pimephales promelas)
J. Ferke, University of Cincinnati / Department of Biological Sciences; R. Flick, US Environmental Protection Agency / ORD/NERL/EMMD; J. Martinson, M. See, US Environmental Protection Agency / Office of Research and Development; E. Pilgrim, US Environmental Protection Agency / NERL Ecological Exposure Research Division; A. Biales, US Environmental Protection Agency / ORD/NERL/EMMD
Exogenous estrogens can interfere with endocrine function and cause decreased fecundity, fitness, and sperm production in fish, as well as feminization of male fish. Physiological effects and alterations of gene expression resulting from estrogen exposure have been thoroughly described in fish. However, little is known about epigenetic alterations, such as DNA methylation, although these changes are believed to be what links gene expression with the development of adverse effects at higher biological levels. This study investigates DNA methylation changes of a nuclear estrogen receptor (ERα) in brain and liver tissue in fathead minnows (Pimephales promelas) exposed to either 2.5 ng/L or 10 ng/L of the synthetic estrogen, 17α-ethynylestradiol (EE2). Methylation differences were assessed across all CpG sites in a 2.5KB region encompassing exon 1 and 1.5KB upstream of the start site of the ERα gene by targeted deep sequencing of bisulfite treated DNA isolated from treatment groups. Additionally, DNA methylation was assessed from fish depurated for 7 and 14 days to better understand the kinetics of methylation. Lastly, ERα methylation status and relationship to dose-dependent gene expression changes fish were evaluated. Results from this work will provide information about tissue-specific gene regulation in response to estrogens and how alterations in methylation status are associated with gene expression.

RP143 The Impacts of Environmental Chemicals on Telomere Length and Adverse Effects in A549 Cells
A.E. Kiflay, University of Copenhagen / Environmental Health
Human exposure to environmental chemicals is associated with cardiovascular disease, lung cancer, chronic respiratory disease and mortality. In this study, we investigated the exposure of one group of chemicals (oxidizing agents) can lead to adverse effects and change the telomere length as a mechanism of health effects in lung epithelial cells in cell cultures. We selected four oxidizing agents such as Potassium Bromate (KBrO3), Hydrogen peroxide (H2O2), Sodium dichromate (Na2Cr2O7) and 4-Nitroquinoline 1-oxide (4NQO) that can cause DNA damage. The compounds are suggested to be used as positive controls for the generation of DNA strand breaks and/or oxidatively damaged DNA. We measured cytotoxicity effects of cell metabolic activity, cell membrane damage and cell proliferation after 24 hours exposure to all chemicals and oxidative stress levels (ROS generation and antioxidant defense) were measured in short term and long-term exposures after 3 hours exposure to all chemicals and the effect of long-term exposure on the telomere length. The results can be summarized as (1) the short-term exposure for KBrO3 leads to low cytotoxicity and oxidative stress effect; (2) the H2O2 causes no cytotoxicity effects and moderate oxidative stress effect; (3) the Na2Cr2O7 leads to high cytotoxicity and moderate oxidative stress effect and (4) the 4-Nitroquinoline 1-oxide (4NQO) leads to high cytotoxicity and oxidative stress effects. The long-term exposure for all the chemicals induces moderate oxidative stress effect in the cells. Long term exposure to all chemicals are associated with no significant change on the telomere length as observed in A549 cells.
RP144 Lack of Latent Effects to Daphnia magna From Exposure to Chlorantraniliprole
A. Samel, FMC Corporation / Environmental Sciences; A. Gerke, Eurofins-EAG Laboratories; M. Woodward, K. Brugger, FMC

Latency is defined as delayed effects of exposure to a molecule after the exposure period is completed or the molecule is no longer detected in the field/area of interest (i.e., water, soil, sediment, etc.). It is the responsibility of the registrant to provide evidence of a lack of latency. The 2013 OECD Aquatic Guidance Document allows registrants to use the acute endpoint for long-term risk assessments if effects are rapid (i.e., first 96 hours of the chronic test) and if latency is not a factor. Because Daphnia magna is the most sensitive of the aquatic organisms exposed to chlorantraniliprole in laboratory studies, the determination of latent effects is based on studies conducted to this test organism. For chlorantraniliprole, the short-term and long-term aquatic risk assessments in the European Union are based on the acute (EC50) endpoint from the Daphnia magna acute toxicity test. This is based on the rapid onset of immobility observed in the daphnid chronic test; immobility is the driver for the NOEC determination. It was, therefore, asserted that there was a lack of latency from exposure to chlorantraniliprole. To determine if latency is a real concern, a study was conducted with Daphnia magna. The study consisted of a short-term (48-hr) exposure to the aquatic invertebrate Daphnia magna followed by a subsequent 19-day test-material-free period. The 48-hr exposure time is consistent with the regulatory Daphnia magna acute toxicity guideline and 21-days total time is consistent with the regulatory Daphnia magna chronic toxicity test guideline. The acute 48-hour EC50 from the guideline test and the latency test considered equivalent. The NOEC values from the guideline chronic daphnid test and the latency test are also considered equivalent. It can be concluded that the results from this higher tier test support the lack of any latent effects to Daphnia magna exposed to chlorantraniliprole. Therefore, it is acceptable to use the acute endpoint for the long-term aquatic risk assessment.

RP145 Fish and invertebrate use of invasive Phragmites in a Great Lakes freshwater delta
A.G. Wynia, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D. Redick, J. Midwood, S. Doka, Fisheries and Oceans Canada / Great Lakes Laboratory for Fisheries and Aquatic Sciences; C. Jacobs, Walpole Island First Nation / Walpole Island Heritage Centre; T. Whillans, Trent University / School of the Environment

Invasive Phragmites australis sspp. australis (herein “Phragmites”) has established and rapidly spread throughout many coastal areas of the Great Lakes. Known to displace native vegetation communities as it forms large, monotypic stands, Phragmites has a bad reputation when it comes to losses of biodiversity and habitat provision for wildlife. However, the extent to which Phragmites provides habitat for fish and invertebrates in coastal freshwater wetlands remains relatively unquantified. Thus, this study assessed whether fish assemblages and invertebrate communities in stands of Phragmites differ from those in stands of two native emergent vegetation communities, Typha spp. and Schoenoplectus spp. The findings showed significant differences in habitat variables among the vegetation communities in terms of water depth, macrophyte species richness, stem density and water quality. While abundance of the functional feeding group filterer-collectors was found to be significantly less in stands of Phragmites when compared to Schoenoplectus, no difference was observed in invertebrate taxa richness among vegetation communities. Lastly, no difference in fish assemblage or invertebrate community was detected when using multivariate analyses, implying that invasive Phragmites provides habitat that appears to be as valuable for fish and invertebrates as other emergent vegetation types in the St. Clair River Delta. The findings of this study will ultimately benefit the literature on invasive Phragmites and its role as fish habitat in freshwater wetlands, and aid management agencies in decisions regarding control of the invasive species.

RP146 Physicochemical assessment of quality underground water samples collected from Ogbete Area in Enugu State, Nigeria
F. Nwobodo, Unaffiliated

Water contamination is significantly becoming a global challenge which must be tackled with all seriousness and maximum amount of energy as life itself is dependent on water. This study examined the contamination level the well water from Ogbete areas of Enugu State in order to ascertain the safety level for human use and possible health consequences associated with the use. Four major locations were sampled during the time of this research and in all the places, Carters street had the highest pH 5.23 which is below the WHO standards limits for drinking water. For conductivity in the four location sampled, it was discovered that the prison training school had the highest conductivity 1445 μS/cm, which is below the WHO limits (8-10,000 μS/cm). The other three locations were below the WHO limits for conductivity, Carters street (285 μS/cm), Moore house (295) and Redcross way (340). For TDS (Total dissolved solids) of the four location sampled, it was discovered that all the four sample were within the standard set by WHO (1000 mg/l). For TSS (Total suspended solids), all the four locations, carters street, prison training school, Moore house and Redcross way were within the standards set by WHO (500 mg/l). For Nitrate, Prison training school was not detected and the other three location, carters street (1247.839 mg/l), Moore house (185.918 mg/l) and Redcross way (19.685 mg/l) were above the standards set by WHO (5.0 mg/l). For alkalinity, the four locations were all below the standards set by WHO (150 mg/l). Results shows that most of the physicochemical, biological and heavy metals parameters considered in this study were significantly above the permissible or allowed by WHO. The result of the statistical analysis showed significant differences among the sampling points. From the results of the above survey, the well water in areas in puvire are not safe for consumption.

Emerging Environmental Contaminants: Human Exposure and Associated Risks

RP147 Particulate Matter Concentration During the Wet Season as Indicators of Atmospheric Pollution in Enugu Urban, Enugu State, Nigeria
C. Okudo, C. Okoye, N. Ekere, University of Nigeria, Nsukka / Pure & Industrial Chemistry

The particulate matter in the atmosphere which alters the original state of the atmosphere making it harmful to man, animals and other life forms constitutes what is known as atmospheric pollution. Particulate matter pollution include PM10 which is in-halable particles 10 micrometers or less in diameters and PM2.5 which is fine in-halable particles generally 2.5 micrometers or less in diameters. It has been identified particularly that Particulate Matter (PM) in the air is the main cancer causing component. Therefore, the purpose of the study is to determine the level of particulate matter pollution in Enugu Urban. Particulate Matter PM10 and PM2.5 concentration was studied bimonthly from April to September, 2018 using CASELLA CEL instrument (Micro Dust Pro). The study area was Enugu Urban from eight locations categorized under, Industrial, Commercial, High density residential, Low density residential areas and one location categorized as rural area. The result of the study shows the ranges in mean value in concentration of particulate matter PM10 and PM2.5 as follows: PM10 for April/May ranges from 49.7±2.9 μg/m3 to 218.0±12.7 μg/m3 while PM2.5 ranges from 14.2±0.7 μg/m3 to 90.0±8.5 μg/m3, PM10 for June/July ranges from 24.8±2.5 μg/m3 to 427.3±13.3 μg/m3 while PM2.5 ranges from 13.7±0.8 μg/m3 to 258.3±13.3 μg/m3, PM10 for August/September ranges from 33.2±0.9 μg/m3 to 304.0±3.9 μg/m3 while PM2.5 ranges from 17.2±1.1 μg/m3 to 210.5±3.0 μg/m3. The PM10 and PM2.5 concentration in almost all the areas studied are above the WHO limits of PM10 -50.1 μg/m3 to 210.5±3.0 μg/m3, The PM10 and PM2.5 concentration in almost all the areas studied are above the WHO limits of PM10 -50 μg/m3 and PM2.5-25 μg/m3. Therefore the
populace of study area is exposed to high volume of inhalable particulate which have great health risk. This high concentration of particulate matter in the study area may be attributed to increase in population and other anthropogenic activities. Therefore periodic monitoring and pollution abatement measures must be strictly adhered to.

**RP148 Elemental Characterization of Particulate Matter in Different Micro Environments of Urban and Rural Areas in Lagos State Nigeria**

E.J. Chiedu, Federal Institute of Industrial Research Oshodi (FIRO) Lagos State / Production, Analytical and Laboratory Management; J.M. Okuo, F. Oyibo, University of Benin / Chemistry; B. Anegeb, Western Delta University Oghara Delta State / Chemistry

The need for comprehensive periodic air quality measurements to assess the extent of airborne particulate matter and trace metals exposure in residential areas in Lagos State in view of the urbanization and different energy cooking source cannot be overemphasized. Total Suspended Particulates (TSP) was collected from July 2017 to April 2018 by gravimetric sampling technique in different indoor-outdoor micro environments of a residential area in Lagos and was analyzed by Atomic Absorption Spectroscopy (AAS) method. High base-line concentrations were obtained with an indoor range of 833.33-1944.45 µg/m³ and outdoor range of 1111.11-1944.45 µg/m³ during the wet season. During the dry season, it ranged from 1111.1-2777.78 µg/m³ in the indoors and 1388.89-2222.22 µg/m³ in the outdoors. Elemental concentrations were subjected to enrichment factor analysis (EF) and principal component analysis (PCA) for source identification. EF analysis was used to assess the relative contributions of natural and anthropogenic metal inputs to the air in the area while, PCA identified road dust and combustion activities as the predominant sources of pollutants emission to the environment.

**RP149 Seasonal Variation Of Heavy Metals In Sediments, Water, Shiny Nose Fish, Shrimp And Periwinkle in Esuk Ekpo Eyo Beach, Akpabuyo, Southern Nigeria**

D. Ekpechi, University of Calabar / Chemistry

The seasonal variation of heavy metal (Cr, Cu, Pb, Cd, Ni) pollution in sediments, water samples and shiny nose fish (Polydactylus quadrifilis), shrimp (Parapeneaeopsis atlantica) and periwinkle (Tympanotonus fuscatus) of Esuk Ekpo Eyo Beach, Akpabuyo, Cross River State, Southern Nigeria was investigated using AAS spectrophotometer. The mean concentrations (mg/l) of Cr, Cu, Pb, Cd, Fe and Ni in sediments for dry and wet season were 1.040.658 mg/l and 0.5460.406 mg/l for Cr, 0.462000.071mg/l and 0.0200.010mg/l for Cu, 0.3440.001594mg/l and 0.02850.0062mg/l for Pb, 0.019170.01693mg/l and 0.021330.01089mg/l for Cd, 0.17520.0112mg/l and 0.15030.1216mg/l for Ni, 64.003.964mg/l and 39.914.187mg/l for Fe. The mean concentrations (mg/l) of Cr, Cu, Pb, Cd, Fe, Zn and Hg in water samples during dry and wet season were 0.12380.0866mg/l and 0.197660.1644mg/l for Cr, 0.028660.0060mg/l and 0.03820.0265mg/l for Cu, 0.030830.0172mg/l and 0.036830.0225mg/l for Pb, 0.037160.0301 and 0.0421660.0710mg/l for Cd, 4.3522.7mg/l and 7.2212.49mg/l for Fe, 0.05080.0214mg/l and 0.071160.0072mg/l for Zn, 0.0140.001mg/l and 0.024000.0077mg/l for Hg. The concentrations (mg/l) of Cr in shiny nose fish, Fe in shrimp and Cd in periwinkle for dry and wet season were 0.0190.007mg/l and 0.036 0.0011mg/l for Cr, 0.3270.001mg/l and 0.7400.001mg/l for Fe, 0.0210.007 and 0.0090.004 for Cd in periwinkle. The estimated daily intake of these metals in Fish, shrimp and periwinkle analyzed using the estimated daily intake formula were all below the JECFA recommended daily intake limits. Physicochemical analysis was carried out to determine the values of pH, TOC, TOM, silt, clay and sand for sediments, also pH, turbidity, TDS, TSS, EC and salinity for water samples. The pollution load index calculated for sediment showed moderately severe enrichment for dry season and minor enrichment for wet season while the modified degree of contamination of the geo-accumulation index in the sediments were less than 1.5 hence no contamination. The results of Pearson’s correlation matrix showed that significant correlations were observed among variables at 0.05 levels.

**RP150 An investigation of the distribution and human health risks associated with metal levels in classroom dusts of nursery schools in Abeokuta, Nigeria**

A.O. Famuyiwa, Y.A. Lanre-Iyanda, S.O. Babajide, Moshood Abiola Polytechnic / Science Laboratory Technology

Many studies have reported evidence of anthropogenic inputs by potentially toxic elements (PTE) in urban dusts of cities around the world. Extensive work has been carried out to study PTE behaviour in developed countries but not much attention has been given to PTE investigation in urban dusts of developing countries such as Nigeria. Of major concern is the potential impact on children because they represent the most sensitive and vulnerable group due to their small body size, developing nervous systems, and high absorption rate. To this end, work was carried out to study PTE levels in urban classroom dusts of Abeokuta, Nigeria. Dust samples were collected in May and June 2017 from forty two nursery and primary schools of Abeokuta, Nigeria to assess the potential adverse effects of the exposure of children to PTE through classroom dusts. In each of the classrooms, about 50 g of bulked dust samples were collected, sieved, acid digested and analysed by Microwave Plasma Atomic Emission Spectrometry (MP-AES). Results showed that dusts studied were characteristically unpolluted as the average PTE concentration at each site did not exceed the soil guideline values. Considering the pollution assessment tools employed, some soil samples showed some form of anthropogenic input from PTE. Health risk assessment was employed to assess PTE exposure from ingestion, inhalation, and dermal contact. Result indicated that the highest risk is associated with ingestion followed by dermal contact and inhalation. For non-carcinogenic effects, the summation of hazard quotient value for the PTE studied was less than the safe level of 1; suggesting minimal or no risks. Only Cr and Ni were considered for carcinogenic risks evaluation and results obtained were below the 1 x 10-6. This study has revealed that the exposure of children to PTE from the investigated classroom dusts would not pose any serious health implications but continuous monitoring is necessary to keep the PTE contents low in the classroom dust.

**RP151 Inter-varietal variation in lead uptake by rice, relationship with the essential elements and the risk assessment; an assessment of 10 rice varieties**

W.A. Bakare, The University of Salford, Manchester / Environment and Life Sciences; D. Mondal, M. Wood, The University of Salford / Environment and Life Sciences

Lead poisoning is a serious public health issue globally and Nigeria is currently ranked first among the countries of the world that are adversely affected. There have been many interventions but exposure through food consumption especially rice is still a big issue. Moreover, there is very limited data, if any on the transfer of lead in different rice varieties grown in Nigeria where lead contamination is one of the most significant public health concerns. The overarching aim of this project is minimisation of lead in rice farm that has been previously characterised in Dareta village Zamfara State Nigeria. The rice and their respective soil samples (n=600) were analysed using Inductively Coupled Plasma Mass Spectrometry (ICP-MS). The mean concentration of Pb in the rice was 0.74 ± 0.33 mg/kg and it varied significantly across the varieties ranging from 0.03 mg/kg to 2.51 mg/kg. The mean concentration of Ca, Fe, Cu, Mg, K, Zn, Mn, Co, and Se were 131.45±18.38 mg/kg, 25.43±17.33 mg/kg, 4.66±1.28 mg/kg, 901.99±104.31 mg/kg, 2025.95±242.99 mg/kg, 25.05±3.99 mg/kg, 23.24±2.99 mg/kg, 0.07±0.03 mg/kg, and 0.11±0.02 mg/kg. The ranges...
Bisalayi also demonstrated good yield and it is commonly planted. The lead accumulation among the rice varieties was in the order of bisalayi < Nerica-L34 < Wita-4 < Sipi-692033 < Nerica-L19 < Art-15 < Ita-315 < Art3-7L < Ncro-49 < Irat-170. Bisalayi also demonstrated good yield and it is commonly planted among the farmers in the northern Nigeria. Lead concentration was significantly different (p < 0.01) among all the 10 rice varieties but similar in the soil samples. All the rice varieties accumulated lead above the international permissible limit of 0.3 mg/kg. The inter-varietal variation (IVV) of lead in rice (IVV = the product of dividing the mean lead concentration ratio in the highest accumulation variety by the mean lead concentration ratio in the lowest accumulation variety) was 13%, 9% for calcium (Ca), 2% for Iron (Fe), 182% for potassium (K), 58% for magnesium (Mg), 161% for Zinc (Zn), 78% for Selenium (Se), 77% for Manganese (Mn), 10% for Cobalt (Co) and 385% for Copper (Cu). The Estimated Daily Intake (EDI) for Pb was compared with the United State Food and Drugs Administration (FDA) maximum ingestible daily allowable limit of lead (Pb-MIDAL) to evaluate percentage contribution of lead by each variety to human body evaluate how many folds the lead is being ingested above the international standard. The EDI of the essential elements were also used with the United State Department of Agriculture (USDA) essential elements’ Recommended Daily Intake (RDI) to assess the percentage contribution of each essential element by each variety of rice to human body. There was no significant difference across the EDI of Pb and the essential elements P>0.05. Some rice varieties contributed essential elements significantly to the RDI while some were not good sources of some of the essentials. Carcinogenic and Non-Carcinogenic Risk Assessment was also carried out.

RP152 Heavy metal(loid) distribution patterns in paddy cultivated lands of CKDu prone area in North Central Province of Sri Lanka

M. Kulathunga, The University of Newcastle / Global Center for Environmental Remediation

The results depicted that irrigation water is the major contribution factor for heavy metal(loid) distribution in the study area. Therefore, regular soil and irrigation water quality monitoring is a prerequisite to reduce heavy metal(loid) accumulation in paddy soil and avoid possible adverse effect through food chain transfer to the residents in the study area. Heavy metal(loid)s in paddy soils varied considerably with the concentration of Pb>As>Cd. Median concentration of As was 0.64 mg/kg with range of 0.27-1.33 mg/kg, Cd was 0.03 mg/kg with range of 0.01-0.08 mg/kg and Pb was 3.13 mg/kg with range of 1.42-6.12 mg/kg. Therefore, Pb possess a risk through transferring soil to rice grain while As and Cd remaining at lower risk. Spatial distribution pattern showed that total heavy metal(loid) s content was higher closer to major irrigation tanks and the surrounding of irrigation channels. Spatial distribution of these metals were lower towards the distant parts of irrigation channels (Figure 1) which is located in north-east and southern part of study area. Paddy cultivated lands in Madirigiriya divisional secretariat of Polonnaruwa district which highest number of CKDu patients were reported in the NCP was selected for the study and 69 soil samples were collected covering entire the division. 0.5 g of each soil sample was digested with concentrated HCl:HNO3 (3:1) in microwave digester. Digested aliquots were analysed for heavy metal(loid)s using inductively coupled plasma mass spectrometry. Spatial variation map for total heavy metal(loid)s of Cd, As and Pb was developed using ArcGIS 10.3.1 version. Heavy metal(loid)s like arsenic (As), cadmium (Cd) and lead (Pb) are toxic to plants and animals resulting in numerous harmful effects to plants and also chronic diseases in human beings. Chronic effects of toxic heavy metal(loid)s is believed to be a factor for the Chronic kidney disease of unknown etiology (CKDu) prevailing in North Central Province (NCP) of Sri Lanka. Paddy is the major agricultural commodity in CKDu prone area and paddy farmers are the major population at high risk of developing CKDu. Therefore, spatial variation of paddy soil heavy metal(oid)s in Madirigiriya area was studied to identify pattern of toxic heavy metal distribution in paddy soils to minimise the future risks of CKDu.

RP153 Risk assessment of heavy metals in canned meat products

G.T. Oritoju, Federal University, Wukari / Hospitality and Tourism Management; O. Oritoju, Federal University, Wukari / Biochemistry Department

In this study, five heavy metals of public health importance were determined in canned meats commonly consumed in Nigeria using Atomic Absorption Spectrophotometer (AAS). Eleven brands of canned meats were collected from major markets in Enugu, Nigeria and were analysed in triplicates for the heavy metal Arsenic (As), Cadmium (Cd), Chromium (Cr), Lead (Pb) and Mercury (Hg). The results obtained in dry weight showed that Pb values ranged from (0.56mg/kg-0.13mg/kg), As (1.46mg/kg-0.55mg/kg), Cd (0.82mg/kg-0.43mg/kg), Cr (0.39mg/kg-0.10mg/kg) and Hg was not detectable in any of the samples. It was observed that the concentration of Pb, As, Cd and Cr in the canned meat samples were higher when compared to the Provisional Tolerable Weekly Intake recommended by FAO/WHO with As and Cd having higher means than Pb and Cr. Also, based on an individual percentage level of exposure, results showed that As and Cd had higher percentages when compared to Pb and Cr. Estimated average daily intake and target hazard quotient (THQ) were also calculated and the ranges obtained for samples 1-11 for Pb (8.26-1.92), As (11.9-22.56), Cd (4.24-2.22), Cr (3.44-0.01) were greater than 1 with exception only seen in samples 8-11 for chromium (Cr) with As having the highest values. Food contamination may therefore, not necessarily be linked with the canning materials. It may however, be associated to the source of the products or other environmental factors. These reported levels therefore calls for concern both on the part of the Government and Nutrition educators with immediate solutions to help eradicate this problem.

RP154 Quantification of metal and metalloid exposure in rodent fur and human hair from Yuma, Arizona

J. Credo, University of Arizona / Northern Arizona University / Chemistry and Biochemistry; C. Checinski, Northern Arizona University / Chemistry and Biochemistry; A. Chandos, Northern Arizona University / Biological Sciences; J. Ingram, Northern Arizona University / Department of Chemistry; C.L. Buck, Northern Arizona University / Department of Biological Sciences; J.A. Baldwin, Northern Arizona University / Department of Health Sciences; R.T. Trotter, Northern Arizona University / Department of Anthropology; F.A. von Hippel, Northern Arizona University / Department of Biological Sciences

Yuma, Arizona is an agricultural hub located on the borders of Arizona, California, and Mexico and produces more than 175 crops consumed nationally and globally. Pesticides are applied year-round to maintain high agricultural yields and represent a source of significant exposure to Yuma residents, especially migrant farm workers who comprise the bulk of the agricultural labor force. Previous work in these communities has focused on a limited set of contaminants, such as lead, but little is known about concentrations of other contaminants, including metals and metalloids used in pesticides. This research, funded by the Flinn Foundation, examines the metal and metalloid concentrations in the fur of 300 wild-caught rodents and the hair of 300 human participants from Yuma County. Utilizing inductively coupled plasma-mass spectrometry and cold vapor atomic absorption spectroscopy, contaminants including lead, manganese, and mercury were detected at concentrations associated...
with neurotoxicity in children and adults in both human hair and rodent fur. These preliminary results demonstrate that local wild-caught rodents are an acceptable model for human exposure for the three elements of concern and suggest neurotoxicity exposure in this population. Future directions include using laser ablation inductively coupled plasma mass spectrometry to establish a temporal basis of exposure in subjects and distinguish between exogenous and endogenous contamination. Additionally, neurohistology and gene expression of sensitive nuclei of local wild-caught rodents exposed to differing concentrations of the contaminants will potentially elucidate the timing, geography, and risks of exposure and lead to effective mitigation strategies.

**RP155 Pulmonary exposure to endocrine disruptors sorbed on urban airborne particles of different sizes: chemical and in vitro biological approaches**

D. Le Bayon, E. Guigon, EPHE UMR 7619; L. Oziol, University of Paris-Sud / UMR CNRS 8079; F. Alliot, EPHE UMR 7619; A. Desportes, EPHE UMR 7619 / UMR METIS; F. Allaoui, University of Paris-Sud / UMR CNRS 8079; M. Binbot, University of Paris-Sud / UMR CNRS 8079 / UMR ESE; S. Derenne, EPHE UMR 7619

Since industrial development, emissions of molecules into the atmosphere have diversified and intensified, leading to an increase in air pollution, to which humans are chronically exposed, especially in urban areas. Indeed, the link between exposure to air pollutants and many cardio-pulmonary diseases is now well established, and it believes to be mainly due to airborne particles. The finer the particles are, the deeper they can penetrate the respiratory tract. Thus, the currently regulated particulate matter (PM) are those with a diameter of less than 10μm (PM10) and less than 2.5μm (PM2.5); they can reach the thoracic part of the respiratory tract and the pulmonary alveoli, respectively. Besides their size, their composition has an impact on the resulting health effects: particles are constituted of an inorganic fraction and an organic fraction that can sorb biological material or semi-volatile organic compounds. Amongst the latter, many are suspected or proven endocrine disruptors. These can contribute, individually or in mixture, to the intrinsic endocrine-disrupting potential of air pollution and might cause hormonal disturbances in humans. In this context, the project aimed at studying the health hazards associated with exposure to urban airborne particles according to their size and composition in bioactive endocrine disruptors, during cold and warm seasons. Since January 2019, atmospheric particles belonging to 3 particle-size classes (total suspended particles, PM10, and PM2.5) have been collected at 3 urban sites in Paris. First, each class of particles has been chemically characterized for a wide range of endocrine disruptors (59 molecules). Then, the collected particles have been tested for their bioactivity using various in vitro bioassays (transactivation assays for estrogenicity, anti-androgenicity or dioxin-like effect testing, genotoxic assay). The initial results indicate that the finest fraction chosen, PM2.5, supports the highest concentrations of the 59 organic pollutants analyzed (for phthalate compounds, up to 5 times more compared to the PM10 fraction). Moreover, the related bioassays show that it is the PM2.5 fraction that presents the greatest endocrine-disrupting potential compared to the PM10 fraction. These initial results, by considering both the distribution of endocrine disruptors and the biological effects by particle size, raise new questions about the health risks associated with atmospheric particles.

**RP156 Determination of Uptake Coefficients for Ozone on Brake Wear Particulate Matter: Implications for Predicting and Improving Air Quality**

L. Matchett, M. Abou-Ghanem, S. Styler, University of Alberta / Department of Chemistry

Particulate matter (PM) in the atmosphere is an important contributor to air pollution; it has been linked to respiratory diseases and is classified as carcinogenic. In urban environments, one of the largest sources of atmospheric PM is from traffic. Traffic emissions are classified as exhaust PM (from tailpipes) or non-exhaust PM (e.g. from brake, tire, and road abrasion). Exhaust emissions are currently decreasing due to heightened regulations, and as such non-exhaust PM is predicted to become the dominant contributor to traffic PM in the coming years. One of the major components of non-exhaust PM is brake wear, and studies performed to date have focused on its toxicity, size, composition, and amount emitted into the atmosphere. However, little is known about the reactivity of these airborne particles with gas-phase species present in the atmosphere. In this study, we investigated the uptake of ozone, an important component of photochemical smog, on brake wear using a coated-wall flow tube. Because the uptake of ozone on other atmospheric surfaces has been shown to display a light enhancement, we determined uptake coefficients of brake wear under both dark and light conditions by intermittent exposure to UV radiation. We found that ozone displays significant uptake on brake wear under dark conditions and that this uptake is enhanced upon illumination. In an attempt to assess the range of brake wear reactivities in the environment, we performed experiments using three brake pad types (ceramic, metallic, and organic), the composition of which was characterized using X-ray fluorescence, and over a range of relative humidities. Understanding the interaction of ozone with brake wear will be important for assessing current ozone regulations and informing future regulations for brake wear emissions, thus improving air quality.

**RP157 Retention and Release Characteristics of Biosolids-borne Azithromycin and Ciprofloxacin**

C. Gravesen, J. Judy, University of Florida / Soil and Water Science; H. Sidhu, University of Riverside / Department of Environmental Sciences; G.A. O’Connor, University of Florida / Soil and Water Science Department

Azithromycin (AZ) and ciprofloxacin (CIP) are commonly prescribed antibiotics frequently detected in municipal biosolids at relatively high concentrations and identified by the USEPA as contaminants of emerging concern. The land application of municipal biosolids is an agronomically beneficial practice but is also a potential pathway of CIP and AZ release into the environment. Understanding retention-release behavior is crucial for assessing the environmental fate of and risks from land-applied biosolids-borne target antibiotics. However, retention-release data for CIP and AZ are limited, as is literature addressing the influence of biosolids characteristics on retention-release of AZ and CIP. The present study utilized batch equilibriums to assess retention and release of a range of environmentally relevant concentrations of CIP and AZ in ten biosolids of varying characteristics. The biosolids included Class A and Class B materials with a range of physiochemical characteristics (e.g. pH, CEC, OM, and Fe and Al content and forms). The relationship between biosolids characteristics and partitioning was examined via multiple linear regression using the penalized and shrinkage method LASSO. Retention was linear (R2 > 0.99 (AZ) and > 0.96 (CIP)) and sorption coefficients (Kd) ranged between 52 and 370 L kg⁻¹ for AZ and between 430 and 2300 L kg⁻¹ for CIP. Desorption also varied but was highly hysteretic, with hysteresis coefficients (H) ranging between 0.01 and 0.15 for AZ, and <0.01 for CIP in all biosolids examined, suggesting limited bioaccessibility. Multiple linear regression analysis linked AZ sorption behavior to total iron content and CIP sorption behavior to oxalate extractable aluminum and total phosphorus content. Limited models predicting AZ and CIP behavior based on biosolids physiochemical characteristics are presented.

**RP158 Discovery of Emerging Halogenated Contaminants of Concern in Great Lakes Lake Trout**

S. Fakouri Baygi, Clarkson University / Chemical Engineering; B. Crimmins, Clarkson University / Civil and Environmental Engineering; S. Fernando, Clarkson University / Center for Air Resources Engineering & Science; P. Hopke, Clarkson University / Institute for a Sustainable Environment; T. Holsen, Clarkson University / Civil and Environmental Engineering

Halogenated contaminants are typically the largest fraction of persistent, bioaccumulative and/or toxic (PBT) chemicals in the Great Lakes. Legacy halogenated contaminants (e.g. PCBs) have been monitored, but many additional halogenated compounds may still be undiscovered. To
understand the impact of unknown PBT halogenated chemicals in Great Lakes, top predator fish (trout) were analyzed using an atmospheric pressure gas chromatographic (APGC) coupled with a quadrupole time-of-flight (QToF) instrument that produces soft ionization full scan high resolution mass spectrometer (HRMS) data. An Isotopic Profile Deconvoluted Chromatogram (IPDC) algorithm was developed to screen for halogenated compounds using the distinct identifiable mass spectral signatures in HRMS data. The IPDC algorithm employs several data reduction techniques including a false positive prediction by neural network, a mass defect filter, a boiling point prediction, and a ranking system for when several candidate molecular formula represent an isotopic feature. The IPDC algorithm detected approximately 224 features associated with legacy contaminants in Lake Michigan Lake Trout collected in 2016 sample and produced a list of 256 unknown isotopic features for future investigations. A temporal trend of the uncategorized halogenated futures were produced to compare between sites years (2005/2006 vs. 2015/2016) to determine spatiotemporal impact of halogenated and potential PBT compounds in Great Lakes.

**RP159 Occurrence of dimethylmonothioarsinic acid in aquatic environment and associated risk**

Y Kim, Yonsei University; M. Cho, H. Park, S. Park, Korea Basic Science Institute; H. Yoon, Korea Basic Science Institute / Seoul Center

Dimethylarsenic acid (DMA) is less toxic, however classified as a possible carcinogen because of metabolic transformation to highly toxic dimethylmonothioarsonic acid (DMMTA). DMMTA can occur in aquatic environment by both chemical and biological thiolation of DMA or oxidation of dimethylthioarsinic acid (DMDTA). The purpose of this study is to assess conditions where highly toxic DMMTA can be formed. Kinetics forming DMMTA in abiotic condition were tested in laboratory by varying concentrations of reactive chemicals and pH condition. In previous study, DMA thiolation to form DMMTA was evaluated to the second order reaction of DMA and hydrogen sulfide at pH 6.0. This experiment was conducted under excess sulfide condition, therefore concentration of hydrogen sulfide was lowered close to natural condition in this study. For the biotic reactions, plant exposed to DMA was decomposed in anaerobic condition. Then, arsenic speciation was conducted to observe an occurrence of highly toxic DMMTA. This research was supported by the National Research Foundation of Korea (grant number NRF-2019R1A2C2007092).

**RP160 Methods for analysis of a novel brominated flame retardant, tris(tribromonopentyl) phosphate, using high-resolution orbitrap mass spectrometry**

C. Brinovcar, A.O. De Silva, Environment and Climate Change Canada / Water Science and Technology Directorate; S. Robinson, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate

The use of organophosphate ester (OPEs) flame retardants has increased since regulation of polybrominated diphenyl ether (PBDE) flame retardants in the early 2000s. Several OPEs are chlorine-substituted such as tris(1-chloro-2-propyl) phosphate (TCP), tris(2-chloroethyl) phosphate (TCEP), and tris(1,3-dichloroisopropyl)phosphate (TDICP). These three substances are of emerging concern due to their persistence, hydrophobic and ubiquitous presence. While these Cl-containing OPEs have garnered attention, brominated OPEs seem less prominent, potentially due to classification of tris(2,3-dibromopropyl) phosphate as a potential carcinogen and its subsequent ban from use in children’s clothing over four decades ago. However, one particular brominated OPE, tristribromonopentyl) phosphate (CAS 19786-97-1, molecular formula C15H24Br9O4P, molecular weight 1018.47 g/mol, acronym TTBrNP) is currently in production and used as an additive flame retardant in polypropylene fibre applications including automotive carpeting, office partitions and synthetic hair appliances. TTBrNP is on Canada’s Domestic Substances List and is scheduled for ecological risk evaluation. As such, a need for analytical methodology emerged. The goal of this study was to develop sensitive, quantitative methods for TTBrNP in water, sediment, and biota. Using ultra high performance liquid chromatography coupled with high-resolution orbitrap mass spectrometry (70,000 resolution), TTBrNP detection was optimized via chlorine-assisted atmospheric pressure chemical (APCI) ionization. The validated extraction methods consisted of solid phase extraction (SPE) for environmental water and ultrasonication assisted extraction in acetone for sediment and biota. Analysis of TTBrNP was applied to environmental samples in the Hamilton Harbour, Ontario, Canada and all samples were < LOD. Accumulation and effects of TTBrNP were evaluated in a laboratory-based waterborne sub-chronic exposure of tadpoles. TTBrNP was consistently detected in tadpoles at all treatment levels. However, overall the propensity for bioaccumulation of TTBrNP was low with whole body bioaccumulation factors corresponding to 16 ± 1 L/kg, suggesting biotransformation and/or limited bioavailability due to hydrophobicity. Debromination and hydrolysis of other flame retardants has been shown. Future work will assess degradation products of TTBrNP.

**RP161 Occurrence of Parent and Nitro-PAHs in Soils of an Industrial City and Associated Cancer Risks**

O. Idowu, Forestry Research Institute of Nigeria / Global Centre for Environmental Remediation (GCER); P. Thavamani, University of Newcastle, Australia / Global Centre for Environmental Remediation (GCER)

Exposure to carcinogenic polycyclic aromatic hydrocarbons (PAHs) in industrial soils could have huge health effects on workers. Apart from parent PAHs, their derivatives, such as nitrated (N)-PAHs, are more toxic even at comparatively lower concentrations. Most PAH derivatives are immediate acting carcinogens that require no enzymatic activation to elicit toxic effects. This study, therefore, investigated the soil concentrations of 13 PAHs and 3 nitrated PAHs (N-PAHs) in soils (n = 14) within the industrial area of the industrial heritage city of Newcastle, Australia. In addition, the potential health impact of PAH and N-PAH exposures was determined through the estimation of the excess lifetime cancer risk (ELCR). The mean concentrations of Σ3N-PAHs and Σ13PAHs in industrial soils were 0.40 ± 0.12 µg/g and 92.14 ± 107.48 µg/g respectively and the most abundant N-PAH and PAH were 1-nitronaphthalene (0.20 ± 0.11 µg/g) and benzo (a) anthracene (21.5 ± 27.8 µg/g). Pearson correlation analysis of Σ13PAHs and Σ3 N-PAHs showed a weak positive correlation (r = 0.18, p = 0.05). Computed ELCR values (8.2×10-7) of accidental ingestion of industrial soils was, however, lower than the USEPA high risk value of 1.0×10-4. This study has shown a reduced risk of cancer development in Newcastle industry workers through accidental soil ingestion.

**RP162 Evaluating the Nocuous Effects of Uranyl Nitrate on Primary Dermal Fibroblast Viability, Metabolism, Proliferation, and Migration**

N. Cruz, R.S. Kellar, M. Salanga, Northern Arizona University / Biological Sciences; R. Buscaglia, Northern Arizona University / Mathematics and Statistics

The increased demand for uranium to serve military and nuclear purposes have left Navajo Nation residents at elevated risk of chemical exposure by contaminating their bathing and drinking water. Uranium chemical toxicity has been regularly studied in kidney and lung epithelium; however, testing of percutaneous exposure has been limited. Using soluble and biologically active depleted uranium, in the form of uranyl nitrate, we demonstrate cytotoxicity on primary human dermal fibroblasts. Dermal fibroblasts were selected because of their roles in skin health and healing. We exposed the cells to uranyl nitrate at environmentally relevant concentrations based on observed levels in the Southwest United States ranging from 0.1 uM to 300 uM (39.4 - 118,212 ppb). Cells were exposed to uranyl nitrate or control solution in cell culture media at standard growth conditions. Exposure outcomes were evaluated for cell viability, metabolic activity, pro-apoptotic markers, and proliferation rates at 24, 48, and 72 hours. Exposure to uranyl nitrate revealed a dose-dependent decrease in cell viability measured by CyQuant Direct(TM) and concomitant decrease in mitochondrial activity measured by
Flame retardants are chemical mixtures added to materials after manufacturing to reduce the amount of time it would take a small open flame to ignite the item. These compounds are volatile and continuously leach out of materials into the environment. Therefore, they are ubiquitously detected in household dust, wastewater, rivers, sediment and soil. Flame retardant metabolites are also consistently detected in urine of adults and children participating in national and regional public health studies. Since they have long range transport and persist in the environment toxic flame retardants, such as polybrominated diphenylethers, have been removed from the market. Compounds with limited toxicological data are being used as replacements, including 2-ethylhexyl-2,3,4,5-tetrabromobenzoxate (TBB) and bis(2-ethylhexyl)-2,3,4,5-tetrabromophthalate (TBPB). TBB and TBPB, have been identified by EPA as priorities in the Toxic Substances and Control Act work plan due to critical gaps in toxicity and exposure data. They occur as part of the Firemaster (TM) 550 and BZ formulations and are reported to be endocrine disruptors, primarily mimicking thyroid hormone activity. Whether they act as antiandrogens remains to be determined, however, our preliminary data suggest that TBB and TBPB can inhibit androgenic activity. Thus, we hypothesize that BPs act as antiandrogens by inhibiting androgen receptor (AR) function and causing disruption of androgen mediated processes, including cell growth and testicular development. Aim 1 will determine the mechanisms by which BPs inhibit AR-mediated transcription of target genes. Preliminary data using an AR-driven luciferase reporter assay suggest that TBB is a competitive inhibitor of AR in the androgen-dependent prostate cancer cell line LNCAp. Further mechanistic studies are being conducted in prostate cancer cell lines. In addition, elucidation of the antiandrogenic effects of BPs on testis development will be done using the model organism, zebrafish (Danio rerio). These studies will determine the AR mechanisms by which BPs act as antiandrogens.

RP165 Emissions and Occupational Exposure Risk of Halogenated Flame Retardants from Primitive Recycling of E-Waste

T. Li, J. Ge, L. Bao, C. Wu, E.Y. Zeng, Jinan University / School of Environment

The production and usage of non-polybrominated diphenyl ether (PBDE) halogenated flame retardants (HFRs) have substantially increased after the ban of several PBDEs. This has resulted in widespread environmental occurrence of non-PBDE HFRs, further amplified by emissions from primitive recycling of obsolete electronics (e-waste). In the present study, chamber experiments were conducted to characterize 15 HFRs (Σ15HFR) from thermal treatment and open burning of typical e-waste. Emission factors of Σ15HFR were 2.6 x 10^3-3.9 x 10^3 ng g^-1 in thermal treatment, slightly higher than those in open burning (8.8 x 10^3-10 x 10^3 ng g^-1). Greater output over input mass ratios of Σ15HFR were obtained in thermal treatment than in open burning. Particulate and gaseous HFRs dominated the emissions in thermal treatment and open burning, respectively, largely due to different temperatures used in the two processes. Particulate HFRs were primarily affiliated with fine particles (Dp ≤ 1.8 μm) peaking at 0.56-1.0 or 0.32-0.56 μm in both thermal treatment and open burning. Occupational exposure to most FRs was relatively low, but several PBDEs may pose potential health risk to workers in e-waste home-workshops. Potentially accruing emissions and health risks of non-PBDE HFRs from primitive recycling of e-waste remain a great concern.

RP166 Human exposure assessment of decabromodiphenyl ethane in different areas of China

J. Liu, K. Shen, Peking University / College of Environmental Sciences and Engineering; J. Liu, Peking University

Decabromodiphenyl ethane (DBDPE) is predominant substitute of decabromodiphenyl ether (deca-BDE), which is widely used as a flame retardant in the electrical and electronic products (EERPs) in China, the biggest manufacturer of both DBDDE and EERPs. Current studies have indicated that DBDPE has similar characteristics of persistent organic pollutants (POPs), and its concentration in the environment of China has exceeded that of deca-BDE. Based on the data survey, interval linear programming and emission calculation, the study investigated the stock and flows of DBDPE in China from 2006 to 2016, including its production,
use and emission; And then conducted an assessment of human exposure to DBDPE in different areas of China by integrated modeling through dynamic substance flow analysis and multimedia simulation. Our results indicated, during 2006–2016, ~230 thousand tonnes (kt) of DBDPE were produced in China, ~196 kt of which was released to the environment from the production, use and disposal activities of DBDPE and EEPs containing it. Except for areas with intensive EEPs production, processing or use in EEPs manufacture, i.e., Guangdong and Shandong, the indoor concentration of DBDPE was higher than that of the outdoor in general areas in China. The environmental concentration of DBDPE in the suburban area is lower than that in the urban area currently, but the urban/suburban concentration ratio of DBDPE was decreasing slowly over time, showing a trend of spatial homogenization and increasing level of overall environmental pollution of DBDPE in China. That also means the increasing possibility of DBDPE contamination on food supply mainly from suburban areas, thus elevating the exposure to DBDPE for people in either urban or suburban areas. The main exposure pathways of DBDPE to people living in different regions are different; for instance, in North China areas, far-field exposure dominates, whereas in South China areas, near-field exposure does. We found that children were at higher health risk than that for adults. As business as usual from now to 2026, while children in all different regions would be in high exposure risk, adults would also face to nonnegligible risk in China.

RP167 Biomonitoring of environmental phenols in human urine from seven Asian countries, Greece and the United States
M. Honda, Kanazawa University / Institute of Nature and Environmental Technology; M. Robinson, K. Kannan, New York State Department of Health / Wadsworth Center

Environmental phenols (EPs), are commonly used for several purpose such as antimicrobial preservatives in personal care products, and are degradation products. For examples: Chlorophenols (CPs) are used in the production of pesticides and preservatives; Parabens, esters of para-hydroxybenzoic acid, are commonly used as antimicrobial preservatives in cosmetics and personal care products. Although several studies report exposure of humans to EPs in Western countries, little is known about exposure of humans to EPs in Asian countries. In this study, we determined concentrations of six parabens and eight chlorophenols in 300 human urine samples collected from nine countries. Additionally, we estimated daily intakes (DI) and potential health risks of EPs. Of the 300 samples analyzed from nine countries, 97.7% and 100% of the samples contained at least one CPs and parabens. For CPs, 2,4-dichlorophenol and 2,4-dichlorophenol were found at the highest median concentrations (median for all nine countries: 1.78 and 0.34 ng/mL, respectively). Urine samples from Japan had the highest concentration of total CPs (median: 16.7 ng/mL) with 2,5-dichlorophenol accounting for 93.1% of the total concentration. For parabens, ethyl-paraben, methyl-paraben, and propyl-paraben were detected frequently at 100, 98.0, and 80.3%, respectively, with representative median concentrations of 0.68, 7.02, and 1.21 ng/mL, respectively, for all nine countries. Urine samples from females (total median concentration: 32.3 ng/mL) contained significantly higher concentrations of parabens than did those from males (5.46 ng/mL). Urine samples from Korea (total median concentration: 227 ng/mL) had the highest concentrations, which were one to two orders of magnitude higher than those found in other countries (3.67 - 29.1 ng/mL). The estimated DI for precursors of dichlorophenols and parabens (on the basis of concentrations measured in urine) varied widely, but several samples showed values higher than the acceptable DI of precursors of 2,4-dichlorophenol and propyl-paraben recommended by the United States Environmental Protection Agency. Our results suggest that EPs exposure is ubiquitous in Asian countries, and some person exceed acceptable DI. The assessment of the global exposure sources and further assessment of potential health risk of these chemicals is needed.

RP168 Prioritizing chemicals for toxicity testing for reproductive effects using non-targeted analysis data of prenatal exposures and literature review
D. Panagopoulos Abrahamsos, A. Wang, J. Vashavsky, University of California, San Francisco / Program on Reproductive Health and the Environment; J. Lam, California State University, East Bay / Department of Health Sciences; J. Fung, University of California, San Francisco / Department of Ob/Gyn and Center for Reproductive Science; J. Robinson, University of California, San Francisco / Department of Obstetrics Gynecology & Reproductive Sciences; P. Allard, Azimuth Consulting Group / Institute for Society and Genetics; T. Woodrauff, University of California, San Francisco / Program on Reproductive Health and the Environment

Maternal chemical exposures are of particular importance because pregnancy is a critical period of unique susceptibility to biological perturbations. About 40,000 chemicals are listed on the inventory of the Toxic Substances Control Act (TSCA), which includes nearly all chemicals registered for use in the US. For the vast majority of reported chemicals, there is very limited to no information about human exposures and/or the potential to adversely affect human health. Only about 350 chemicals (approximately 1%) are biomonitoried regularly via U.S. NHANES. Recent advances in non-targeted analytical techniques enabled us to screen biological samples for a broad spectrum of chemical compounds. We published a proof of concept study scanning for about 700 environmental organic acids in blood samples from pregnant women in San Francisco, confirming the presence of numerous organic chemicals in women's blood. We found that over half of the candidate chemicals matched to formulas in our environmental organic acids database that have not been biomonitoried by U.S. NHANES. As biomonitoring advancements move towards large-scale chemical screening, we need to develop approaches to select which of these chemicals to subsequently test for toxicity. We are using a yeast screening assay and a C. elegans assay for developmental and reproductive toxicity. Our chemical selection was based on four main criteria: (i) chemicals suspected to be important for human health, (ii) chemicals of interest to policy makers, (iii) chemicals from non-targeted analysis and (iv) positive and negative controls for the toxicity testing. For the first two criteria we followed a structured literature review approach, where we searched for chemicals of interest to academic and governmental organizations in the environmental health field. For the third criterion we used chemicals that were detected in our previous studies on suspect screening of blood samples from 200 women in San Francisco. For the fourth criterion, we used chemicals that are known to be reproductive and/or developmental toxicants in rodents and in nematodes. With the selected chemicals, we composed a database that will serve as a guide for further toxicity testing. The database consists of about 160 chemicals from various chemical groups, with the largest ones being per- and polyfluoroalkyl substances, pesticides and flame retardants. Our results will eventually be used to develop predictive algorithms for reprod/developmental toxicity.

RP169 Characterization of Electronic Cigarette Liquids by 1D and 2D NMR Spectroscopy
O. Dada, University of Alabama, Birmingham / Environmental Health Science; I. Kavouras, CUNY Graduate School of Public Health and Health Studies / Department of Environmental, Occupational, and Geospatial Health Sciences; M. Chalbot, College of New Rochelle / Environmental Health Sciences

Electronic cigarette (e-cig) liquids (e-liquid) have unknown quantities of unidentified chemicals used as solvents, flavors and preservatives. While some of them are classified as “generally regards as safe” chemicals when used as food additives, their effects when inhaled are largely unknown. This extraordinary variability in e-liquids have substantially influenced the robustness and accuracy of studies investigating the characterization of e-liquids chemical content. Apart from nicotine and major solvents (propylene glycol and glycerin), other chemicals with potentially harmful effects may be present in e-liquids. Thus, it is important to understand
the chemical constituent of e-liquids as there may be a dependence on e-vapor chemical content and this can substantially impair the toxicological and risk assessment process of e-cigarettes and their potential implications to human health. This study assesses the functional characteristics of different e-liquids from varying commercially available products by harnessing the unique molecular fingerprint obtained by nuclear magnetic resonance (NMR) spectroscopy, to estimate the prevalence of known compounds (nicotine, propylene glycol and glycerin) and identify the molecular structure of other unknown compounds. We used a series of 1D and 2D homonuclear (1H–1H COSY) and heteronuclear (1H-13C HSQC and 1H-13C HMBC) NMR experiments. A total of 43 commercially available e-liquids representing 96% of the retail market based on popular flavor and nicotine content were analyzed. 50 μl of e-liquid was mixed with 350 μl of ultrapure water and 200 μl of deuterated phosphate buffer (pH7.4). Spectra of samples from NMR were processed using Advanced Chemistry Development (ACD) NMR Spectrus Processor software. For all the flavors, the spectra width was divided into 6 regions and integrated for all flavors to identify functional groups. Results showed presence of known compounds, multiple signals corresponding to aliphatic, hydroxylated aliphatic, alene and aromatic functional groups were found in the 1D (proton) spectra. The 2D NMR analysis was able to decipher the connectivity between functional groups. NMR spectroscopy is able to determine the functional groups of certain chemicals in e-liquids. These chemicals may be precursors of e-vapor toxicants produced during the heating of e-liquid. Also, these chemicals illustrate need for further studies and control over the chemical constituents and properties of e-liquids.

**RP170 Evaluation of the Use of Tree Leaf Bioactives to Improve Productivity and Mitigate Greenhouse Gas Emissions in Ruminant Farming**

E. Ugbogu, Abia State University / Biochemistry; A.Z. Salem, Autonomous University of Mexico State / Facultad de Medicina Veterinaria y Zootecnia; O.C. Ugbogu, Abia State University, Uturu / Department of Microbiology; O. Emmanuel, Abia State University, Uturu / Department of Biochemistry

In the last two decades, there are global worries concerning the environmental impact of greenhouse gases (GHGs) especially carbon dioxide (CO₂) and methane (CH₄) emitted during ruminant farming. These gases contribute significantly to global warming which causes environmental degradation. Many strategies have been exploited by researchers to optimise ruminant production via enhancing dietary feed with the aim of improving animal health, reduce energy loss and decrease GHG emissions using feed additives such as antibiotics. However the ban of the use of antibiotics by European Union in 2006 due to the associated risk factors such as toxic effects to the host animals, adaptability of rumen microbes and detrimental effects on humans have led to renewed impetus for the search of alternative feed additives without any potential harmful effects. Recently, leaf tree bioactives are being exploited as safer and effective feed additives to improve animal health and inhibit rumen methanogenesis. Today, there are substantial scientific evidence that tree leaves have promising potentials to enhance animal productivity and reduce CH₄ production. Leaves from trees comprise of various bioactives such as tannins, alkaloids, phenolics, saponins and essential oils that have great potentials to favourably modify rumen fermentation and improve reproduction, milk production, meat quality and reduce GHG emissions during ruminant farming. This study therefore evaluates and summarises all the available research works on the use of leaf bioactives to improve productivity and reduce GHG emissions in ruminant production.

**RP171 Photochemistry at the surface of urban road dust: Implications for contaminant lifetime and atmospheric composition**

S. Sylvor, M. Abou-Ghanem, C.D. Cote, University of Alberta / Department of Chemistry; S.R. Schneider, University of Toronto / Department of Chemistry; A. Burnett, Z. Chen, K.M. Naude, M. Lyu, S. Gao, University of Alberta / Department of Chemistry; L. Gan, Central South University; A.J. Holod, T.H. Chou, University of Alberta / Department of Chemistry

In both Canada and the United States, dust resuspension from paved and unpaved roads is the largest anthropogenic source of primary fine particulate matter. Because road dust contains a variety of toxic species, many studies have focused on its composition and potential health effects; by contrast, little is known regarding its atmospheric reactivity. Here, we use a molecular probe technique to show that illumination of urban road dust leads to the production of singlet oxygen, an important atmospheric oxidant. In particular, we show that the production of singlet oxygen increases with decreasing particle size, and provide evidence that light-absorbing organic carbon participates in singlet oxygen production. We also present results from investigations of the interaction of ozone, a representative urban pollutant, with road dust. We find that the uptake of ozone by road dust is higher than that by desert-sourced dust, and is enhanced in the presence of light. Further, we provide evidence for the participation of road salt (i.e. chloride) in the observed chemistry. Together, our work provides evidence that photochemistry at the surface of road dust can influence both the lifetimes of dust-associated pollutants and the composition of the surrounding atmosphere. As vehicle exhaust emission regulations become more strict in coming years, the relative contribution of road dust to urban particle matter loadings will increase, and the road dust-mediated processes described here will only increase in importance.

**Alternatives Assessment and Informed Substitution: The Transition to Safer Chemicals, Materials, Processes and Products**

**RP172 Stakeholder engagement to support the PFAS in Food Packaging Alternatives Assessment**

J. Rhoades, SRC, Inc. / Environmental Health Analysis; C. Hard, SRC, Inc.; C. Rudisill, SRC, Inc. / Environmental Health Analysis; B.J. Penttila, Washington State Department of Ecology

PFAS substances are used in food packaging primarily for oil, grease, and water resistance and can migrate into food during use, or leach into the environment during disposal. In 2018, Washington State passed a new law to prohibit all PFAS in plant fiber-based food packaging. The ban takes effect following the identification of safer alternatives as specified in the toxics in packaging law (RCW 70.95G). An alternatives assessment (AA) is being conducted to identify and assess alternatives to PFAS in Food Packaging. There are a diverse number of parties that have a stake in the transition from PFAS to non-PFAS alternatives in food packaging including chemical manufacturers (PFAS and non-PFAS), food packaging manufacturers, suppliers, NGOs, trade organizations, retailers, purchasers/users, and end-of-life managers. Incorporation of stakeholder interests is an important component of the AA process. For this assessment, the process for stakeholder engagement follows guidelines in the IC2 stakeholder involvement module. Stakeholders were identified and recruited through an internal initial screen and solicited on the WA PFAS CAP website. Stakeholders were asked to participate in a web-based survey to determine the type of input and information they could provide. The general approach of stakeholder engagement includes building a rapport, mapping out the knowledge-base and obtaining input and information to help inform base-case PFAS chemical selection, alternatives candidates identification, scoping, manufacturing considerations, consumer concerns, and input on AA modules (hazard, exposure, performance, cost & availability assessments). Because some of this information is proprietary.
to some stakeholders, a confidential business information (CBI) protocol was developed by WA State to facilitate the sharing of information necessary to conduct the assessment. The formal stakeholder process includes engagement through email, one-on-one telephone discussions, webinars, online surveys, and targeted group phone discussion. Pertinent information is provided for stakeholder review and comment. This presentation highlights the stakeholder engagement process for the AA for PFAS in food packaging, how stakeholder input was incorporated into the assessment, and the challenges associated with obtaining information required for the assessment.

**RP173 Selection of a Representative PFAS for Washington State’s Food Packaging Alternatives Assessment**

C. Hard, SRC, Inc.; J. Rhodes, C. Rudisill, SRC, Inc. / Environmental Health Analysis; B.J. Penttila, Washington State Department of Ecology

The Washington State Law RCW 70.95G passed in 2018 prohibits the use of all per- and polyfluorinated substances (PFAS) in plant fiber-based food packaging. The function of PFAS in direct food contact packaging is to impart oil, grease, and/or water resistance to the material. The ban goes into effect two years after the identification of safer alternatives are identified. Data on PFAS-based and PFAS-free food packaging products will be collected and compared in order to inform the decision as to whether safer alternatives to PFAS food packaging are available. The alternative assessment will be based on consideration to chemical hazard, exposure, performance, cost, and availability. As there are currently 19 PFASs approved by the U.S. Food and Drug Administration for use in food contact materials (FCMs) to impart oil, grease, and/or water resistance, an exhaustive assessment of all of these substances is not practical. In order to provide adequate comparison between the candidate alternatives, a representative PFAS formulation, known as a “base case” was identified. The process of choosing the base case involved mapping the U.S. Food Contact Notifications (FCNs), reviewing published monitoring studies, and incorporating stakeholder input. Mapping the FCNs required the identification of all PFAS substances used for direct food contact plant fiber-based packaging that met the functional requirements and obtaining representative structures for these substances so that they could be categorized and compared. This led to the finding that all approved FCN’s were for PFAS polymers, with a majority of these being side-chain fluorinated compounds. The use of C6 side-chain polyfluorinated chemistries in food packaging was supported by independent research, monitoring studies of detected compounds found in FCM’s, and initial stakeholder comments. The base case for the alternatives assessment will be chosen based on its ability to meet the functional requirements, its approval for a wide range of food types and conditions, and access to existing published data available regarding substance identity, environmental fate, production, disposal, and hazard.

**RP174 Alternatives Assessment of Perovskite Compositions and their Methods of Fabrication for Photovoltaic Applications**

M. Llanos, McGill University / Department of Geography; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences

As non-renewable energy resources are becoming increasingly difficult and costly to source, the need for competitive renewables intensifies. Among these are solar cells, showing exponential growth in installed capacity over the past decade. Perovskite-based solar cells have emerged as a new category of photovoltaics, gaining traction in the scientific community due to their high power conversion efficiencies, attractive combination of physical properties, and potential for low cost manufacturing. Despite this, perovskite technology has not yet been commercialized, in part due to concerns surrounding the toxicity of lead (Pb) in the benchmark composition CH3NH3PbI3. Concerns also exist regarding the use of toxic solvents (e.g. dimethylformamide) in the popular solution-based approach to fabricating CH3NH3PbI3. This study conducts an alternatives assessment of 32 perovskite solar cells and their methods of fabrication to determine safer alternatives to the benchmark CH3NH3PbI3 on the bases of hazard, performance, and costs. This alternatives assessment is conducted using the U.S. National Research Council’s Framework to Guide Selection of Chemical Alternatives. This study includes the collection and comparison of 5 performance indicators, estimated levelized costs of energy (LCOE), and hazard data from 142 data points within 8 categories of which to date an average of 32.5% have been filled for each chemical. As the demand for solar panels increases, this research could be utilized to inform and promote the sustainable development of this technology, ultimately guiding the entrance of perovskite solar cells into the photovoltaic market.

**RP175 Effects of Two Bisphenol A Alternatives, Bisphenol AF and DD-70, on Pipping Success, Development, and mRNA Expression in Chicken Embryos**

H. Gyasi, University of Ottawa; T. Sharin, Environment and Climate Change Canada / University of Ottawa; D. Crump, J. O’Brien, Environment and Climate Change Canada / National Wildlife Research Centre

Reports of Bisphenol A (BPA) estrogenic activity has resulted in increased efforts to find suitable BPA alternatives for use in consumer and industrial products. Bisphenol AF (BPAF) and 1,7-bis-(4-Hydroxyphenylthio)-3, 5-dioxaheptane (DD-70) are two potential chemical substitutes for BPA; however, there are few studies on the ecotoxicological properties of these compounds. Here, we conducted egg injection studies to determine effects of these two compounds on avian embryonic viability, development, and hepatic mRNA expression at two distinct developmental periods (midincubation [day 11] and pipping [days 20-21]). BPAF or DD-70, dissolved in dimethyl sulfoxide, were injected into the air cell of unincubated, fertilized chicken embryos at four concentrations up to a maximum of 114 and 88.2 µg/g for BPAF and DD-70, respectively. Embryonic concentrations of BPAF and DD-70 decreased between midincubation and pipping indicating embryonic uptake and metabolism. The estimated median lethal dose (LD50), based on embryonic viability at midincubation, was 210.4 µg/g (95% confidence interval = 89.3-495.7 µg/g) for BPAF and 128.6 µg/g (95% confidence interval = 30.94-534.4 µg/g) for DD-70. DD-70 did not alter physical development whereas exposure to 114 µg/g BPAF significantly increased gabbler size. Gonad weight in males and gonadal somatic index in both sexes were decreased by both BPAF and DD-70, although these effects were not significant. Significant changes in hepatic gene expression, measured using PCR arrays, were observed at both developmental stages. Impacted genes were related to several toxicity pathways including xenobiotic metabolism, lipid and cholesterol homeostasis, thyroid hormone pathway and response to estrogen. Overall, our results show that BPAF and DD-70 caused effects on viability, development and gene expression in an avian species; however, these were observed at much greater concentrations than those currently detected in the environment. Several lines of evidence suggested estrogenic activity, which indicates a concern for chronic low dose toxicity and therefore, warrants further investigation.

**RP176 In-Silico Risk Assessment of Several Pesticide Transformation Products Generated by Exposure to an Advanced Oxidative Process**

B. Skanes, University of Guelph / School of Environmental Science; D. Brewer, A. Charchoglyan, University of Guelph / Advanced Analysis Centre; R.S. Prosser, University of Guelph / School of Environmental Sciences

Advanced oxidative processes (AOPs) are gaining popularity in produce post-harvest treatment due to their ability to extend product shelf life through reduction in biological contamination. While this is beneficial to consumers and producers alike, consideration must be given to what these treatments may be doing to pesticide residues on the surface of produce. Whereas commercial pesticide residues have been thoroughly investigated for their potential toxicity during their development and registration, in most cases very little is known about their transformation products (TPs). The current study selected several widely used pesticides (boscdil, captan, fenbuconazole, glyphosate and pyraclostrobin) and...
exposed them to an AOP utilizing ultra-violet light, ozone and hydrogen peroxide. The AOP was able to reduce the concentration of parent pesticides with boscalid and pyraclostrobin being reduced by 39% and 7% by 3% hydrogen peroxide and 75% and 100% by 40 min of ultra-violet irradiation respectively. Using targeted and untargeted mass spectroscopy techniques and the literature, structures were identified for the detected TPs. In-silico toxicity assessments of the TPs, extrapolation of the abundance of TPs relative to the maximum residue limit for the parent residue and statistics on human produce consumption enabled a preliminary risk assessment of pesticide transformation products on the surface of produce created by an AOP.

Structural Fires and Wildfires: Environmental Hazards and Firefighter Health

RP177 Revisiting the assessment of toxicity of wildland fire-fighting chemicals: A focus on short duration, high concentration exposures

During the application of fire-fighting chemicals, misapplications can occur such that chemicals are inadvertently applied to surface water. Misapplications to flowing waterbodies such as streams and rivers may result in aquatic organisms experiencing a relatively brief, pulsed exposure to an initially high concentration, especially for organisms close to the misapplication site. In general, as the retardant plume moves downstream, the peak concentration decreases and the exposure time increases as mixing and dilution continually modify the plume characteristics. Aquatic organisms downstream of a misapplication experience very different exposures depending on their proximity to the spill. Moreover, each organism experiences a continuous range of concentrations as the plume moves downstream. To capture the physics of river mixing, a new spill calculator was developed using the advection-dispersion model for use in estimating effects of misapplications of fire retardant. The model predicts distance and timing of downstream concentrations to allow for the assessment of the potential effects on threatened and endangered species and critical habitat. Maximum concentrations and durations of exposure were estimated from the model using real-world misapplication data. Traditionally, toxicity testing for species of interest typically involves a standard 96-hour exposure to a constant concentration. However, to better understand the potential toxicity of high-concentration, short exposure duration events, 30-60 day post hatch rainbow trout (Oncorhynchus mykiss) were exposed to an AOP utilizing ultra-violet light, ozone and hydrogen peroxide respectively. Using targeted and untargeted mass spectroscopy techniques and the literature, structures were identified for the detected TPs. In-silico toxicity assessments of the TPs, extrapolation of the abundance of TPs relative to the maximum residue limit for the parent residue and statistics on human produce consumption enabled a preliminary risk assessment of pesticide transformation products on the surface of produce created by an AOP.

Current Methods in Teaching at the Interface of Chemistry and Toxicology

RP178 “Toxic” Discourse: Separating Truth from Half-Truth in the Classroom
A.M. Simpson, Penn State Erie, The Behrend College / Biology

In an age where information is gleaned largely from social media, the generation of students in our classrooms faces a daunting challenge: distilling accurate information from a swarm of sources. In many situations, it is difficult to discern the validity of these sources of information, particularly when students are still working to build a foundational understanding of how the world works (i.e., natural and social sciences). Environmental activism— even with its noble intentions— can occasionally fall victim to the passion of its advocates, whereby activist groups share ideas and concerns in ways that can be misleading. To assess the ability of our students to critically interpret popular science media, a class activity will be incorporated into two separate courses at Penn State Erie during the Fall 2019 semester. One course will be composed of upper-classmen/ women and cover the principles of toxicology, while the other course will contain strictly non-science majors and cover basic human anatomy and physiology. In each course, the students will be shown a short video produced by an advocacy group depicting the dangers of “toxic chemicals” in society. Following the video, the students will work together in small groups to synthesize their takeaway messages from the content; these responses will be recorded and compared between the two courses. This comparison will provide preliminary insight into how our students interpret online content. Indeed, as scientists and educators, we are tasked with training our students to think critically and apply their education when consuming potentially misleading information. It is imperative that we prioritize the development of these skills in the classroom.

RP179 Accessing integrated chemistry and toxicity data via the USEPA CompTox Chemicals Dashboard
A.J. Williams, C. Grulke, R. Judson, A. Richard, K. Paul Friedman, J. Dunne, J. Edwards, US Environmental Protection Agency / National Center for Computational Toxicology

The USEPA National Center for Computational Toxicity (NCCT) has been generating and building software applications and web-based chemistry databases for over a decade. During this period the center has analyzed thousands of chemicals in hundreds of bioassays, has researched high-throughput physicochemical property measurements and investigated approaches for high throughput toxicokinetics. Over the past few years some of the data have been delivered through prototype web-based “dashboards” for public consumption. The latest of these web applications, the CompTox Chemicals Dashboard, is an integrated access point to obtain information associated with 875,000 chemical substances and providing experimental and predicted data of various types. This includes physicochemical and fate and transport data, bioactivity data, exposure data and integrated literature searches. Real-time predictions and generalized read-across are possible and advanced search capabilities are available to support EPA-related projects including mass spectrometry non-targeted analysis. This presentation will provide an overview of the CompTox Chemicals Dashboard and the efforts to provide a seamless experience for both chemists and toxicologists. This abstract does not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

RP180 Improving student learning in introductory STEM courses supports the interdisciplinary goals of One Health
C. Singleman, Queen’s College / Center for Teaching and Learning; J. Valad, P. Johnson, S. Avila, E. Fernandez, Queen’s College

The concept of One Health focuses on understanding the intersection between human, animal, and environmental health. The pursuit of interdisciplinary research to fulfill the goals of One Health requires strong foundational STEM education. Thus, recent declines in numbers of students pursuing STEM degrees is concerning. A common hypothesis cites the lack of underrepresented minorities in STEM fields as a factor in this decline. Through a partnership between Queens College (QC) and Queensborough Community College (QCC) we aim to increase retention of underrepresented students in STEM majors by redesigning introductory STEM courses to improve student learning and engagement. Teaching approaches differ greatly at the two institutions, not only between departments but also between campuses. This program connects teaching faculty and fosters improved communication stressing cohesive education within the disciplines. Through a Department
of Education grant, HSI-STEM Bridges Across Eastern Queens works with faculty in STEM disciplines to redesign introductory courses in biology, chemistry, environmental science, geology, math, and physics. Each campus’ redesign team has developed unique strategies for course redesign. Some redesigns used small-scale active-learning activities in class, while one course implemented a complete overhaul creating invisi-
tive lab activities reflecting challenges and troubleshooting of independent research. As each department has approached their redesign differently, we can evaluate implementation and effectiveness of course modifica-
tions using a randomized control trial model, where some sections of the course are modified and others are taught without modifications. Tracking student retention in STEM majors at both colleges is essential as up to 70% of the transfer students to QC come from QCC. Establishing better communication between colleges and departments fosters a consistent learning environment for students pursuing STEM education and careers, regardless of their transfer status. How students are educated early has a significant impact on choices they make for the remainder of their college experience and their careers. Redesigning introductory STEM courses to expose these students early to dynamic ways of thinking about scientific challenges will not only enable them to be better thinkers, but also better scientists who have the tools to approach complex problems faced in inter-
disciplinary studies.

Oil Toxicity Testing: Current Experimental and Analytical Methods, Exposure Metrics and Risk Interpretation

RP181 Flow-Through Passive Dosing and Fluorometry to Generate and Confirm Dynamic Exposures in Toxicity Tests used for Spill Effects Model Calibration
A.J. Smith, ExxonMobil Biomedical Sciences, Inc. / Environmental Sciences; C.A. Sutherland, A. Bleich, ExxonMobil Biomedical Sciences Inc. / Toxicology and Environmental Sciences; A. Redman, ExxonMobil Petroleum and Chemical / Toxicology and Environment Science Division; T. Parkerton, ExxonMobil Biomedical Sciences Inc. / Toxicology & Environmental Science

Aquatic hazard assessment of petroleum substances rely on use of water accommodated fractions (WAFs) that are intended to provide constant lab exposures over the course of the test period. However, if spilled, field exposures of these substances are typically shorted, highly dynamic and modulated by the fate properties of the hydrocarbon constituents. Consequently, adverse effects observed in lab tests cannot be extrapolated to quantify effects in the field. To improve spill impact predictions, a time-variable effects (TVE) model is needed. The objective of this work is to describe a flow-through passive dosing system than can be used to generate high fidelity dynamic dissolved hydrocarbon exposures that can be evaluated in toxicity tests. Application of this system to evaluate acute sub-lethal and lethal TVE of 2-methyl naphthalene to juvenile rainbow trout under multiple time variable exposure scenarios is described.

Integration of fluorometric analyses of test media over time provided a simple, cost-effective analytical tool to confirm dynamic exposure concentrations across tests. Collective TVE for the different exposures investigated are used to illustrate how such data can inform calibration of a TVE model that is based on the target lipid model framework which has been widely used to predict effects of hydrocarbons under constant expo-
sure regimes. Future research needs for addressing the role of different potential organismal or environmental modulating factors on time-
dependent toxicity and extending this work beyond single compounds to petroleum substances is highlighted.

RP182 Chasing and assessing oil spill toxicity accurately: A novel approach
G.A. Burton, E.C. Cervi, University of Michigan / School for Environment and Sustainability; G.H. Rosen, SPAWAR Systems Center, San Diego / Energy and Environmental Sustainability; M. Colvin, Naval Information Warfare Center, Pacific / Energy and Environmental Sustainability; B. Chadwick, Coastal Monitoring Associates / Environmental Sciences

An in situ exposure and effects tracking system was developed for assessing oil spills. This NOAA funded project is on-going and the preliminary technology is being tested in oil seeps near Santa Barbara, CA. The assessment tool combines two demonstrated systems, the SEA Ring (Sediment Ecotoxicity Assessment Ring, SERDP project ER-201130) and the Drifting Exposure (DrEx) Systems (under SERDP ER-201432). A combination of the in situ bioassay capabilities of the SEA Ring, and the tracking and sampling capabilities of the DrEx provide a robust approach that allows for real-time toxicity assessments at oil spill sites. The system is called the Drifting Exposure and Effects Assessment Ring (DEEAR) and comprised of a GPS float with iridium modem, the drifter drogue, the SEA Ring exposure system, and ancillary sensors and samplers. The DEEAR is a multi-system, pumping ambient water (and oil/dispersants if present) through organism exposure compartments, for up to two weeks. In addition, passive sampling devices, such as solid phase microextraction fibers (SPMEs) and polyethylene sampling devices (PEDs) can be placed within the exposure compartments to capture organic contami-
nants for laboratory analyses. It is equipped with a UV fluorescent sensor to identify the presence of oil compounds and verify whether or not the system is within the spill. The sensor responses are logged continuously during deployment with potential to interface to the Iridium modem and provide real-time monitoring. The system is being tested with a variety of invertebrates and early life stage fish. This technology may enhance future assessments to ascertain adverse toxicity of oils and dispersants in a more effective manner.

RP183 Oil toxicity evaluated in non-model organisms and by non-standard toxicity testing
M. Grasell, University of Miami / Marine Biology and Ecology; G.K. Cox, University of Guelph / Department of Integrative Biology; K. Schauer, R.M. Heuer, University of Miami, RSMAS / Department of Marine Biology and Ecology and C. Pasparakis, J.D. Stieglitz, University of Miami / Marine Biology and Ecology; D.A. Crossley, University of North Texas / Department of Biological Sciences; D.D. Benetti, RSMAS University of Miami / Department of Marine Ecosystems and Society

Open ocean oil spills necessitate evaluation of toxicity using pelagic organisms because they appear to be more sensitive than costal and standard model species used for toxicity testing. Understanding sublethal organ and cellular specific responses to oil exposure in these organisms will improve impact and risk assessment. It is currently unknown how ambient PAH and blood PAH concentrations are related in any aquatic organisms, making it difficult to assess exposure of individual organs and cells. Consequently, oil exposure studies on individual organs and isolated cells may be challenging to evaluate in the context of environmentally relevant PAH exposures. Circulating levels of PAHs are products of uptake and clearance from the blood stream, and the relationship between ambient and circulating levels will depend on the compound in question. In the present study, circulating PAHs in the blood of mahi-mahi (Coryphaena hippurus), a pelagic teleost fish, were quantified following a 24h exposure to dilutions of high-energy water accommodated fractions (HEWAF) of crude oil. Blood PAH concentrations were surprisingly high, and in many cases exceeded those of the exposure water. Further, PAHs in the blood were associated mainly with blood plasma proteins, rather than blood cells or plasma fluid. These results provide new perspectives on recent studies reporting effects of PAHs on isolated heart cells from mahi-mahi as well as bluefin tuna following exposures to HEWAFs in physiologi-
salines. For the first time, we are now able to relate environmental concentrations of PAHs to those affecting internal organs in marine
organisms and the results lend support to studies of isolated cell systems. This research was made possible by a grant from The Gulf of Mexico Research Initiative to the RECOVER consortium.

**RP184 Fluorescence monitoring for characterization and quantification of oil in various contaminated water samples for the study of oil fate and toxicity**

*S. Brown,* Queen’s University / Dept. of Chemistry / School of Env. Studies; *J. Adams, E. Hataley,* Queens University / School of Environmental Studies; *B.N. Madison,* Royal Military College of Canada / Department of Chemistry and Chemical Engineering; *P.F. Hodson,* School of Environmental Studies / Queen’s University Kingston Ontario; *D.M. Orihel,* Queen’s University / Department of Biology / School of Environmental Studies; *J. Mason,* C. Wheler, Queen’s University / School of Environmental Studies

Polycyclic aromatic compounds (PACs), including their alkylated forms, are among the most significant components of oil to be monitored in water following a spill. Recent reviews of oil toxicity testing have highlighted the need for monitoring concentrations of key oil contaminants in toxicity experiments. The conventional method for analysis of PACs in water is GC-MS, but results may not be available for weeks or months, and in a commercial lab may cost $300 to $700 per sample, compromising the number of samples that can be analyzed. We have developed a new fluorescence spectrophotometry method for analysis of oil-related PACs in water samples that provides rapid (hours), inexpensive (<$5 per sample) and quantitative results. It allows the routine analysis of hundreds of samples for detailed descriptions of PAC concentrations among treatments, over time, and between replicates, plus rapid feedback to adjust experimental conditions. The results can be calibrated by a small number of GC-MS analyses to provide a comprehensive analysis program for a project. Our method preserves water samples with ethanol to combine PACs in water, oil droplets, and particulates into a uniform liquid phase. This improves signal uniformity and increases fluorescence by 10-fold compared to fluorescence in water only. The simplest application is screening samples for PACs, where only samples above a threshold fluorescence signal are sent for GC-MS analysis, avoiding the waste of analytical resources on ‘non-detects’. The fluorescence spectrum can demonstrate deviations in PAC compositions between the original oil and water samples; water typically contains a higher proportion of low molecular weight PACs than oil. In cases where the water sample spectrum does not match the source oil, GC-MS results can be used to calibrate the fluorescence response to the actual PAC composition.

**RP185 Crude Oil and PAH Components Impact the Cholesterol Biosynthetic Pathway and Cardiac Development in Fish Embryos**

*V. McGruer, S.M. Vriet, S. Dasgupta, D.C. Volz, D. Schlenk,* University of California, Riverside / Environmental Sciences

In 2010, the Deepwater Horizon (DWH) oil operation released over three million barrels of crude oil into the Gulf of Mexico. The timing of the spill coincided with the spawning of many marine species in the region including mahi-mahi (Coryphaena hippurus). Previously, RNA-sequencing and subsequent mRNA analysis in oil-exposed mahi found a significant increase in the abundance of transcripts along the cholesterol biosynthetic pathway, including HMG-CoA reductase (HMGCR) and squalene synthase (FDFST) - enzymes key to cholesterol formation. Recent studies have also demonstrated a significant decrease in total cholesterol in mahi embryos treated with high energy water accommodated fractions of surface oil from DWH. Cholesterol is essential to maintaining membrane stability in eukaryotic cells, and disruption of this equilibrium may have implications for ion channel function in polycyclic aromatic hydrocarbon (PAH)-exposed cardiomyocytes. To better characterize mechanisms underlying oil-induced cholesterol declines, zebrafish embryos were exposed until 72 hours post-fertilization (hpf) to three concentrations of phenanthrene (a reference PAH), with subsequent qPCR analyses of HMGCR and FDFST as well as cholesterol-specific whole-mount immunohistochemistry. Imaging with fluorescence microscopy revealed a significant decrease in antibody-bound cholesterol (14.2% ± 0.6) in the larval body with an even greater reduction in the heart (43.6% ± 1.9). This reduction corresponded with phenanthrene-induced pericardial edema and bradycardia, as well as increased yolk size. Studies are currently underway to address whether the reduction in cholesterol observed at 72hpf is a result of the maldeveloped heart, which then impairs yolk utilization, or if changes in cholesterol may be impacting downstream development, including heart formation. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).

**Occurrence and Fate of Contaminants in the Environment: A Session in Honor of Dr. Derek Muir**

**RP186 How many chemicals in commerce have been determined in environmental media? A 40-year bibliographic analysis**

*G.J. Getzinger,* Duke University / Civil and Environmental Engineering; *M. McBride,* CAS / Science IP; *L. Ferguson,* Duke University / Civil and Environmental Engineering; *D.C. Muir,* Environment and Climate Change Canada / Aquatic Contaminants Research Division

An estimated three-hundred thousand chemical substances are inventoried and regulated globally, with thousands of new substances added to these registries each year. Despite the best efforts of environmental chemists over the past forty years, the number of chemicals detected in environmental media is poorly known, but can be estimated to be on the order of thousands while the number of routinely monitored chemicals is far smaller, hindering efforts to accurately assess chemical risk. To address the disparity between known and possible environmental contaminant chemical space, high-throughput and broad-spectrum unknown chemical screening approaches are now applied. Measuring progress in the detection of unexpected or previously unreported contaminants requires detailed and systematic analysis of previously reported contaminants, which remains lacking. Therefore, we have conducted a systematic review of contaminant occurrence reports in the scientific literature with the goal of defining and chemically classifying known environmental contaminant chemical space. We have constructed a comprehensive database of known contaminants by surveying the Chemical Abstracts Service CPlus database over the years 1978-2018 and leveraging metadata annotations to extract substances associated with analytical studies and occurrence in environmental media. The database query yielded 72,922 citations and 101,430 Chemical Abstracts Registry Numbers (CASRN). Removing duplicate CASRN gave 23,600 substances. Where possible, CASRN were parsed to discrete 2-D chemical structures and mapped to various commonly used chemical identifiers (e.g., InChI, InChI key, PubChem, DTXCID). Chemical structures or identifiers were then compared to publicly available chemical registries and inventories (e.g., REACH, TSCA, OECD, EPA IUR), chemical-class specific databases (e.g., DrugBank, Pesticide Action Network) and mass spectral libraries (e.g., NIST, MassBank). We highlight here results of on-going analysis focused on determining the link between chemical registries and databases and contaminant discovery, delineation of commonly occurring chemical use-classes and substructure motifs in known contaminant chemical space, and understanding structural determinants for detection and the impact of reporting on the subsequent detection of structurally related substances. Results will inform efforts to identify novel environmental contaminants through bottom-up analytical approaches and will highlight a useful framework for performing comprehensive retrospective analysis of scientific literature related to contaminant occurrence.
RP187 Compositional space: A guide for environmental chemists on the identification of persistent and bioaccumulative organics using mass spectrometry

X. Zhang, Ontario Ministry of the Environment, Conservation and Parks / Laboratory Services Branch; R.A. Di Lorenzo, Hospital for Sick Children; P.A. Helm, Ontario Ministry of the Environment, Conservation and Parks / Environmental Monitoring and Reporting Branch; E.J. Reiner, Ontario Ministry of the Environment, Conservation and Parks; P.H. Howard, SRC, Inc.; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J.G. Sled, Hospital for Sick Children; K. Jabot, McMaster University / Chemistry and Chemical Biology

Since 2001, twenty-eight halogenated groups of persistent organic pollutants (POPs) have been banned or restricted by the Stockholm Convention. Identifying new POPs among the hundreds of thousands of anthropogenic chemicals is a major challenge that is increasingly being met by state-of-the-art mass spectrometry (MS). The first step to identification of a contaminant molecule (M) is the determination of the type and number of its constituent elements, viz. its elemental composition, from mass-to-charge (m/z) measurements and ratios of isotopic peaks (M+1, M+2 etc.). Not every combination of elements is possible. Boundaries exist in compositional space that divides feasible and improbable compositions as well as different chemical classes. This contribution explores the compositional space boundaries of persistent and bioaccumulative organics. A set of ~305,134 compounds (PubChem) was used to visualize the compositional space occupied by F, Cl, and Br compounds, as defined by m/z and isotope ratios. Persistent and bioaccumulative organics, identified by in silico screening of 22,049 commercial chemicals and 184,600 mixed halogenated alkanes, reside in more constrained regions characterized by a higher degree of halogenation. In contrast, boundaries surrounding non-halogenated chemicals could not be defined by composition alone. The use of sophisticated computational methods will be described to bridge this gap. Finally, a script tool (R code) was developed to select potential POPs from high resolution MS data. When applied to household dust (SRM 2585), this approach resulted in the discovery of previously unknown perfluoroalkyl flame retardants, viz. the ring-closed and decarboxylated analogues of 2,3,4,5-Tetrachloro-6-(3-(tridecafluorohexyl)sulfonyloxy)phenylaminocarbonylbenzoic acid (CAS: 68815-72-5). These were likely high volume chemicals used in the production of milk-white polycarbonate plastics used in computer cases and other electronics. Their ultimate fate may well be degradation into perfluoroalkyl sulfonic acids, which are notoriously persistent and bioaccumulative.

RP189 The Leaching of Additive-derived Flame Retardants (FRs) from Plastics in Avian Digestive Fluids: The Significant Risk of Highly Lipophilic FRs

H. Guo, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences; X. Zheng, South China Agricultural University; X. Luo, B. Mai, Guangzhou Institute of Geochemistry / State Key Lab. Organic Geochem

Plastics can be incidentally ingested by birds and can serve as sources of additive-derived environmental pollutants in birds. Many indigestible matrices, such as soil and sediment, are also ingested by many bird species. The bioaccessibility of environmental pollutants in co-existed plastic debris and other indigestible matrices for birds are still unclear. This study investigated the leaching of incorporated flame retardants (FRs) from different sizes of recycled acrylonitrile-butadiene-styrene (ABS) in avian digestive fluids, and explored the impact of co-ingested sediment on the leaching of FRs in digestive fluids. High levels of polybrominated diphenyl ethers (PBDEs) 153, 183, 197, and 209, 1,2-bis(2,4,6-trimethoxy)ethane (BTBPE), and decabromodiphenyl ethane (DBDPE) were detected in recycled ABS plastics. The positive and significant correlations between the leaching proportions and log KOW of FRs in ABS suggested that the ingested plastics incorporated with FRs might be important source of highly lipophilic FRs in birds. The leaching tests with mixtures of FRs incorporated plastics and sediment revealed that hexa- to deca-BDEs, BTBPE, and DBDPE were prone to migrate from plastics to sediment in the avian digestive tract, which led to less bioaccessible fractions of FRs in gut fluids. Thus, the findings in the present study provided insights into the transfer of additive-derived FRs from plastics to birds, and indicate the significant contribution of FR-incorporated plastics to bioaccumulation of highly lipophilic FRs.

RP190 Occurrence and distribution of organophosphate flame retardants in sediment and bivalves from Korean coastal waters

W. Choi, S. Lee, H. Lee, Hanyang University; H. Moon, Hanyang University / Marine Sciences and Convergence Engineering

Organophosphate flame retardants (OPFRs) are well-known alternatives of brominated flame retardants (BFRs); e.g., PBDEs and HBCDDs) regulated by domestic and global authorities. OPFRs have been highly consumed in industrial and commercial products as flame retardants and plasticizers. In this study, 18 OPFRs were measured in sediment and bivalve samples collected from 50 locations along the Korean coasts in 2016 to investigate occurrence, distribution, and a potential for bioaccumulation of these contaminants in coastal environment. Total concentrations of OPFRs in sediment and bivalves from all sampling locations ranged 0.67 to 346 (mean: 71.0) ng/g dry weight and from 1.60 to 203 (mean: 41.2) ng/g dry weight, respectively, indicating wide ranges of contamination status depending on the sampling site. Tris(1-chloro-2-propyl)phosphate (TCP) and tris(2-butoxyethyl)phosphate (TOEPO) were predominant contaminants in sediment samples, whereas TCP and tris(2-ethylhexyl)phosphate (TEHP) were predominant in bivalve samples. Highest concentrations of OPFRs were found in sediment and bivalves collected near industrial complexes and largest harbor zones, indicating potential contamination source of these contaminants in coastal environment. Significant correlations (r=0.389-0.884, p < 0.05) were found for nine OPFRs in sediment samples. Total organic carbon (TOC) in sediment was significantly correlated with individual OPFRs.
RP191 In Situ Microbial Degradation of PBDEs in Sediments Revealed by Positive Matrix Factorization and Compound-Specific Isotope Analysis

C. Huang, Guangzhou Institute of Geochemistry / State Key Lab. Organic Geochem; Y. Zeng, Guangzhou Institute of Geochemistry; X. Luo, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, / Chinese Academy of Sciences; B. Mai, Guangzhou Institute of Geochemistry / State Key Lab. Organic Geochem

Polybrominated diphenyl ethers (PBDEs) are a class of environmental pollutants that have frequently been detected in various environmental samples. However, little is known about the fate of these compounds, and in particular, about the microbial degradation potential in situ. In the present study, positive matrix factorization (PMF) and compound-specific isotope analysis were used to investigate the in situ biodegradation of PBDEs in sediment cores collected from a pond at an e-waste recycling site in South China. The potential microorganisms relevant to the degradation of PBDEs were also assessed to aid in the understanding of in situ biodegradation. The PMF results suggested that reductive debromination took place in the sediments. The debromination signal (ratio of the concentration of factor 5 (PMF result) to the total PBDE content) was positively correlated with the relative abundance of Dehalococcoidetes at different core depths. The clear 13C enrichment of five PBDE congeners positively correlated with the relative abundance of Dehalococcoidetes at different core depths. The clear 13C enrichment of five PBDE congeners with increasing core depth indicated that a measurable change in isotope fractionation might have occurred during PBDE biodegradation. The in situ biodegradation was further validated by the widespread detection of mono-BDE congeners (BDE 2, BDE 3) and diphenyl ether in the sediments. This study provides new evidence to enhance our understanding of the in situ biodegradation of PBDEs and suggests that the extensive removal of bromine from PBDEs was mediated by indigenous microorganisms at the e-waste site.

RP192 Anthropogenic and natural polybrominated diphenyl ethers of aerosols and marine fish liver samples: Implications for long-range transport and exposure

J. Bautista, Memorial University / Chemistry; N. Babichuk, Memorial University / Environmental and Occupational Health; A. Sarkar, Memorial University / Faculty of Medicine; C. Young, York University / Department of Chemistry

The usage of polybrominated diphenyl ethers (PBDE) as fire retardants in furniture and electronics have become a health concern. These species are known to act as endocrine disruptors. Recently, natural PBDE analogues produced from phytoplankton, blue mussels, and sponges have been discovered which may contribute to a greater PBDE pool. Methoxy- and hydroxy- PBDEs found in marine environments are identifiable among other environmental PBDEs and may have more significant health impacts than anthropogenic PBDEs. Previous work has assumed the impact of natural PBDE analogues is limited to ocean environments; however, PBDEs may also be transported into the atmosphere through the formation on marine aerosols. Hence, long range transport (LRT) may also be possible through the atmosphere, leading to exposure far from the ocean. The atmospheric fate and potential health impacts of these species depends on the aerosol size on which they are found. Size-selected marine aerosols were collected with a nano-Micro Orifice Uniform Deposition Impactor (nano-MOUDI) setup from a rooftop atmospheric site in St. John’s, Newfoundland (NL). Aerosols ranging from 10 nm to 10 um in diameter were sampled over a year to capture seasonal impacts. PBDEs can also undergo LRT through the oceanic migration of marine fish via the bioaccumulation within their livers. Known economic fishery staples of cod fish and Greenland halibut occupy different food webs and niches that may describe how PBDEs are distributed. Fish liver samples (2014) were taken around NL island from the Gulf of St. Lawrence and the open Atlantic Ocean. Samples were solvent extracted and analyzed using gas chromatography coupled to mass spectrometry (GC-MS). Temporal trends will be discussed in this session, as well as implications of aerosol concentrations and fish consumption to human exposure and long-range transport for both anthropogenic and natural PBDEs.

RP193 Understanding the photolysis of oxybenzone: Rates and degradation products

S. Landeweert, K. Meerbott, Florida International University / Chemistry and Biochemistry; N. Quinet, Florida International University (FIU) / Southeast Environmental Research Center SERC; P.R. Gardinali, Florida International University / Chemistry & Biochemistry and SERC

Recently, much controversy has arisen over the use of sunscreens containing the active ingredient oxybenzone due to its reported potential adverse effects on coral. However, since most of the research on this compound has focused on its toxicological effects, comparatively little is known about its behavior and ultimate fate in the environment. Nevertheless, it is important to understand how and into what oxybenzone degrades in order to both better understand its persistence and prevalence in the environment. One of the major degradation pathways for organic compounds in surface waters is photodegradation. In this study the direct photolysis of oxybenzone was measured using a Suntest XXL® weathering chamber, which mimics sunlight, allowing for the study of oxybenzone’s behavior under more realistic environmental conditions than a typical UV reactor. In order to test for both direct photolysis and degradation mediated by other aquatic species, the test was carried out in deionized (DI) water, a sodium chloride salt solution, a nitrate salt solution, water with added dissolved organic matter, and seawater taken from Biscayne Bay. Samples were taken over a period of a week and analyzed using liquid chromatography-orbitrap mass spectrometry. Both the degradation of the parent compound and the formation of degradation products were monitored. After one week in the Suntest, oxybenzone in DI water did not show any significant degradation compared to a dark control, leading to the conclusion that direct photolysis is not an important mechanism for degradation of oxybenzone in the environment, and that its decay is most likely mediated by other reactive species in the water column.

RP194 A stratified multi-year European-wide voluntary product stewardship monitoring project to determine D4 and D5 in influents

D. McNett, The Dow Chemical Company / Toxicology Environmental Research and Consulting; J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting; T. Boehmer, Evonik Nutrition & Care GmbH; R. Gerhards, Gerhard Consulting; R. Mait, Bramlee Consulting, LLC; T. Guerrero, ACC/SEHSC; E. Frauman, European Chemical Industry Council - Cefic aisbl; T. Barber, S. Claes, J. Dierckx, ERM

In January 2018, the European Union issued a REACH restriction on the use of octamethylcyclotetrasiloxane (D4) and decamethylcyclopenta- siloxane (D5) in wash-off personal care products (PCPs), with a 2-year phase-out period. The goal of the restriction is to reduce the amount of D4 and D5 released into the aquatic environment. The Silicone Industry in coordination with government agencies initiated a monitoring program to assess the amount of D4 and D5 being released to residential wastewater treatment plants (WWTPs). The field sampling and analytical methods used in this project are based upon protocols developed for the EPA Enforceable Consent Agreement (ECA) Siloxane Monitoring project on D4 (2014). After conducting a method validation process, an analytical procedure was established, which achieves sub-ppb detection levels. A quality control scheme ensures that sources of contamination or analyte losses are identified and minimized. Six WWTPs were selected across Europe, representing different use-patterns of PCPs. Three time
Polycyclic aromatic hydrocarbons (PAHs) are a group of toxic compounds in the environment. PACs sources in the environment include biogenic, petrogenic and pyrogenic and are generally a mixture of multiple sources mixed in environmental monitoring matrices. Most monitoring programs only analyze the PACs include the 16 EPA parent PACs. When including all other unsubstituted and substituted PACs, there are thousands of potential congeners which could be measured to assess both toxicity and source allocation. In this study, 59 river sediment samples obtained from across southern Alberta, Canada were analyzed by gas chromatography-tandem mass spectrometer (GC-MS/MS) and two-dimensional high-resolution time of flight mass spectrometry (GCxGCxHRToFMS) for comprehensive PAC chemical fingerprinting. Chemical fingerprinting helps distinguish between different sources of PAH in the environment. Data collected by these two techniques were statistically analyzed to determine the chemical patterns (fingerprints) of the predominant sources in the river systems. In addition to the conventional use of native PACs for source identification, patterns of individual alkyl PACs identified using the GCxGCxHRToFMS were also investigated to determine if additional source designation could be determined. Recent research has shown that these individual alkyl PACs can be more toxic than their unsubstituted analogs. Therefore, this information can aid in the evaluation of potential risk and used in risk assessment. Preliminary evaluation of data shows dominant petrogenic sources from coal type sources. In addition, we identified high creosote like signatures in samples collected from urban areas.

RP196 Chemical fingerprinting of polycyclic aromatic compound sources in sediments using gas chromatography high resolution time of flight mass spectrometer
LG. Idowu, G.T. Tomy, The University of Manitoba / Department of Chemistry; C. Sandau, P. Richards, Chemistry Matters; J. Stetefeld, University of Manitoba / Chemistry
Polycyclic aromatic compounds (PACs) are ubiquitous contaminants in the environment and many of them have been identified as carcinogens. The associated toxicity of PACs makes monitoring and identification of sources of PACs in the environment important for assessing exposure to humans and wildlife. PACs sources in the environment include biogenic, petrogenic and pyrogenic and are generally a mixture of multiple sources...
RP198 Halogenated Phenolic Compounds in Wild Fish from Canadian Areas of Concern

E.A. Gilroy, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; L.M. Campbell, Saint Mary’s University / Department of Environmental Science; S.B. Brown, J.P. Sherry, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Concentrations of halogenated phenolic compounds were measured in the plasma of brown bullhead (Amietius nebulosus) from four Canadian Areas of Concern along the Detroit River-St. Lawrence River corridor, to assess exposure to suspected thyroid-disrupting chemicals. Hydroxylated PCBs (OH-PCBs) were detected in every sample collected in three of the AOCs; the detection frequency was lower in samples from the Detroit River AOC. The OH-PCBs most frequently detected were pentachloro, hexachloro, and heptachloro congeners, which are structurally similar to thyroid hormones. Pentachlorophenol (PCP) was detected at highest concentrations (1.8ng/g) in the plasma of fish from Prince Edward Bay, the Bay of Quinte Lake reference site, and Hillman Marsh (the Wheatley Harbour reference site), suggesting local sources of contamination. Elevated PCP concentrations were also detected in the plasma of brown bullhead from exposed sites in the Toronto and Region AOC (0.4-0.6ng/g). Triclosan was regularly detected in the Toronto and Region AOC (0.05-0.9 ng/g), consistent with wastewater emission. Greater concentrations were occasionally detected in the plasma of brown bullhead from the Bay of Quinte AOC. Concentrations of PBDEs were highest in the Toronto and Region AOC, and at two of the Bay of Quinte AOC exposed sites near Trenton and Belleville. Distribution patterns reflected the properties and usage of the compounds under investigation and the characteristics of each AOC.

RP199 Optimization and Validation of LC-MS Method for the Separation and Quantitation of Mixture of Seven Active Pharmaceutical Compounds

O.S. Olattunjii, University of KwaZulu-Natal, Westville / School of Chemistry and Physics; E.O. Omotola, University of KwaZulu-Natal / School of Chemistry and Physics

Electrospray ionization liquid chromatography-mass spectrometry method was optimized and validated for separation of lamivudine(LVD), acetaminophen(ACM), vancomycin(VAN), ciprofloxacin(CPX), sulphotahemoxazole(SPZ), diclofenac(DCF), and ivermectin(IVT) all belonging to different therapeutic group. Mobile phase composition and ratio, mobile phase pH, flow rate, injection volume, and column oven temperature were optimized and tested. Optimum separation was achieved on a RP C18 column, (2.1x100 mm, 3 um), in a gradient stream mobile phases consisting of 0.1 % formic acid in Millipore water(A) and acetonitrile(B). The gradient program started with 5% B to 80% B in 12 min; then reducing to 50% in 14 min, followed by an increase to 65 % in 17 min, and finally down to 5 % in 19 mins. The optimum conditions for effective separation of the seven compounds were; 0.4 mL/min flow rate, 38øC column oven temperature and an injection volume of 1 µL. The MS analyses were performed in the positive electrospray ionization mode ESI (+) for all pharmaceuticals. Resolutions within the peaks were: 4.28, 1.26, 2.47, 3.31, 10.21, and 11.19 for LVD, ACM, VAN, CPX, SPZ, DCF and IVT respectively. Excellent linearity was observed for all of the standard calibration curves within a linear range of 0.01-1.00 ng/ µL and the correlation coefficients were above 0.99 (n=5). The sensitivity achieved for the method allowed for LODs(ng/ µL) ranging from 0.01(LVD) to 0.05(CPX) and their respective LOQs; 0.04 to 0.15. Intra and inter day analyses were used to define the method/instrument precision, which in all cases were ≤ 10 % (RSD, n=5).

RP200 Mercury and persistent organic contaminant trends in predatory fish and sediments in Great Slave Lake; climate and other drivers

M. Evans, Environment and Climate Change Canada / Water, Science and Technology Directorate; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Keating, Environment and Climate Change Canada / Water and Science Technology Directorate; X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J.P. Smol, K.M. Rühland, Queen's University / Department of Biology

Great Slave Lake (GSL) is a core biomonitoring site under the Northern Contaminant Program, providing important information on concentrations and trends of mercury and persistent organic contaminants (POCs) in lake trout and burbot in a large subarctic Canadian lake. Both species are important in local subsistence fisheries and lake trout in the commercial and sport fisheries. Fish were caught from the West Basin (WB), which is a relatively productive due to the Slave River influence, and the East Arm (EA), which is less productive because of its deeper, low conductivity waters. Legacy POCs concentrations declined over 1993-2017, particularly HCH and DDT and as anticipated with reduced global usage. POCs declined at a more rapid rate in WB than EA fish where trends of decline were not statistically significant for many POCs. The higher rate of decline in the WB than EA fish may be related to the higher concentration of particulates in the former, which rapidly transported POCs to the lake floor reducing contaminant loss through the GSL outflow into the headwaters of the Mackenzie River. Similarly, POCs concentrations tended to be lower in WB fish than EA fish. In contrast, mercury concentrations were slightly higher in WB than EA fish, possibly because of mercury inputs from the Slave River and/or greater mercury methylation rates in the warmer waters of the WB. Mercury showed a general trend of increase, which was related to climate trends, primarily temperature, and increasing lake productivity, as evidenced from sediment core studies. Warming trends may also be impacting trends in POCs as compounds stored in the watershed, both in the immediate vicinity of Great Slave Lake and upstream in the developed regions of Saskatchewan, Alberta, and British Columbia and elsewhere, are mobilized and transported north through river and atmospheric pathways. While increasing productivity may reduce POC and mercury concentrations through growth biodilution, a richer forage-fish food base and enhanced mercury methylation rates may counteract this. Fish condition factor and stable isotope data are used to explore trends in fish growth and trophic feeding.

Fate and Effects of Metals: Biogeochemical Perspective

RP201 Developing and Testing RNA-Cleaving DNAzymes for Bioavailable Metal (Pb2+) Sensing

G. Gill, S.D. Smith, Wilfrid Laurier University / Department of Chemistry and Biochemistry

The on-site and real-time detection of metal ions is important for environmental monitoring and risk assessment. For appropriate management decisions, it is necessary to specifically sense the bioavailable fraction of metal rather than total metal. DNA-based sensors (so called DNAzymes) are a promising new technology for possible bioavailable metal monitoring that have not yet been fully tested in real waters. In clean, buffered, laboratory waters specific DNAzymes interact with specific metal ions and produce signal (e.g., fluorescence) that can be used to determine total metal concentration. In more complex, natural, solutions it is likely that the free ion concentration is reduced by complexation (e.g., to dissolved organic matter, DOM) and the signal would not be proportional to total metal, but possibly proportional to the bioavailable fraction of total metal; i.e., the fraction of metal available to interact with the DNA. Our research utilizes an existing metal specific RNA-cleaving DNAzyme for Pb2+ (GR5) in test waters representative of natural solutions. In GR5 lead
acts as a specific co-factor in DNA catalyzing the cleavage of RNA-containing fluorogenic substrate. In these samples we systematically vary pH, calcium and DOM concentrations and assess changes in DNAzyme generated fluorescence signal compared to calculated lead speciation. Also, to directly compare to bioavailable lead, our new DNAzyme-based approach is applied to exposure solutions from Daphnia magna toxicity tests. Our testable hypothesis is that DNAzyme fluorescence responds to bioavailability if the dose-response curves for survival (y-axis) at various conditions collapse to one curve when the exposure (x-axis) is represented as the lead-specific DNA response, rather than total lead. After this assessment of DNAzyme responses in natural waters, it will be possible to start to develop tools for real-time, on-site detection of bioavailable metals. Funded by Global Water Futures.

RP202 Heavy Metals and Trace Metals Profile of Infertile Women and Women with History of Miscarriage in A Nigerian Population
C. Ikaraoha, Imo State University Owerri / Chemical Pathology Unit / Dept. of Medical Laboratory Science; C. Unadike. Imo State University Owerri / Department of Medical Laboratory Science; f.E. Nwaneri, Imo State University / Medical Laboratory Science; U. Edward, Imo State University Owerri / Department of Medical Laboratory Science

Extensive heavy metals exposure remains in developing economies such as Nigeria, where current environmental and industrial policies/regulations are not resolutely enforced. Regardless of signals that environmental heavy metals exposure may play important role in the pathogenesis of infertility and miscarriage in humans, it has been adequately investigated in human population from a developing economy like Nigeria. The aim of this study is to determine the role of blood Lead, Arsenic, Cadmium, Chromium and Mercury in development of infertility and miscarriage in Nigerian women. Blood Mercury, Arsenic, lead, Chromium and cadmium levels were determined by Atomic Absorption Spectrophotometry (AAS) in Twenty (20) infertile women and 20 women with history of miscarriage attending Gynaecological Clinic at IMSUTH Orlu, Imo State, Nigeria, who were age-matched with 20 female controls after obtaining their Informed Consent. Data obtained were subjected to Statistical Analysis using SPSS version 21. There were significant increases in blood Cd, Pb, As, Hg and Cr (p=0.000, p<0.000, p=0.034, p=0.000 and p=0.000 respectively), but no significant different in Al (p=0.163) in infertile women compared to controls. Blood Cd, Pb, As, Hg and Cr were significantly higher (p=0.000, p=0.000, p=0.031, p=0.018 and p=0.001 respectively) in miscarriage versus control. There was no significant difference in blood Al (p=0.163) in miscarriage compared to controls. The blood levels of Cd, Pb, As, and Hg were significantly higher (p=0.01, p=0.012, p=0.040 and p=0.010 respectively), in infertility compared to miscarriage. There were no significant differences in the blood chromium and aluminium (p=0.118, and p=0.163) in infertility compared to miscarriage. The blood levels of Zn, Cu, Se, Mn and Co were significantly lower (p=0.000, p=0.038, p=0.000, p=0.0003 and p=0.000 respectively) in infertile women compared to control. Blood Pb was significantly correlated with Cd and Al (r=0.493, p=0.027 and r=-0.590, p=0.006 respectively) in women with history of miscarriage. There were significant correlation of As with Hg, Cr and Al (r=0.648, p=0.002 and r=-0.454, p=0.044 respectively) in infertile women. Blood Zn was significantly correlated with Pb (r=0.675, p=0.001) in infertile women. Correlation of Se with Al was significant (r=-0.455, p=0.044) in infertile women. Cu was significantly correlated with As (r=-0.550, p=0.012) in infertile women. There was significant correlation of Cu with As and Cr (r=-0.523, p=0.018 and r=-0.528, p=0.017 respectively) in women with history of miscarriage. It appears that increases in blood heavy metals parallels decreases in trace metals in both female infertility and miscarriage, thus may be implicated in incidence of both disorders.

Toronto Flood Protection and River Building Project

RP203 Toxicological Assessment of Aquatic Receptors in Surface Water and Porewater
B. Wilson, Jacobs; J. Sprenger, Jacobs Engineering Group; M. Janes, Waterfront Toronto / Projects

Plans are underway to flood protect and revitalize underutilized brownfield lands in the Toronto Port Lands through re-naturalizing the mouth of the Don River and extending the river south and west; however, due to the former industrial use of the Port Lands, the planned river route and related redevelopment infrastructure traverse through a heavily contaminated area containing non-aqueous phase liquid, as well as other contaminants. As a result, an evaluation of potential risks to aquatic receptors from migration of groundwater-to-surface water and ground-water-to-porewater pathways was completed. The contaminant drivers identified for the evaluation were petroleum hydrocarbons (PHC) F1 and F2. Measured and predicted groundwater concentrations were compared to conservative ecological benchmark concentrations to identify risk to aquatic receptors. Based on the comparison, significant risk management measures, remedial activities, or both would be required to manage theoretical risks associated with groundwater contamination through these pathways. Therefore, the evaluation of these exposure pathways was refined through a bioassay study to provide additional lines of evidence to support the selection of an appropriate site-specific benchmark that would be protective of aquatic receptors following future predicted fate and transport. The toxicity testing involved collecting and testing groundwater from wells that exhibit worst-case PHC groundwater concentrations within 30 metres of the planned river route. These existing groundwater concentrations acted as surrogates for future surface water and porewater concentrations in the extended Don River. Based on the toxicity test results, site-specific groundwater ecological benchmarks for PHC F1 and PHC F2 were derived to be protective of the groundwater-to-surface water and groundwater-to-porewater exposure pathways. The benchmarks were initially identified as a range of target values based on the site-specific PHC mixture in groundwater. The range was proposed instead of a single bench-mark concentration, in order to account for uncertainties associated with the test procedures (for example, volatile groundwater concentrations, and consistency in groundwater sample handling during the bioassay). The benchmark ranges were then carried forward for further refinement through groundwater modeling and the design process. The final range recommended for PHC F1 was >143 to 1,400 μg/L and for PHC F2 was >335 to 802 μg/L.

Broadening the Scope of Chemical Assessments Using Toxicokinetic Data

RP204 Bioaccumulation of hydrophobic linear siloxane compounds in rainbow trout (Oncorhynchus mykiss)
M. Cantu, F. Gobas, Simon Fraser University / Resource & Environmental Management

Given the wide use of hydrophobic siloxane compounds, more care is being taken by legislators around to globe to regulate any potential bioaccumulative and toxic substances in the environment. Likewise, the abundance of the global production of siloxanes demonstrates the importance of these bioaccumulation studies and how best to aid in the addition of the knowledge of how these compounds interact in the environment. Also, with the current guidelines set by government bodies, only one chemical is tested at a time. The present proposal aims to help prove the importance of chemical mixture studies in the hopes of showing the complex nature of a cocktail of chemicals within the environment and any given organism that comes in to contact with said chemicals. The main objective of this study has been to determine in vivo and in vitro biotransformation rates of various siloxanes in rainbow trout fish. Alongside these, concentration-dependent biotransformation will be assessed by
reviewing the depuration rate constant over time at varying concentrations to determine if $K_1$ is dependent on the concentration of siloxanes within the organism. Preliminary results have shown varying results between the cyclic and linear siloxanes. Specific plans for these studies are as follows: (1) run individual siloxane exposures to juvenile rainbow trout fish (D4, D5, D6, L3, L4, L5) at a concentration of 4.5 mM siloxane/g food for and update duration lasting 21 days. Since the depuration rates for the cyclical siloxanes are very slow, and through previous work done in our lab, this high concentration should suffice to represent a depuration rate value, this will also save time and cost for the project. Also, the depuration phase will be extended out further than that of the linear siloxanes. (2) After analysis of linear samples have been completed, subsequent studies will be run at lower and varying concentration to determine if depuration rates are concentration-dependent. (3) The final in vivo experiment will be run as a mixture of all 6 siloxane compounds at various concentrations to determine if the presence of multiple compounds will alter the depuration rate of other compounds.

**RP205 Assessment of in vitro intrinsic clearance and the prediction of bioaccumulation for plant protection products**

A. J. Jones, FMC Agricultural Solutions / Environmental Sciences; B. Kern, D. Nabb, FMC Agricultural Solutions

The potential use of in vitro methodologies to predict the bioaccumulation of chemicals in fish is of particular interest to the scientific community. Recent mandates in the European Union and other geographies to reduce the number of vertebrate organisms used in regulatory testing have spurred the investigation and development of in vitro methods to predict fish bioaccumulation (e.g., OECD Guideline 319A, Determination of in vitro intrinsic clearance using cryopreserved rainbow trout hepatocytes). However, at present, there is still a lack of data regarding the ability of the methodology to predict bioaccumulation in whole fish. We investigated numerous plant protection products across multiple classes of chemistry and modes of action to determine if the in vitro - in vivo extrapolation is possible. Results indicate that the in vitro intrinsic clearance method based entirely on liver metabolism tends to over-predict fish bioaccumulation. However, this result was not unexpected since there are multiple pathways in which a fish could metabolize an exogenous compound. Overall, the in vitro intrinsic clearance method using rainbow trout hepatocytes does present a promising alternative method to the in vivo fish bioaccumulation study for the eight plant protection products assessed. A better understanding of the other sites of metabolism need to be better investigated and understood to better predict bioaccumulation in fish.

**RP206 CBD = Cannabinoid Biotransformation Discoveries: Towards an understanding of cannabinoids (CBD) biotransformation in fish using in vitro technologies**

Biotransformation of chemicals using in vitro technologies is increasing and essential to chemical risk assessment. In vitro technologies such as those described in the OECD TG 319A and 319B using trout liver subcellular fractions and cells can be applied to test metabolism, determine a Bioconcentration Factor (BCF) and identify metabolites of the different cannabinoids. Acceptance and legalization of industrial hemp, cannabinoids (CBD and THC) and marijuana is rapidly growing in North American countries and around the world. In many instances, new regulations will be considered and implemented after the fact. Likewise, in vitro technologies to test chemicals for risk assessment is increasing and widely accepted due to the reduction in the use of number of animals, cost and time of experimentation. While CBD has brought to light benefits in treating human ailments, there is notable lack of discussion around the environmental impact that these compounds will bring on the environment and freshwater supplies in many areas worldwide including North America. There is a need for more research to fill the information gaps that haven’t been covered due to the previous illegal status of these compounds. Freshwater treatments updates will need to be in place in order to keep up with the cannabinoids and metabolism products. However, before these can be implemented, the objectives of our initial studies are to understand basic cannabinoids metabolism, in particular CBD. Using the fish liver S9 and hepatocyte in vitrometabolism technology in different species of fish including trout will help better understand potential impact in aquatic environments. The main objectives of this project are to expose trout liver S9 factions and cryopreserved hepatocytes with CBD and determine if there is: a- metabolism and the extent of it (metabolic rate) in trout and b- differential metabolism of the different cannabinoids. Hatchery raised rainbow trout were maintained at 13°C. Fish were acclimated to laboratory conditions (1 month), euthanized and livers were perfused with a saline buffer (HBSS) at pH 7.8. After each perfusion, liver S9 factions and cryopreserved hepatocytes were prepared following protocols established for rainbow trout. CBD was then exposed to the biological material and incubations performed at different times and conditions according to the OECD TG 319A and 319B. Cannabinoid analyses is ongoing and conducted using chromatographic methodologies.

**RP207 Biotransformation of chemicals in different species using in vitro metabolism approaches**

K. M. Johanning, KJ Scientific; C. Kropf, H. Segner, University of Bern / Centre for Fish and Wildlife Health; Q. Fontenot, Nicholls State University / Biological Sciences Department; J. Nevarez, Louisiana State University / School of Veterinary Medicine; K. Berg, University of California, Davis; A. Long, G. Garcia, KJ Scientific; A. Ferrara, Nicholls State University / Biological Sciences

Biotransformation of chemicals in different species is relevant in bioaccumulation assessment and is an area that requires research. Recently, OECD Test Guidelines (TGs) 319A and 319B were approved for in vitrometabolism assessment of chemicals using rainbow trout liver S9 and cryopreserved hepatocytes for chemical risk assessment. Although these TGs were developed using rainbow trout, the methodology can be adapted and used across species. Aquatic and terrestrial organisms display a wide range of feeding modes, reproductive strategies and live in variety of environments. For the present study we used liver S9 sub-cellular fractions from a variety of organisms including aquatic (rainbow and brown trout, Siberian sturgeon, bowfin, carp, alligator gar and American alligator) and terrestrial (rat, mouse, monkey and human). We compared fish species that inhabit different environments such as the alligator gar that resides in high temperature waters (> 30°C) with low DO, and a wide range of salinities to rainbow trout, the reference fish for in vivom and in vitrometabolism and bioaccumulation studies. Trout, sturgeon, gar and alligator were maintained for 2 to 4 weeks under corresponding natural temperature and photoperiod regimes prior to euthanasia and liver S9 preparation. Bowfin were obtained from the field and rat, mouse, monkey and human liver S9 sub-cellular fractions were acquired from commercial sources. Fish were euthanized and livers perfused with a buffered clearing solution (pH = 7.8), excised, homogenized, and centrifuged to obtain liver S9 according to the OECD TG 319B. Liver S9 fractions of the different fishes were used in metabolism studies with a pharmaceutical (diclofenac), pyrene (PAH), a pesticide and to determine conventional enzyme activities (EROD, GST). Alligator gar and bowfin EROD and GST activities were similar to rainbow trout and exhibited significant metabolism of pharmaceuticals such as diclofenac. Alligator (reptile) did not metabolize pyrene as expected. The highest pyrene metabolic activity was observed in human and mouse S9. Ancient fishes such as alligator gar and bowfin diverged from the teleost evolutionary line prior to the teleost genome duplication (TGD), thus these ancient fishes may possess unique adaptations to cope with xenobiotics. This is an ongoing study and other species of regulatory importance such as the bluegill, carp and largemouth bass will be included.
Environmental Risk Assessment of Pharmaceuticals: Connecting Across Disciplines

RP211 Occurrence of fluoroquinolones drugs residues in river water by liquid chromatography

L.K. Silva, Federal Institute of Maranhao / Department of Chemistry; G.S. da Silva, Federal Institute of Maranhao; N.M. Brito, Federal Institute of Maranhao / DAQ; A.P. Ferreira, Instituto Federal do Maranhão / DAQ; R.L. Jesus, Federal Institute of Maranhao / DAQ; M.S. DINIZ, Federal Institute of Maranhao

Antimicrobials are an important class of pharmaceuticals that have been found in natural water and fluoroquinolones (FQs) are an example of this group. FQs antibiotics are widely used in the treatment of infectious diseases, to improve livestock growth and in the aquaculture. They can reach the environment through untreated wastewater, animal excreta, disposal of unused drugs or by the direct discharge of aquaculture products. Even in trace quantities, they are able to impact the aquatic systems because they are toxic and may result in bacterial resistance. In view of this problem, the purpose of this study is to investigate the occurrence of FQs residues such as levofloxacin (LEV), ciprofloxacin (CIP) and norfloxacin (NOR) in Anil River, located in Sao Luis, Maranhao, Brazil. The research was developed at Federal Institute of Maranhao, using samples of surface water collected on May and December 2017 from river in different days and in two sites (A and B), according to National Water Agency (ANA) recommendations, stored in amber glass bottles and refrigerated at 2°C for 24h. Before being analyzed, the pH were adjusted to 3 with H3PO4, afterward the samples were filtered and prepared by solid-phase extraction process with HLB® Oasis cartridges. The obtained extract was evaporated to dryness using nitrogen and then reconstituted in mobile phase used on chromatographic process. The analyses were performed on a Shimadzu LC20-AT high performance liquid chromatograph equipped with a Shimadzu RF-20A fluorescence detector, using a Luna C18 column (250mm x 4.6mm; 5μm), flow rate 1.2mL/min, temperature column at 35°C, excitation wavelength of 280nm and emission wavelength of 450nm, mobile phase was methanol and buffer (0.04M NaHPO4, pH 3) in gradient mode. All samples revealed contamination by at least one of FQs in a range of concentrations 15.8-100.6 μg.L-1 (LEV), 11.4-112.7 μg.L-1 (CIP) and 10.3-67.7 μg.L-1 (NOR). LEV was not found on site A, NOR was detected in all samples and CIP was present in May on both places and only on place A in December. The presence of LEV, CIP and NOR antibiotics confirms the contamination on Anil River by domestic sewage, because these drugs are widely used in several types of human infections. The result demonstrates the importance of effective actions against contamination on rivers by domestic sewage, since they could have compounds such as FQs, that may cause a strong negative impact to aquatic organisms.
RP212 Occurrence of antibiotics and related resistance genes in the feed and in the digestate of biogas plants

Manure is commonly used to feed biogas plants in the aim of the energetic valorisation of organic waste. Despite the several advantages offered by this practice, a new environmental concern could emerge. In fact, antibiotics are frequently used in livestock farming and a notable fraction of these chemicals is mostly excreted in unchanged and/or as active metabolites in animal waste. The residual antibiotics that persist after the biogas production can act as environmental contaminants when the digestate is used as soil fertilizers: they can have biocidal effects on susceptible natural microbial populations and/or promote the resistance gene spread. The AZeR0 Project (AOA) is a three-year joint collaboration between the Water Research Institute of the National Research Council (CNR-IRSA, Italy) and the lab of Biomass and Biotechnologies for Energy of the National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA, Italy). Its main objectives are: 1) to assess the occurrence of some of the mostly used veterinary antibiotics (e.g. sulfamethoxazole-SMX and ciprofloxacin-CIP) in cattle manure and digestate; 2) to study the kinetics of antibiotic biodegradation during the anaerobic digestion process; 3) to evaluate the antibiotics degradation in aerobic conditions, once the digestate is spread on soil. Feed and digestate samples were collected from various livestock farms equipped with biogas plants in the Lazio Region (Italy). They were analysed in order to verify the occurrence of residual SMX and CIP concentrations by liquid chromatography couples with MS-MS detection, to evaluate the structure and composition of the natural microbial community and to detect the presence of resistance genes (e.g. sul1, sul2, sul3, intI1) by qPCR. The preliminary results showed that SMX and CIP occurred both in cattle manure and digestate. CIP was found at higher concentrations (1 - 7 mg/kg soil) than SMX (0.04-0.25 mg/kg soil) confirming its higher environmental persistence. Resistance genes sul1, sul2 and the proxy intI1 were detected both in cattle manure and digestate. A significant correlation between sul1 and intI1 presence was found.

RP213 Updates to the proposed Canadian framework for the environmental risk assessment of active ingredients in drugs and addition of cumulative trigger

J. Chateauvert, Health Canada / Environmental Impact Initiative; J. Maeck, C. Hughes, Health Canada

Currently, manufacturers and importers of active ingredients in drugs must notify under the New Substances Notification Regulations: Chemicals and Polymers or the New Substances Notification Regulations: Organisms (collectively the NSNRs) under the Canadian Environmental Protection Act, 1999 in order for the Government of Canada to conduct an environmental risk assessment. However, there are concerns and gaps within the current NSNR system for active ingredients in drugs which Health Canada wishes to address. As a result, a new proposed Canadian regulatory framework is being developed specifically for active ingredients in human and veterinary drugs regulated by the Food and Drugs Act to assess risks to the environment and to human health resulting from environmental exposure. Under this proposal, active ingredients in drugs would be subject to notification and assessment at three different stages (i.e. import/manufacture, investigational uses - for organisms only - and at market authorization). Health Canada has recently updated the proposal based on valuable feedback received from industry stakeholders via a Cost-benefit Analysis Survey that was distributed in 2018. The changes focus on further streamlining the proposal with a view to decreasing potential costs to both industry and government and to address concerns and gaps identified by industry. This presentation will describe these changes, with an emphasis on how the changes to the notification requirements at the import/manufacture stage will enable Health Canada to conduct cumulative assessments on active ingredients in drugs across the industry. The purpose will be to obtain feedback from international counterparts, industry stakeholders and meeting attendees, on the most current modifications to Health Canada’s regulatory proposal for environmental risk assessment of active ingredients in drugs.

RP214 Quorum sensing inhibitors attenuate the antibiotic-induced bacterial resistance mutation

D. Wang, J. You, Jinan University / School of Environment

The indiscriminate use of antibiotics has exacerbated the emergence and spread of antibiotic resistance genes (ARGs), which is seriously threatening global public health. Quorum sensing inhibitors (QSIs) are attractive alternatives to antibiotics due to their inhibitory properties on bacterial pathogenicity and the advantage of not developing resistance. While QSIs have broad prospects of application, their potentials in affecting the emergence of ARGs in bacteria were hardly studied. In this work, we investigated two representatives of QSIs, i.e., cinnamaldehyde (CIN) and 4-nitropyridine-N-oxide (NPNO), for their effects on the antibiotic-induced mutation of E. coli against rifampicin. The antibacterial activities of the two QSIs and tetracycline (TET) and chloramphenicol (CHL) were examined by bacterial growth inhibition tests using 96-well plates, then the mutation rates of E. coli exposed to QSIs, antibiotics, and their combinations were determined at sub-inhibitory concentrations using Luria-Delbruck protocol (p0 method). It was found that the antibiotics at sub-inhibitory concentrations stimulated the resistance mutation of E. coli, with mutation rates significantly higher than those of the spontaneous mutations. On the contrary, QSIs alone induced a slight decrease in the mutation rates of E. coli. With respect to the combined exposures, QSIs exhibited remarkable antagonistic effects on the antibiotic-induced mutations, with mutation rates reduced by 75% in some cases. Our research revealed the capacity of QSIs to attenuate the antibiotic-induced resistance mutation of bacteria, which is likely a common property for QSIs. Since resistance mutation is a major approach for the emergence of ARGs, the replacement of antibiotics with QSIs may provide an opportunity to prevent the emergence and spread of ARGs.

RP215 Nonsteroidal Anti-inflammatory Drugs Manufacturing Industry Effluent Induced Malformations on Xenopus laevis

I. Pérez-Alvarez, National Autonomous University of Mexico / Environmental Toxicology; H. Islas-Flores, Facultad de Química, Autonomous University of Mexico State / Toxicología Ambiental; J.F. González-Moreno, Universidad Autónoma del Estado de Mexico / Toxicología Ambiental; L.M. Gómez-Olíván, National Autonomous University of Mexico / Farmacia

Over the past decade the presence of pharmaceuticals has been detected in bodies of water, on concentrations of ng/L-mg/L. Industrial effluents are one of the main sources of emerging pollutants such as pharmaceuticals to waste water treatment plants as well as bodies of water, the group of NSAIDs is one of the most widely consumed worldwide and therefore its production is high as well as the elimination of waste that comes from its manufacture; usually waste water treatment plants installed in industries are not able to remove all the residues that results of the production of pharmaceuticals so these elimination products can reach water bodies and get in contact with aquatic organisms, inducing adverse effects such as oxidative stress, genotoxicity, cytotoxicity to name some. The main objective was to demonstrate the toxic potential of a NSAID manufacturing industry effluent. FETAX assay was carried out, for which 20 Xenopus laevis frog oocytes were exposed in medium blastula stage for each exposure group at concentrations of 0, 0.1, 0.2, 0.4, 0.8, 1.5, 3%, it was carried out in triplicate, the oocytes were kept at a constant temperature 21±2°C.
during 96 h, until they reached stage 46 or larval stage, CL50, CE50 for malformations as well as the determination of the MCIG were obtained as well as the evaluation of the abnormalities. Several malformations were observed, highlighting: cardiac and facial edema, microcephaly and axial malformations, in addition to a remarkable growth inhibition at a concentration of 0.1% and a teratogenic index of 2.60, which indicates that this effluent is a mixture with teratogenic potential for Xenopus laevis and probably can generate adverse effects in other aquatic organisms.

**RP216 Non-target dung fauna population model to evaluate environmental impacts following use of an active pharmaceutical ingredient (API) in cattle**

A.M. Deines, Exponent, Inc / Ecological & Biological Sciences; J.P. Staveley, Exponent; D. Huggett, M. Terneus, Boehringer Ingelheim Animal Health / Drug Safety

Regulatory approval of veterinary medicinal products requires an effects assessment of the use of these products on the environment. Dung fauna are one group of organisms potentially affected by drug residues excreted into the environment from treated cattle. Adverse effects to the dung fauna community could have direct negative consequences for ecosystem function and services such as dung degradation, and be indicative of effects to other non-target organisms. We developed a matrix population model of the widespread yellow dung fly (Scathophaga stercoraria) to evaluate population-level effects of API residual levels in dung pats following treatment of cattle. The objective was to evaluate whether effects on the yellow dung fly population could be mitigated by a treatment regime which creates “dung refugia” by leaving a portion of a herd untreated. The novel feature of this matrix model was that it evaluated the extended period during which relevant insecticidal concentrations would be excreted after treatment. The model incorporated both the changing concentration of API in dung over a summer grazing season, as well as temperature-dependent life-history parameters of yellow dung fly populations. Model simulations evaluated the potential for long-term population maintenance of yellow dung fly when treating different percentages of the cattle herd while also incorporating variability in life-history parameters. Key population predictions and parameters derived from the population model in the absence of API inputs were verified with independent population data from the literature. The model accurately estimated the adult survival probability compared to survival rates derived from stage-class data. The model was also able to replicate population data across two growing seasons based on initial conditions. The presence of dung refugia consistently supported populations of the yellow dung fly within a single growing season as well as supported long-term maintenance of yellow dung fly populations. The ability of the model to capture observed population dynamics and simulate the efficacy of dung refugia supports using this approach to evaluate non-target effects. The results from this type of modeling can be used to support veterinary medicinal product submissions to allow for regulatory decisions regarding appropriate management strategies for their use in the practice.

**Environmental Radiation Sciences**

**RP217 Uranium Concentrations In Soil And Vegetation Near A Uranium Processing Facility**

M. Jin, A. McAllister, Canadian Nuclear Safety Commission / Environmental Risk Assessment Division

Accuracy of any environmental risk assessment is highly dependent on the quality of the data used in mathematical models designed to predict contaminant behaviour in various environmental compartments. Canadian Nuclear Safety Commission (CNSC) has raised concerns regarding the validity of some generic (not site-specific) parameters used for modeling the long-term behaviour of uranium in soil and its transfer from soil to vegetation near a uranium process ion facility. To address the CNSC concerns, a soil characterization study was carried out near the facility in areas associated with the highest expected air concentrations of uranium and uranium deposition rates and available to the public. The measured uranium concentrations in soil and vegetation and the location-specific soil model parameters were used to estimate future long-term uranium soil concentrations to confirm that uranium would not accumulate to levels that may be a concern for human health or the environment.

**RP218 Quantifying historical releases and ambient levels of metals and radionuclides near decommissioned uranium mine sites**

R. Goulet, Canadian Nuclear Safety Commission / Directorate of Environment / Radiation Protection and Assessment; V. Clulow, Laurentian University / Northern Ontario School of Medicine / Department of Biology; D. Sauve, Environment Canada

Assessing recovery of aquatic ecosystems affected by mining operations requires knowledge of ambient levels of radionuclides and metals before initiation of activities. However, such ambient levels of pre-existing conditions are often not available for many mining operations initiated decades ago. The objective of this study was to quantify historical releases of radionuclides and metals and derive their ambient pre-operation levels. For this purpose, we obtained two sedimentary profiles in a harbour downstream of an impacted river and collected water and surface sediment samples every 2.5 km over 120 km along an impacted river and 220 km along an adjacent, non-impacted river. Using a gamma pulse from atomic bomb fallout in 1963, our sedimentary core profiles accurately reflected releases from the uranium mining operation from its onset in 1955 to its closure in 1993. Using sedimentary core profiles and comparisons of 48 water and sediment samples collected within an impacted river to 89 water and sediment samples collected in an un-impacted river, we derived ambient levels of metals and radionuclides in water and sediment of lakes and rivers. Ambient water concentrations in lakes and rivers were similar at pH of 6.78, 10 mBq 226Ra/L, and 2.5 µg U/L. We measured ambient levels in lake sediments at 107 mBq 210Po/g, 0.3 mBq 210Pb/g, 116 mBq 226Ra/g, 126 mBq 228Th/g, 97 mBq 230Th/g, and 122 mBq 232Th/g, as well as 67 µg Cu/g, 56 µg Ni/g, 65 µg Pb/g, 11 µg U/g and 1 µg Zn/g. River sediment levels were consistently lower than lake sediments. Our study provides a framework to reconstruct historical releases and obtain ambient levels of contaminant helpful in identifying contaminant of potential concern and to assess recovery of aquatic ecosystems.

**RP219 Radiation Dose Assessment for Fossil Groundwaters in the Nubian Aquifer, Egypt**

M.J. Sherif, N. Sturchio, University of Delaware / Earth Sciences

The Nubian Sandstone Aquifer System (NSAS) in hyperarid Northeast Africa and the Middle East is a huge water resource of inestimable value to the population for agricultural and domestic use. However, natural radioactivity affects Nubian aquifer groundwater quality throughout the region, posing a threat to the health of millions of people. Long-lived radium isotopes (226Ra and 228Ra) were measured by HPGe gamma spectrometry in 64 groundwater samples from deep NSAS wells in oasis areas of the Western Desert of Egypt. More than 80% of these samples had total Ra activities (226Ra + 228Ra) in excess of the maximum contaminant level (MCL) of the US Environmental Protection Agency (EPA), the European Union (EU), and the World Health Organization (WHO) for Ra in drinking water. Activities up to 2500% of the MCL for total Ra were measured in some locations. The highest Ra activities occur where groundwaters are anoxic and have the longest residence times. The annual radiation doses to humans from Ra via daily ingestion of Nubian aquifer water were calculated for different ages and compared to the Individual Dose Criterion (IDC) of the World Health Organization (WHO). The annual dose for an infant ingesting 0.5 L/day could be up to 14 mSv/year, and for an adult (2 L/day) it could be up to 1.43 mSv/year. These results indicate that groundwater from the NSAS in the Western Desert of Egypt should be used with caution, and Ra removal may be necessary in some locations before water is used for human consumption. Effects on the food chain of Ra accumulation in soils irrigated by Nubian aquifer water should be examined further for its additional exposure potential.
**RP220 Level of Environmental Perturbation and its Health Impact in Imiringi community, Bayelsa State, Nigeria**

_U. Anekwe, Federal University Otuoke_

Environmental perturbation level and its Health Impact have been analyzed in Imiringi community in Ogbia local government area. An in situ measurement approach of background ionizing radiation (BIR) was adopted. The mean exposure rate ranged from 14 to 32μR/h with an average value of μ23Rh-1 showing that the environment has been degraded. Dose rate and equivalent dose rate ranged from 121.8 to 278.4nGyh-1 and 0.45 mSvy-1 respectively. The mean value of the indoor annual effective dose equivalent (AED), outdoor AED, and excess lifetime cancer risk (ELCR) were computed to be 0.936 mSvy-1, 0.312 mSvy-1 and 0.810 x 10-3 respectively. Analysis of dose to human organs; testes and ovaries, showed that they received 0.66 and 0.45 mSvy-1 respectively and this condition suggested that elevated background radiation may not contribute to problem of infertility in this particular area. The indoor and outdoor AED were within the permissible value of 1.0 mSvy-1 for general public and below the limit of 20 mSvy-1 for radiological workers as recommended by ICRP whereas exposure rate, dose rate and ELCR exceeded the recommended values. The perturbation recorded in this environment may be attributed to the oil and gas activities such as hydrocarbon drilling, gas flaring, presence of turbines, flow stations, crude oil pipelines and incidents of crude oil spills. It is therefore advisable that the operators of the existing facilities should take proactive measures to forestall sudden elevation of ionizing radiation that may result to health challenge amongst native dwellers.

**RP221 Impact of 17-α ethinylestradiol and phosphorus-32 on Arabidopsis thaliana seed development**

_L. Manglass, Clemson University / Environmental Engineering and Earth Science; C. Vogel, P. Zhou, C. Eimen, Clemson University; N. Martinez, Clemson University / Environmental Engineering and Earth Sciences_

Synthetic estrogens such as 17-α ethinylestradiol (EE2) and short-lived radionuclides are found in wastewater effluent from sewage treatment as they are not efficiently removed during the treatment process. While the toxicological mechanisms and impact of estrogen on the environment are not entirely defined, estrogen contamination in wastewater has demonstrated impacts on growth and development of ecosystem biota. Furthermore, EE2 is more persistent in the environment than natural estrogen. Radionuclides used in nuclear medicine for the treatment and diagnosis of diseases are also released to the environment via waste-water treatment effluent because, like EE2, they are primarily excreted through urine. While radionuclides used for nuclear medicine have short half-lives such that they should only remain the environment after release for a short duration (a few weeks or less), the increased popularity of nuclear medicine procedures may result in a consistent release of radionuclides to environmental systems near effluent release points. Generally, the existing literature on multiple stressor studies between radiological and non-radiological contaminants is sparse, and studies specifically comparing estrogen and ionizing radiation are focused on human health, not environmental impact. In this study, root length assays on *Arabidopsis thaliana* seeds were conducted for 10 days on agar plates to examine the impact of EE2 and ionizing radiation both individually and in combination. Environmentally relevant concentrations of EE2 in the range of 0.5-40 ng/L were used with phosphorus-32 at dose rates in the range 10 mGy/day with both contaminants incorporated directly into the growth media. Endpoints assessed include root length, rosette development, and germination rate. The results of this study suggest that the introduction of EE2 into growth media induces early germination and faster root growth in *A. thaliana* seeds, where the addition of phosphorus-32 may have a synergistic effect that amplifies the impact on root length.

**RP222 Effects of Ionizing Radiation on Heart Rate, Instar Development, and Swimming Behavior in Daphnia pulex**

_S. Ladney, California State Polytechnic University, Pomona / Biological Sciences_

Anthropogenic activities in the manufacturing and nuclear industries are responsible for the exposure of aquatic organisms to toxic chemicals. In aquatic ecosystems, the microcrustacean Daphnia is essential to sustaining larger organisms within the aquatic food web. It is also an ideal model organism in ecotoxicology, ecology, and evolutionary biology due to its short generation time, asexual reproductions and phenotypic plasticity. Mutagenic agents, such as ionizing radiation, are comprised of ionized radioactive particles that are emitted in electromagnetic waves. These electromagnetic waves can elicit a cascade of negative effects that impact the survivability and individual fitness of Daphnia by disrupting critical cellular processes. To better understand how these contaminants affect aquatic systems, this study is designed to explore the behavior and development of *D. pulex* in the presence of low-dose ionizing gamma radiation across two generations. Four groups containing 30 female Daphnia from the parent generation will be exposed to 0, 10, 100, 1000 mGy of acute gamma radiation. Recent studies provided strong evidence that there are transgenerational effects within irradiated daphnids. Exposure to such contaminants have been found to cause physiological stress and compromised fertility, and even increased mortality. We hypothesize higher irradiation levels can negatively affect the cardiac output and fertility of the parent generation, which could affect the fecundity and performance of the subsequent generation. Once the parent generation has given birth, the heart rate, antennae growth, and instar development of the offspring will be monitored via live imaging analysis. Our results will test how radioactive toxicants influence the health and behavior of aquatic model organisms. Such knowledge will provide a better understanding of how these organisms are affected and how they respond when exposed to such environmental pollutants.

**RP223 Addressing Sustainability Needs with Isothiazolinone Chemistry: The favorable environmental profile of DCOIT**

_C. Britton, D.M. Laganella, I. Watt, DuPont / Microbial Control_

In critical end-uses such as wood preservation and antifouling paints, pesticides are required to meet highly stringent product stewardship and regulatory assessment standards. Ideally, sustainable preservatives should be highly efficacious to control a broad spectrum of target organisms while posing minimal risk to non-target organisms and the environment. Where environmental exposure can be predicted either during manufacturing or service life, subsequent leaching and ultimate environmental fate are key factors that must be considered if a chemical is to be truly considered sustainable. The organic, non-metal-based active ingredient 4,5-Dichloro-2-octylisothiazol-3(2H)-one (DCOIT), currently used in many environmentally-sensitive preservation applications globally, meets all of these requirements. By examining key aspects of DCOIT’s environmental toxicology, fate (e.g., biodegradation, soil mobility) and ultimate impact (i.e., risk) in various practical applications, we demonstrate the important role that DCOIT can play to deliver environmentally sustainable solutions.
RP224 Comparing relative efficacies of granulated activated carbon and biochar to reduce the loading and toxicity of pesticides in vegetated ditch systems

J. Voorhees, B.M. Phillips, University of California, Davis / Environmental Toxicology; L.B. McCalla, S. Zamudio, University of California, Davis / Marine Pollution Studies Laboratory at Granite Canyon / Environmental Toxicology; K. Faulkenberry, University of California, Davis / Aquatic Toxicology; R. Tjeerdema, University of California, Davis / Environmental Toxicology; M. Cahn, University of California, Davis / UC Cooperative Extension; J. Clarke, California Leafy Greens Research Program

Vegetated treatment systems significantly reduce pesticide loads in agricultural runoff. Previous studies have shown that the addition of granulated activated carbon (GAC) as a final filtration treatment can further reduce pesticide loading. Laboratory studies suggest biochar is an equally effective carbon material and a potentially more cost-effective and convenient alternative to GAC. This study evaluated the efficacy of a grass-lined ditch with carbon installations of GAC or biochar to reduce toxicity and concentrations of imidacloprid and permethrin in simulated irrigation runoff. A 180-meter section of ditch grown with red fescue was evaluated. The V-shaped ditch was five meters wide and one meter deep. Biochar or GAC was placed at the bottom of the ditch in one-meter long geotextile mesh sleeves. Simulated irrigation water was introduced to the ditch at a rate of 4.75 L/s. Toxicity and chemical concentrations were measured at the input, before the carbon filtration, and at the output. Toxicity was evaluated using water column exposures with the amphipod Hyalella azteca, and the midge Chironomus dilutus. Although toxicity to C. dilutus was reduced or removed more often than toxicity to H. azteca, results indicate that both carbon types were equally effective. Preliminary results show chemical concentrations were reduced by an average of >90%. This study further demonstrates the utility of using GAC in field-based treatment systems, as well as the potential for biochar as an equally effective substitute.

RP225 Sources, characteristics and opportunities for pesticide use and usage information applied to listed species risk assessment

C.M. Holmes, Applied Analysis Solutions, LLC; J. Amos, Waterborne Environmental, Inc. / Geospatial Data Technologies; M.E. Kern, Waterborne Environmental, Inc. / Ecotoxicology Risk Assessment; N. Snyder, Waterborne Environmental, Inc.; J.L. Cowles, NovaSource / Tessenderlo Kerley, Inc. / Product Safety; K. Henry, NovaSource / Tessenderlo Kerley, Inc. / Ecological Sciences

The challenges inherent in national-level pesticide endangered species risk assessments are many, varied and have been the topic of meetings, workshops, presentations and publications for many years. One challenge is the identification and incorporation of pesticide usage information in the risk assessment process. Pesticide “usage” differs from pesticide “use,” where “use” is defined by registered labels and describes limits on how the pesticide may be applied (i.e., maximum rates and number of applications), while “usage” describes documented applications with specific information on each individual event. Incorporating usage information into the risk characterization during the Biological Evaluation and Biological Opinion development process is an area of renewed interest. This poster will describe several sources of pesticide usage information (e.g., USDA Agricultural Chemical Use Program, CA DPR Pesticide Use Reporting), and how relevant field-level pesticide application information can be extracted. Examples will be given showing how these data can be utilized to refine our understanding of specific active ingredients and their associated spatial and temporal variation across use areas, and how this can inform the exposure analysis within each Step of the ESA consultation process.

Different Knowledge Systems, One Vision: Stories of Braiding Indigenous Knowledge and Western Science in Environmental Assessment and Management

RP226 Relationships 101: How understanding local protocols can help shape research and relationships

E. Hayward, Trent University / Environmental and Life Sciences

Moving towards research and environmental problem solving that involves Indigenous peoples requires a thorough understanding of colonial histories and legalities of the lands your research is taking place on. These shared histories have a large influence on the success of partnerships with Indigenous Peoples and communities, but often there is limited opportunity for researchers wanting to become involved in this type of work to become educated in this field. Within Canada, Indigenous peoples and our traditional territories continue to be governed by our own official governments and governing systems which hold the Law of Nature at the core of all decision-making processes. This has significant influence on environmental decision making and values within our communities. This presentation will give a brief introduction to two local Indigenous governing systems (Haudenosaunee and Anishinabek), as well as how the Indian Act has limited the way local Indigenous peoples may continue our responsibility as caretakers of the land. Many Indigenous peoples are registered as Aboriginal people under the ‘Indian Act’ of Canada and are limited by its wide-ranging control of everyday life. Understanding the way this act impacts our respective Nations and continued systems of governance, and our ability to uphold the Law of Nature, is fundamental to becoming aware of local community protocols for the development of relationships and the sharing of knowledge.

RP227 Towards effective First Nations’ source water protection: A technical and Indigenous Knowledge collaboration

R. Marshall, University of Guelph; M. Desjardine, Chippewas of Nawash Unceded First Nation; J. Levison, S. Gharaabaghi, University of Guelph

First Nations in Ontario face complex water management issues that put them at high risk for source water contamination. Current source water protection options for First Nations include either joining the provincial source water protection process, an option only available to the 27 of 133 First Nations in Ontario that fall within a designated source water protection area, or to conduct an on-reserve source water protection plan. However, neither option meets most First Nations’ needs for a variety of technical, cultural, and jurisdictional reasons, and few communities have adopted these processes. Particularly for First Nations situated above sensitive fractured rock aquifers, the lack of effective options for source water protection leaves communities vulnerable. Through a partnership with the Chippewas of Nawash Unceded First Nation - a community situated above fractured sedimentary rock - this research aimed to develop an effective First Nations’ source water protection framework informed by 1) hydrogeological studies and 2) interviews with First Nation community members and key informants from industry, academia, government, non-governmental organizations, and Conservation Authorities. Hydrogeological data collection activities included pumping and slug tests; down-hole geophysical data collection; sampling for waste derived contaminants; and conducting two tracer experiments to examine transport times from a septic bed to groundwater. Results indicated that groundwater is being contaminated by septic systems on reserve, and current source water protection options fail to provide adequate protection for First Nations situated above fractured sedimentary aquifers. The interviews conducted as the second component of this research examined community priorities, member-identified risks to water sources, and source water protection approaches that are built on Indigenous Knowledge and better suited to Indigenous land management practices. As a result of these studies, a source water protection framework was developed in partnership with the Nawash Water Protection Committee that is informed by Indigenous
Knowledge, best practices from several sectors, and groundwater research. Recommendations and lessons learned are provided for practitioners from First Nations, industry, government, and academia aiming to support First Nations in protecting their source waters.

**Oil Sands Monitoring Program: Synthesis of Results and Progress Towards Cumulative Effects Monitoring**

**RP228 A cumulative effects monitoring framework for Oil Sands Monitoring**

M. Dube, Alberta Environment and Parks / Environmental Monitoring and Science Division; K. Cash, Government of Canada / Environment and Climate Change Canada; F.J. Wrona, R. Hazewinkel, Alberta Environment and Parks / Environmental Monitoring and Science Division; S. Swanson, Swanson Environmental Strategies, Ltd.; F. Wyatt, Government of Alberta / Environmental Monitoring and Science Division

The Oil Sands Monitoring (OSM) program is mandated to assess cumulative effects that are attributable in whole or in part to the oil sands industry. A commitment to cumulative effects monitoring is fundamental to the OSM design but has been difficult to implement in practice. Cumulative effects assessments in the oil sands region have been conducted on a project scale in support of Environmental Impact Assessments. However, cumulative effects monitoring of oil sands development at a regional scale requires multiple stages, including spatio-temporal trajectories that can be compared to the observed environmental condition. We are also establishing conceptual models—simplified and integrated program-scale hypothesis about the influence of OS industry on cumulative effects. The conceptual model represents the structure of the monitoring program, documents our collective understanding of the system, facilitates communication among knowledge holders, and encourages consideration of the system as an integrated whole. Geospatial analyses and mechanistic models (e.g. atmospheric dispersion models) based on the relationships identified in the conceptual model establish spatio-temporal trajectories, the basis for cumulative effects assessment. These trajectories represent testable predictions that support a risk-informed approach to monitoring and inform stratification in monitoring design. In addition to the temporal predictions presented in classical cumulative effects assessment, these predictions also include spatial inferences of the accumulated state, essentially ‘filling in the blanks’ in the accumulated state assessment. Cumulative effects monitoring tests in space and time and informs revision or validation of the predictions. Changes identified through monitoring trigger an adaptive response designed to further evaluate the stressor-response pathways through focused monitoring and to initiate investigation of causative/solutions or inform the management and regulatory systems.

**RP229 A decadal synthesis of research on air emissions and atmospheric deposition in the Canadian oil sands region**

In 2019, the Oil Sands Monitoring (OSM) Program reviewed of the last 10 years of peer-reviewed literature on regional ambient environmental monitoring of air, land and water in the oil sands (OS) region of northeastern Alberta. The objectives of this review were to provide an integrated synthesis of published information and improve understanding of cumulative environmental effects of industrial development in the OS region by identifying environmental changes and, if changes are occurring, assessing evidence for a causal link to OS industrial development. The air theme accounted for more than 40% of the ~300 papers reviewed for the project. During our review, several air sub-themes emerged, including acidification and fertilization (25% of air papers), ambient air quality in local communities (22%), polycyclic aromatic compounds (PACs; 18%), metals and trace elements (14%), estimating/measuring air emissions (12%), mercury (4%), greenhouse gases (3%), and wildfire (2%). Atmospheric deposition has been studied extensively in the OS region, and was considered in many studies (e.g., transport and deposition of PACs, metals/trace elements, acidification/fertilization and mercury). In the case of PACs and metals, deposition has been investigated through several monitoring approaches (e.g. snowpack, lichens, foliation, moss, and passive monitoring). These studies exhibit a consistent spatial pattern in all examined receptors: measured deposition is highest at sites in closest proximity to central OS mining and upgrading operations, with depositional flux decreasing strongly with distance (exponential decline over 25-50 km). We will present a detailed synthesis of these and other findings, including recent results on ambient air quality assessments, source attribution, and terrestrial acid deposition monitoring in the OS region. While this presentation focuses on emissions and atmospheric deposition, the findings should be considered holistically in the context of the OS regional environment, and integration among other theme areas is required. For example, atmospheric deposition is a key pathway for airborne contaminants to enter the surrounding aquatic and terrestrial ecosystems.

**RP230 Reviewing the results of aquatic monitoring and research in the Canadian Oil Sands**

The current Oil Sands Monitoring Program (OSM) is an industry-funded, multi-stakeholder governed environmental monitoring program tasked with evaluating impacts of industrial development in the Canadian oil sands (OS). Since OSM began in 2012, many studies, organized into themes of air, water, and land have been completed, implemented and funded either directly by OSM or by other agencies. These OS studies contribute to our understanding of cumulative effects associated with both OS and non-OS associated stressors in the regional ambient environment. Initial investigation in OSM were focused on the minable region north of Fort McMurray, but have since widened to include consideration of in situ OS development also. A conceptual model framework—diagramming industry-related stressor influence on the local and regional environment including, for example, atmospheric emissions, potential seepage from tailings ponds, and land disturbance—has guided monitoring and research priorities. In 2019, as part of its state of the environment assessment, OSM undertook a review of the OS-related peer-reviewed literature published between 2009-18, a total of more than 300 papers, ~18% of which are relevant to the theme of surface water, and we report our findings here. Among studies of water, the relevant and primary effect pathways are atmospheric deposition directly into water bodies or their watersheds, hydrological alteration of those watersheds, water withdrawals, discharge of waters suitable for release (e.g. overburden drainage), and seepage of tailings waters. Secondary pathways include surface runoff of snowmelt and increased erosion from cleared land. Studies to address these effect pathways have been and are being undertaken on accumulation of polycyclic aromatic compounds (PACs) and metals in snow, lake sediments, and river sediments, changes in long-term patterns of discharge in the Athabasca, the health of aquatic organisms, and the characterization of dissolved organics present in oil sands process-affected water (OSPW). This presentation will describe in more detail the current knowledge of the ambient aquatic environment surrounding OS developments, the approaches used to identify change, and the potential sources of such changes on the chemical, physical, and biological states of lakes and rivers in the Oil Sands Region of northeastern Alberta.
Groundwater in Canada’s oil sands region is a potential conduit of oil sands process-affected water (OSPW) to the natural environment. However, this is only one of several potential stressor-response pathways identified in the literature on potential effects of OS development on groundwater and the larger ambient environment. As part of an accumulated environmental state assessment conducted within the Oil Sands Monitoring (OSM) program, we reviewed and synthesized relevant peer-reviewed literature from 2009-2018, more than 300 papers, of which ~16% were relevant to the groundwater theme. Literature highlighted the complexity of the geological setting in the region as a common theme. The marine origin of shales and evaporites produces groundwater that can be highly saline. The influence of saline groundwater is evident in increasing salt concentrations in the Athabasca River and its tributaries as they transit Cretaceous and Devonian formations. Groundwater also flows through the bitumen bearing geologic formations, picking up the water-soluble organic compounds believed to be a source of toxicity in OSPW. This, combined with the heterogeneity of local groundwater flow systems, presents significant challenges distinguishing natural groundwaters from OSPW. Conventional plume delineation suggests that OSPW is migrating through groundwater in some locations and these locations are focal points for ongoing monitoring and research. Effort has been invested in chemical profiling of groundwater and OSPW and promising approaches using ultra high-resolution mass spectrometry techniques are being developed. However, even with methodological advancements, detecting OSPW-related signals in surface waters remains extremely difficult due to high dilution factors. Researchers are also examining the origin of metals and metalloids, particularly arsenic, in groundwater. While these metals and metalloids appear to be unrelated to OS mining activity, there is some evidence of thermal mobilization of arsenic associated with steam injection at in situ OS operations. This effect is directly related to the influence of in situ activity on groundwater temperature, and appears to be transient. This presentation will characterize the natural geologic setting of groundwater in the oil sands region and discuss the added influence of oil sands extraction on groundwater quality and quantity as potential stressors for groundwater connected ecosystems.

**RP232 A decade of terrestrial biological monitoring and research in the Canadian Oil Sands**

Since 2012, a jointly run Government of Alberta and Government of Canada environmental monitoring program, governed in collaboration with local indigenous communities and funded by industry, has operated in the oil sands (OS) region of northern Alberta. This Oil Sands Monitoring (OSM) Program currently exists within the mandate to determine the extent of environmental changes due to OS operations, and assess the accumulated state of the environment in the OS region. In 2019, as part of an accumulated environmental state assessment, the Oil Sands Monitoring Program (OSM) reviewed and summarized >300 peer-reviewed papers from 2009-18. ~20% of which addressed terrestrial biological research and monitoring. We found that, despite an increasing number of publications, the breadth of topics is largely limited to a few key stressors and to a limited numbers of species of interest. Of the stressors directly considered, landscape disturbance (natural and anthropogenic) was the most prevalent, appearing in more than half the papers. Landscape disturbance has diverse effects on mammals and birds, generally with neutral or positive effects on young forest and disturbance specialists and negative effects on old growth and intact forest specialists. Linear disturbances specifically change behaviour patterns of many species, largely by facilitating movement relative to otherwise intact forests; the ecological implications of these behavioural changes are complex. The second most-often considered stressor was chemical contaminants, with literature suggesting that accumulation in plants and wildlife in the oil sands region varies in terms of both level of concern and confidence in oil sands source attribution, the latter being confounded by local geology or regional urbanisation. Assessments of wildlife contaminant burdens was largely limited to a few sentinel species, including colonial waterbirds, swallow nestlings, and small mammals, though many plant species were also used as indicators for atmospheric deposition. Caribou was the most commonly considered focal species, while mammals in general were the largest species group considered, followed by birds and plants. Caribou populations are reduced and declining, largely due to increased wolf predation resulting from increased caribou habitat overlap. This overlap is driven by a combination of larger deer populations in the region (an effect of both climate change and land disturbance) and wolf selection for linear developments (e.g. seismic lines).

**RP233 Response of Slimy sculpin in the Steepbank River, Alberta, adjacent to oil sands mining activity**

J. Bennett, Environment Canada; G. Tetreault, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; T. Clark, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; H. Keith, Hatfield Consultants; J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division

Since 2009, the Canadian and Alberta governments have been developing monitoring plans for surface water quality and quantity, air quality and biodiversity of the lower Athabasca River (LAR) and its tributaries (2010-2013). The objectives of the fish monitoring program were to: 1) assess the current status of fish in the LAR, 2) identify existing differences between upstream reference and within the oil sands deposit exposure sites, and 3) identify trends/changes in fish health relative to historical studies. This study examines the fish health endpoints in Slimy sculpin (**Cottus cognatus**) in the Steepbank River, AB, in terms of growth, gonad size, condition, and hepatic 7-ethoxyresorufin-O-deethylase (EROD) activity as an indicator of exposure to oil-sands related compounds. The sampling program followed historical sampling methods (1999-2000) to provide comparable data (e.g. sculpin health) over time with an additional upstream site added as development progressed. Consistent changes were documented in sculpin collected from downstream sections of the Steepbank River within the oil sands deposit in 2010 through 2013. Sculpin demonstrated increased liver size with corresponding induction of EROD activity consistent with historical data and reductions in energy investment relative to reproductive development and gonadal steroid production capacity. There was no consistent evidence of changes in fish health metrics with increased surface mining development, particularly adjacent to the Steepbank River Mid site.
RP234 Estimation of Substance Loads from Surface Waters and Groundwater in the Lower Athabasca River - A Mass Balance Approach

Y. Yi, Alberta Environment and Parks / Environmental Science and Monitoring Division; C. Cooke, Alberta Environment and Parks / Environmental Monitoring and Science Division; N. Glozier, K. Pippy, Environment and Climate Change Canada / Water Science & Technology Directorate

Water quality and quantity monitoring in the Lower Athabasca River region are important components of the Oil Sands Monitoring (OSM) Program. The high-frequency, flow-weighted, multiple-year water quality sampling, in combination with daily stream flow monitoring, provide an opportunity to estimate and evaluate substance loads (including major ions, nutrients, and trace elements) in the Lower Athabasca River and its tributaries at various time scales. This study synthesizes concentration, river discharge and industrial water usage in the Lower Athabasca region collected during OSM, and estimates daily substance loads, including dissolved chloride, dissolved calcium and total suspended solids, at key locations along the lower Athabasca River and major tributaries. With the consideration of upstream, downstream and tributary loads, a mass balance approach is further taken to assess groundwater contribution to the surface water loading in the mainstem of the Athabasca River. The results provide reliable surface water load estimations in the region, with a fine temporal and spatial resolution. Insights into temporal and spatial patterns in the groundwater loading to the lower Athabasca River will also be shown. Substances loads in the surface water progressively increase from upstream sites to downstream sites along the Athabasca River, while the groundwater contribution shows a reach-specific pattern. The assessment of groundwater loads and possible quantification of groundwater discharge advance our understanding of complex groundwater-surface water interaction in the region.

RP235 Shifts in Invertebrate Communities in Streams within the Increasing Footprint of the Oil Sands Surface Mining Area in Comparison to Reference Areas

N. Glozier, A. Ritcey, ECCC / Water Science & Technology Directorate

In 2012, the governments of Canada and Alberta launched the Implementation Plan for Oil Sands Monitoring, which included a phased monitoring plan for aquatic ecosystem health. A key objective was to improve the understanding of benthic invertebrate community status in tributaries of the Lower Athabasca River (LAR) in relation to exposure to oil sands surface mining as well as to natural bitumen deposits. From 2012-2017, benthic invertebrate and water quality samples were collected from over 100 sites in LAR tributaries including the Steepbank, Ells, and Mackay rivers and several catchments in the Birch Mountains. Reference sites were divided into two categories (inside or outside of the natural bitumen deposit). Potentially impacted sites were grouped based on the extent of disturbance (activity) in the upstream catchment. Multivariate results indicate that over all catchments, little difference exists in community structure between the two reference categories. The PERMANOVA routine in PRIMER was used to assess community differences in reference and potentially impacted sites within tributaries. PERMANOVA results from these tributaries suggest that benthic communities shift further from reference condition as the proportion of mining activity in the catchment increases. This is more prevalent in catchments with higher activities levels. Potential environmental drivers of community change were also assessed, including water and sediment chemistry, flow characteristics, geology, and land cover.

RP236 A comprehensive study design for developing baseline data prior to the potential release of petroleum coke-treated oil sand process waters into the Athabasca River

K. Hicks, Alberta Environment and Parks / Biology; K.R. Munkittrick, Wilfrid Laurier University / Biology; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; J. Culp, Environment and Climate Change Canada; B. Kilgour, Kilgour & Associates, Ltd.; J. Linehan, Suncor Energy, Inc. / Sustainability and Communications; W. Zubot, Syncrude Canada, Ltd.; G. Scrimgeour, Alberta Environment and Parks / Environmental Monitoring and Science Division

The oil sands industry has historically adhered to a zero discharge practice relating to the release of oil sands process affected water (OSPW) from mineable oil sands operations to the receiving environment. However, current government policy does allow for the possible release of OSPW if a treatment technology can be demonstrated, through pilot studies, to effectively treat water and thus if released would not result in adverse environmental effects. Syncrude Canada has developed a coke-slurry treatment technology for OSPW, which through small-scale studies have demonstrated to effectively decrease many toxic constituents of OSPW, and thus may allow for the safe return back into the environment. In addition, a variety of studies have been initiated to evaluate the feasibility of returning treated water during a pilot scale study. The regional oil sands monitoring program recently optimized water quality monitoring stations and turned off 3 stations in the midst of the development area (M4, M5 and M6) due to the lack of significant differences between stations M3 to M7 (a distance of 60 km); the turned off stations are in close proximity to where potential discharges of treated OSPW could occur. The main objective of this study (enhanced monitoring) was to examine the adequacy of existing baseline data and monitoring to determine potential local scale responses to a pilot discharge. The design is to evaluate whether, in the absence of a discharge, a fine scale gradient design (14 stations within 60 km) would detect differences in the plethora of endpoints in the existing regional monitoring program, including endpoints of importance to Indigenous communities. Monitoring includes water quality and sediment quality parameters, biological communities (algae, benthic invertebrates, and fish), fish health, and body burdens of contaminants across trophic levels. Overall, this baseline data collected at sites located in close proximity will provide information on the inherent variance, and ultimately the sampling intensity required to be able to detect impacts from a potential pilot release of treated OSPW, should release be allowed. The existing regional and enhanced data will be used to develop monitoring and forecast triggers that could be used in decision-making for releases within the reach of development.

RP237 Atmospheric emissions from the Fort McMurray oil sands mining operations and their impact on boreal lakes: spatial and temporal trends and climate

M. Evans, Environment and Climate Change Canada / Water, Science and Technology Directorate; A. Mohamed, University of Regina / Lab. Environmental Biology; B. Wissel, University of Regina / Department of Biology; D. Jeffries, Environment and Climate Change Canada / National Water Research Institute; D. Andrews, Western Resource Solutions; K. Scott, Saskatchewan Ministry of Environment; C. Whitfield, University of Saskatchewan / School of Environment and Sustainability; C. Cooke, Alberta Environment and Parks / Environmental Monitoring and Science Division

Since the late 1960s, bitumen-mining activities in the Fort McMurray area have emitted a variety of compounds, including acidifying and nutrient species, which, once deposited may affect the ecological features of lake systems. Early surveys identified acid-sensitive regions in Alberta (AB) and Saskatchewan (SK) where low-conductivity lakes had little buffering capacity. With oil sands industry expansion in the late 1990s, research and monitoring programs began to investigate these concerns; this presentation highlights major findings under research monitoring. In AB, limnological surveys provide no evidence that increasing oil sands
mining and concomitant changes in acidifying and nutrifying emissions acidified lakes over 1999-2017 but there was evidence of increasing pH (alkalization) and base cations concentrations. Chlorophyll concentrations increased while nitrite-nitrate concentrations decreased and dissolved organic carbon concentrations remained unchanged. Trends often differed regionally. SK research monitoring began in 2012 with less statistical power to detect trends but sediment core studies provide no evidence of increasing acidification. Several drivers may be affecting observed trends (or their lack). First, sulfur emissions from the oil sands industry have declined in recent years with improvements in emissions technology although nitrogen (a weaker acid) emissions continue to increase. Increasing nitrogen emissions from agricultural fields to the south and globally confound detecting localized impacts of emissions from the oil sands developments. Second, while acid-sensitive lakes occur in regions such as the Stony Mountains, AB and the Athabasca Plain, SK, at distances of more than 100 km from the developments, broad-scale global factors strongly affect these lakes. Studies have shown that emission depositions (e.g., metals, PAHs) are detectable only with ca. 50-80 km of the developments because of dilution effects with increasing distance from point sources. Third, the region is experiencing a long-term warming trend with consequences such as increased permafrost melt and release of base cations from the watershed to the lakes; growing forest fire activity is an additional source of base cations to many lakes. We conclude that estimation techniques for critical loads and exceedances may need to be refined for the boreal forest region with its unique watersheds and lakes and impacts of increasing alkalization investigated.

**RP238 Spatial and temporal patterns of mercury in fish in the Athabasca and Peace River regions in relation to the oil sands operations and mercury deposition trends**

M. Evans, Environment and Climate Change Canada / Water, Science and Technology Directorate; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate / Aquatic Contaminants Research Division; A. Mohamed, Department of Biological Science / University of Toronto, Scarborough / Lab. Environmental Biology; D.C. Muir, J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C. Cooke, Alberta Environment and Parks / Environmental Monitoring and Science Division; J. Keating, Environment Canada / Water Science and Technology Directorate; X. Wang, Environment Canada; A. Gleason, Environment and Climate Change Canada

Oil sands mining operations in the Fort McMurray area began in the late 1960s and, with improving technology, have been expanding exponentially in recent decades. Operations have been controversial given the size and extent of the open pit mines and tailings ponds, located along a ca. 75 km stretch of the Athabasca River north of Fort McMurray. Among the many environmental issues raised has been the enhanced release of mercury (Hg) into the environment from emissions, the disturbed landscape, and groundwater seepages. Early investigations reported (2009) increased concentrations of mercury in walleye inhabiting the Athabasca River although this trend was not evident in later studies (2012) using the larger data base that was available at that time; limited years of monitoring constrained the sensitivity of analyses to detect trends. With the inception of the Joint Oil Sands Monitoring Program in 2012, large-bodied fish have been sampled from an increasing number of locations along the Peace, Athabasca and Clearwater Rivers in addition to some lakes, allowing for a fuller and updated analyses of temporal and spatial trends in mercury in fish. Here we present the results of our trend analyses focusing on predatory fishery collected under JOSMP and complementary programs, placing these data into the context of findings under snow deposition and sediment core studies over this region. Overall, there is little evidence of trends of mercury increase in fish that can be related to growing oil sands operations. Fish mobility along the Peace and Athabasca River ecosystems and limitations in the frequency of monitoring affect the statistical power to detect trends.

**Invasive and Vertebrate Pest Species Control: Hazard and Risk to Non-Target Species and Innovations on the Horizon**

**RP239 Blood clotting assays to assess anticoagulant rodenticide exposure and effects in birds of prey and avian scavengers**

Birds of prey and avian scavengers are widely exposed to anticoagulant rodenticides (ARs), and in some instances individuals succumb from poisoning. Unresolved are the consequences of sublethal AR exposure (coagulopathy, anemia, altered behavior) on health and survival of non-target raptors that often encounter a multitude of stressors. In a wildlife rehabilitation setting, AR intoxication may be masked by more acute injuries related to collision with vehicles or electrocution, complicating interpretation of proximate from ultimate cause of mortality. Coagulation function (prothrombin time, Russell’s viper venom time) was assessed in 62 birds of prey and scavengers (bald eagle Haliaeetus leucocephalus, Cooper’s hawk Accipiter cooperi, red-tailed hawk Buteo jamaicensis, barred owl Strix varia, great horned owl Bubo virginianus, barn owl Tyto furcata) admitted to a wildlife rehabilitation clinic in British Columbia, Canada. Twenty-three percent of these birds exhibited prolonged clotting time or failure to form a clot altogether, a biologically significant proportion given the fortuitous and likely biased nature by which raptors are found and admitted to rehabilitation facilities. Hepatic AR concentration was determined in 10 individuals that died or were euthanized. While visual inspection of these data suggest longer clotting times in AR exposed birds, there was no relation (p>0.4) between AR residues and clotting time. Citrated blood plasma samples were also obtained from free-ranging barn owl nestlings (n=19; Lower Mainland of British Columbia, Canada) and from California condors (Gymnogyps californianus; n=29 with 8 sampled twice; Pinnacles National Park, California). In contrast to birds admitted to the rehabilitation facility, there was no evidence of prolonged clotting time in barn owl nestlings or condors, suggesting that either those individuals were not exposed to ARs through their diet or any exposure was limited or transient, and certainly below the threshold that causes coagulopathy. The utility of avian coagulation tests for diagnosing AR exposure remains promising, although there is a need to establish species specific reference values and standardize assay methodologies.

**RP240 Pharmacokinetic/pharmacodynamic analysis of first-generation anticoagulant rodenticide warfarin with Egyptian fruit bats (Rousettus aegyptiacus)**

S. Nakayama, K. Manago, K. Takeda, A. Morita, Hokkaido University; Y. Ikenaka, M. Ishizuka, Hokkaido University / Graduate School of Veterinary Medicine

Anticoagulant Rodenticides (ARs) have been used to eliminate wild rodents since rodents cause various damage to both human and ecosystem. Sensitivity to rodenticide is known to be differ among species. The one factor is diversity of target molecule VKOR (vitamin K epoxide reductase), and the other is metabolism of ARs. Structural differences of VKOR are known to have effect on sensitivity to ARs. Metabolic capacity is also known to have species differences, which influence chemical sensitivity. To investigate these factors of wildlife in ARs spread area is considered to be good indicators to estimate their sensitivity. Bonin fruit bats (Pteropus pselaphon) is the only mammalian and endemic species of the Bonin (Ogasawara) islands and listed in a national treasure by the Japanese government and a critically endangered species by IUCN. Although rodenticides application is implemented in Bonin island, little is known about possible effects on fruit bats including Bonin fruit.
bats. In this study, we used fruit bats commercially available in Japan; Egyptian fruit bats (Rousettus aegyptiacus) for in vivo pharmacokinetic/dynamic study to investigate their sensitivity to rodenticide. All animal care and experimental procedures were approved by the Animal Care and Use Committee of the Faculty of Veterinary Medicine, Hokkaido University. Four Egyptian fruit bats and four SD rat were female and ten weeks old. After acclimation, 4 mg/kg (body weight) of warfarin was administered orally to rats and bats. Blood were taken from tail vein of rats or wing vein of bats at 10 minutes, and 1, 2, 4, 6, 10, 17, 24, 30, 48 and 72 hours after administration. Prothrombin time was measured with CoagCheck XS. Concentration of warfarin and hydroxywarfarin were measured by high-performance liquid chromatography coupled with electrospray ionization triplequadrupole mass spectrometry. Egyptian fruit bats showed no markedly changed prothrombin time, while rats required longer blood coagulation time after warfarin administration. Furthermore, according to Pharmacokinetics of warfarin, Egyptian fruit bats seemed to have the ability to metabolize warfarin rapidly. Pharmacokinetics of hydroxywarfarin showed the basis of rapid excretion. The majority of hydroxylwarfarin in plasma was 4′-OH warfarin. 10-OH warfarin was also detected. In conclusions, our in vivo results using Egyptian fruit bats suggest that Bonin fruit bats could have lower susceptibility to warfarin than rats.

Integrative Avian Ecotoxicology in a Changing World

RP241 Bioaccumulation and biomagnification of polybrominated diphenyl ethers in a terrestrial food chain at an urban landfill

H. Currier, Minnow Environmental, Inc.; K. Fremlin, Simon Fraser University / Biological Sciences; J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch Ecotoxicology and Wildlife Health Division; K.G. Drouillard, University of Windsor / Great Lakes Institute for Environmental Research; T. Williams, Simon Fraser University / Department of Biological Sciences

Biota samples from the municipal landfill located in Delta, BC, Canada, have some of the highest polybrominated diphenyl ether (PBDE) levels reported in Canada. We followed a population of European starlings (Sturnus vulgaris) breeding in a remediated area in the landfill to identify exposure routes and bioaccumulation of PBDEs in a simple terrestrial food chain. This population was compared to a reference farm site located 40 km east in Glen Valley. We analyzed samples of starling eggs, chick livers, and invertebrate species consumed by starlings for PBDE concentrations. We also collected soil samples from starling foraging areas. All samples from the landfill had higher PBDE concentrations than the Glen Valley farm and were dominated by BDE-99 and BDE-47. Stable nitrogen (δN15) and carbon (δC13) isotope analysis of starling blood samples and L. Charity, and 1 gull embryo on Bellow). Chick productivity in terns in Saginaw Bay (mean of 0.76 chicks/nest) was significantly below that of reference sites (1.21 chicks/nest). In the River Raisin AOC, productivity of gull chicks was poor in 4 of 9 years, with complete reproductive failure in 2010. In gull chicks the mean phytohemagglutinin (PHA) skin response for T-cell mediated immunity was suppressed 54-56% at both AOCs and 50% in Grand Traverse Bay. This response was suppressed 48% in terns and 39% in herons in Saginaw Bay. Mean antibody responses in gull chicks at the River Raisin AOC and in Grand Traverse Bay were two to three-fold lower than at the reference site. Ongoing immunological and reproductive impairments at these contaminated sites are consistent with the effects of persistent pollutants such as PCBs and PCDDs.

RP243 Elemental concentrations in feathers of Bonin Petrel (Pterodroma hypooleuca) on Midway Atoll

K. Shaw, National Institute of Standards and Technology / Chemical Sciences Division; D.K. Hyrenbach, L. Fraser, Hawaii Pacific University / Natural Science; J. Liu, G.P. Cobb, Baylor University / Department of Environmental Science; J.M. Lynch, National Institute of Standards and Technology / Chemical Sciences Division; D. Klein, Texas Tech University / Department of Environmental Toxicology

Seabirds are often used as indicators of environmental contamination because they are long lived, feed at multiple trophic levels at varying distance from land, and their feathers can be sampled non-lethally. Bonin Petrel (Pterodroma hypooleuca) are a small gadfly petrel who breed in the Northwestern Hawaiian Islands. Bonin Petrel feed on mesopelagic prey including lanternfish (Myctopphidae), hatchetfish (Sternoptychidae), and squid. Mesopelagic fish and squid generally have greater mercury (Hg) concentrations due to methylation processes in deep water with lower amounts of oxygen, making Bonin Petrel an ideal species to monitor Hg. In addition to Hg, the sulphydryl groups in the keratin structure of the feather bind other elements while the feather is growing. This study provides a new baseline for future monitoring and compares elemental concentrations to Bonin Petrel feathers sampled approximately 15 years after the last published study on this species from Midway Atoll (Burger and Gochfeld, 2000). Bonin Petrel carcases were collected from Sand Island in Midway Atoll (28.2101° N, 177.3761° W) by U.S. Fish and Wildlife Service personnel in 2014 and 2015 and identified as hatch-year (n=42) or after hatch-year (n=42). Breast feathers and the first primary feather were taken from each bird and analyzed via inductively coupled plasma- mass spectrometer (ICP-MS) for As, Cd, Cr, Pb, and Se and for Hg via cold vapor atomic-absorption spectroscopy (CV-AAS). Of these six elements, Hg was the greatest concentration in after hatch-year birds (9.880 ± 4.710 ng/g) and the second greatest concentration in hatch-year birds (2.130 ± 0.953 ng/g). These concentrations are lower than those reported by Burger and Gochfeld (after hatch-year: 19.700 ± 1.080 ng/g,
gotten stuck and died. These petroleum seeps are both naturally occurring.

Kimberly, Westminster College / Biology
K. Kornhauser, Westminster College / Environmental Science; D. Salt Lake RP245 The Rozel Tar Seeps: Impacts to Avian Fauna at the Great Salt Lake

values with the ultimate goal of developing a mercury TRV for common loon. This effort builds upon the approach developed in both the Great Lakes Initiative (GLI 1993) and Mercury Study Report to Congress (MSRC 1997). During the development of both the GLI and the MSRC, the results of several mallard studies (Heinz 1974, 1976a, 1976b, and 1979), which demonstrated that exposure to dietary methylmercury reduced reproductive success, were determined to be the most appropriate toxicity endpoints for the derivation of an avian TRV. In the two decades since the development of the GLI and MSRC, mercury toxicity studies on a wide diversity of bird species have provided additional information about the potential toxicological effects of mercury and the relative sensitivity of birds. Like the mallard studies used in the GLI and MSRC, the common loon data demonstrate that exposure to dietary methylmercury reduces reproductive success and indicate that common loon may be more sensitive to mercury exposure than mallard. The current work through this collaboration includes analysis of published and previously unpublished data to characterize the effects of mercury and to derive toxicity values with the ultimate goal of developing a mercury TRV for common loon that reflects the current toxicity literature.

RP245 The Rozel Tar Seeps: Impacts to Avian Fauna at the Great Salt Lake
K. Kornhauser, Westminster College / Environmental Science; D. Kimberly, Westminster College / Biology

The Great Salt Lake is one of the largest migratory stops for many species of birds in North America. Along the banks of the Great Salt Lake, at Rozel Point, there are tar seeps, where some species of birds have gotten stuck and died. These petroleum seeps are both naturally occurring and human created at Rozel Point. The temperature that the seeps become sticky, the possibility of prey animals drawing predators in, and the appearance of the tar seeps are all important aspects of why birds are drawn to these seeps. Using motion sensor cameras and temperature monitoring devices, the animals that are visiting the tar seeps and the temperature variation of the seeps were monitored. One of the largest human created oil wells at Rozel Point was recapped in January of 2019. The impacts of this recapping will be monitored throughout the summer season of 2019 to determine if there are fewer birds entrapped due to the reduction of oil escaping from the ground at this well.

RP246 Effects of repeated low dose chlorpyrifos exposure to European starlings during migration
C.A. Morrissey, University of Saskatchewan / Department of Biology; M.L. Eng, University of Saskatchewan / Toxicology

Chlorpyrifos is one of the most widely used organophosphate insecticides used in over 98 countries and 50 different crops worldwide. Previous research in birds has focused on short term lethal toxicity, but there is growing evidence that chlorpyrifos can cause behavioural and neurological deficits associated with low dose longer term exposure in humans and wildlife. Here, we orally exposed 32 captive adult European starlings to control (0 µg/g bw) or low doses of chlorpyrifos (nominal conc: 0.5 and 2 µg/g bw; measured conc: 0.8 µg/g bw or 3.1 µg/g bw) that are within the range of estimated chronic exposures for avian species, and < 5% of published LD50 value for starlings. Exposure was during a fall migratory period over 15 days and birds were followed for an additional 15 days to assess recovery and latent effects. We monitored migratory orientation using Emlen funnels, daily activity, mass and plasma acetylcholinesterase (AChE) activity over time. We found predictable mass gain associated with migratory fueling but with no differences among treatments. Exposure to chlorpyrifos significantly inhibited AChE by an average of 7% (0.8 µg/g bw dose) and 33% (3.1 µg/g bw dose) relative to controls. AChE enzyme levels returned to normal within 5 days after dosing ceased. Analysis of video data will assess migratory behavior, where we hypothesize that activity will be depressed and orientation patterns will be altered in exposed birds relative to controls that could persist even after the AChE levels have returned to normal. These data suggest that repeated low level exposures during important life stages such as migration warrant consideration in avian risk assessments of chlorpyrifos.

RP247 Artificial athletic turf infill associated with systematic toxicity in an amniote vertebrate
G. Xu, McGill University / Department of Chemical Engineering; N. Lin, R. Cheong, C. Ridsdale, R. Tahara, T. Du, McGill University; D. Das, Health Canada; J. Zhu, Health Canada / Environmental Health Science and Research Bureau; L.P. Silva, A. Azimzada, H. Larsson, McGill University; N. Tufenkji, McGill University / Department of Chemical Engineering

Artificial athletic turf containing crumb rubber (CR) from shredded tires is a growing environmental and public health concern. However, the associated health risk is unknown due to the lack of toxicity data for higher vertebrates. We evaluated the toxic effects of CR in a developing amniote vertebrate embryo. CR water leachate was administered to fertilized chicken eggs via different exposure routes, i.e., coating by dropping CR leachate on the eggshell; dipping the eggs into CR leachate; micro-injecting CR leachate into the air cell or yolk. After three or seven days of incubation, embryonic morphology, organ development, physiology, and molecular pathways were measured. The results showed that CR leachate caused mild to severe developmental malformations, reduced growth, and specifically impaired the development of the brain and cardiovascular system, which were associated with gene dysregulation in aryl hydrocarbon receptor, stress-response, and thyroid hormone pathways. The observed systematic effects were probably due to a complex mixture of toxic chemicals leaching from CR, such as metals (e.g., Zn, Cr, Pb) and amines (e.g., benzothiazole). The chicken embryo offers a valuable mammalian analogue to predict the effects of environmental toxicants such as CR.

RP248 Application of weathered MC252 crude oil to zebra finch (Taeniopygia guttata) eggs causes metabolic effects in embryos
C. Goodchild, Oklahoma State University / Integrative Biology; S. DuRant, University of Arkansas

Brooding birds externally exposed to crude oil can transfer oil from their feathers to the external surfaces of their eggs. Previous studies have documented that application of crude oil to the surface of bird eggs can cause embryotoxicity, yet the potential effects of sublethal crude oil application on avian embryo development are unknown. As has been
demonstrated in other taxa, embryonic exposure to crude oil can cause heart malformations. In this study, we used zebra finch (Taeniopygia guttata) eggs to examine the potential for cardiotoxicity in avian embryos after external application of crude oil to the eggshell. First, we conducted a pilot dosing experiment to determine a sublethal application. We then conducted a second experiment to measure embryonic heart rate and metabolic rate. We found that >2.5 µl of crude oil caused the embryo to become non-viable. Additionally, we detected a decrease in embryonic heart rate and metabolic rates in eggs exposed to 2.5 µl of crude oil. This study suggests that sublethal oiling of bird eggs may lead to post-hatch effects on cardiac function.

**RP249 Transcriptional profile in embryonic double-crested cormorants exposed in ovo to diluted bitumen**

S.J. Wallace, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement; S. de Solla, Environment and Climate Change Canada / Wildlife Landscape and Science Directorate; V.S. Langlois, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement

With oil transport intensifying in Canada, it is important to develop appropriate biomarkers of polycyclic aromatic compound (PAC) exposure if a spill occurs. Studying how genes change throughout early development can help to establish a baseline expression level prior to contamination as well as to identify developmental stages that may be more or less sensitive to contaminant exposure. Double-crested cormorants (Phalacrocorax auritus; DCCO) are colonial waterbirds that are increasingly being included in ecotoxicological studies and yet little is known about their transcriptome regulation during embryonic development. The research objectives of this study were 1) to establish the expression profiles of several key genes and 2) to assess the effects of PACs during DCCO embryonic development. 150 eggs were collected from Mohawk Island in Lake Erie, a relatively uncontaminated site. Eggs were artificially incubated from egg collection until 24 days of incubation. Five eggs were sampled every 4 days for a total of 6 time points. Targeted gene expression analyses indicated that in general, the expression levels of genes involved in xenobiotic metabolism were relatively non-existent early in development before the liver matures (day 12); whereas genes involved in oxidative stress defense continually increased throughout embryonic development. Therefore, we assessed the effects of polycyclic aromatic compound exposure in early embryonic DCCO before detoxification systems are fully formed. An additional 215 DCCO eggs were collected from relatively uncontaminated sites in Ontario and were injected with a dilution ranging from 1:10 to 1:10,000 of one of the diluted bitumens produced in Canada (Clearwater or Cold Lake Blend) prior to incubation. Vehicle only (corn oil) and non-injected controls were included in the experimental design. Embryos were sampled at day 12 when the liver is maturing and tissues were preserved for transcriptomic analysis. Preliminary results suggest that early developing embryos exposed to PACs have an upregulation of genes associated with xenobiotic metabolism and oxidative stress defense compared to controls. Overall, comparing transcriptional profiles in unexposed vs. PAC-exposed embryonic DCCO can assist in identifying molecular mechanisms of action and developing appropriate biomarkers for oil exposure in avian species.

**RP250 Comparison of Transcriptomic Responses to Ethinylestradiol in Two Life Stages of Japanese Quail**

Y. Jeon, McGill University / Department of Natural Resource Sciences; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; E. Boulanger, McGill University / Natural Resource Sciences; A. Farhat, Environment and Climate Change Canada; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre; O. Soufan, J. Xia, McGill University / Institute of Parasitology; J. Head, McGill University / Natural Resource Sciences

The use of toxicogenomic endpoints and increased reliance on early-life stage (ELS) animal exposures are two strategies that have been proposed to improve toxicity testing for regulatory risk assessment. However, it is unknown whether transcriptomic measures in ELS organisms are predictive of those measured in their adult counterparts. The present study aims to compare hepatic transcriptomic responses of ELS and adult Japanese quail (JQ) following exposure to ethinylestradiol (EE2). Exposures were conducted according to an egg injection protocol that we are proposing for standardization (for ELS) and USEPA OCSPP 850.2100 avian acute oral toxicity test guidelines (for adults). EE2 was dissolved in dimethyl sulfoxide and injected into the air cell of JQ embryos prior to incubation at 0, 3.33, and 33.3 µg/g egg. Adult JQ were fed a single dose of EE2 (dissolved in corn oil) at 0, 0.5, and 5 mg/kg body weight by gavage. The highest concentration was chosen so as not to exceed a 20% mortality rate. In embryos, the mortality rate was 14% at the high dose and embryo growth was significantly reduced. In adults, no adverse effects were observed at any of the administered doses. Liver tissue was collected from 5 JQ embryos per dose group at mid-incubation, and from 5-6 adult JQ per dose group 4 days after dosing. Transcript quantification, differential expression analysis and enrichment analysis were performed using the Kallisto workflow in Galaxy (galaxy.ecotoxplorer.ca), the EdgeR method in EcoToxXplorer (www.ecotoxplorer.ca), and the ClusterProfiler R package, respectively. ELS and adult JQ, respectively, showed 223 and 94 differentially expressed genes (DEGs), 11 of which were common. Fold change values were significantly correlated for these 11 DEGs between the two life stages. In 9 of the 11 common DEGs, ELS showed a higher magnitude of dysregulation than adult JQ. The neuroactive ligand-receptor interaction pathway was significantly enriched in both life stages. The results of this study contribute to the evaluation of toxicogenomics and ELS approaches as alternative toxicity testing methods, which are faster, cheaper, and more ethical, and to a large-scale Genome Canada-funded project (EcoToxChip; www.ecotoxchip.ca) aimed at transforming ecological risk assessment.

**RP251 Transcriptomic and Developmental Effects of Two Organophosphate Flame Retardants on Chicken Embryos**

Organophosphate flame retardants (OFRs) are used in a variety of products such as clear coats, resins, insulation, and plastic; therefore, research regarding their potential toxicological effects is warranted. In a previous in vitro screening study, two OFRs - isopropylphenyl phosphate (IPPP) and p-tert-butylphenyl diphenyl phosphate (BPDP) - were prioritized for whole animal toxicity testing based on their effects in cultured chicken hepatocytes. This study investigates the toxicity of BPDP and IPPP in chicken embryos at different developmental stages by measuring morphological and transcriptomic effects. Chicken eggs were injected with 0-250 µg/g of either OFR and then artificially incubated. Liver tissues were collected at day 11 (mid-incubation) and day 20 (1 day pre-hatch) for transcriptomic evaluation using a custom-designed PCR array. In addition, day 20 embryos were assessed for morphological endpoints and blood was collected for genetic sex determination. Neither compound decreased embryonic viability up to the highest concentration tested.
However, at 250 μg/g, gall bladder size was significantly decreased for both compounds, while IPPP exposure led to a reduction in head-bill length and tarsus length as well as an increase in liver somatic index. PCR array analysis revealed significant differences in gene expression for both compounds and time points with the most pronounced effects occurring at mid-incubation. Genes related to xenobiotic metabolism (e.g., CYP3A7 and ALDH1A1) showed the greatest upregulation (up to 100-fold). Given these changes observed in early-life stage avian embryos, further research into the long-term effects of IPPP and BPDP should be prioritized.

RP252 Genetic Diversity Comparison of Tree Swallow Populations in the Great Lakes Region using RNA-sequencing
C. Mansfield, C.W. Matson, C. Tseng, Baylor University / Environmental Science; S. Sanders, Indiana University, National Center for Genome Analysis Support; C.M. Custer, T.W. Custer, US Geological Survey / Upper Midwest Environmental Sciences Center; B. Papudeshi, Indiana University, National Center for Genome Analysis / National Center for Genome Analysis

The Great Lakes Surveillance Program provides the opportunity to monitor toxicogenomic responses of Tachycineta bicolor populations to legacy contamination throughout the Great Lakes region. Since 2011, nestling samples are collected, DNA/RNA extracted, and chemical extractions used to produce a contaminant profile for each site. Our lab has recently finished producing both a de novo transcriptome and a reference genome for T. bicolor, which were used for DGE and population genetic analysis. Earlier variant calling using RNA-sequencing reads yielded 66,169 single nucleotide polymorphisms (SNPs) across 144 samples. Using the intersection of several variant calling pipelines (GATK, Freebayes, Varscan, VBoost, SNPiR) producing a consensus SNPs. Approximately 20,000 SNPs were used construct a linkage map for T. bicolor, allowing for further filtering of our high-quality SNP dataset. The final set high-quality SNPs were used to calculate population heterozygosity and genetic distances between areas of concern (AOC) which aid in the construction of phylogenetic trees to identify populations with increased concentrations of mutation rates. Principal component analysis and partial least squares analyzed indicate strong separation between Waukegan, Sheboygan, and the Maumee River: three of our more contaminated sites. Random forest, ad-mixture analysis, and k-means modelling were able to distinctly identify the Western Coast of Lake Michigan and the Maumee River as separate populations from the other AOCs located in the Great Lakes Regions. These results coincide with high concentrations of PCBs, PAHs, and high DNA damage profiles. Taken together, these data suggest the influence of legacy contamination upon the genetic diversity of T. bicolor nestlings.
The Fathead Minnow Reference Genome Assembly and Annotation: Overview and Utility for Sequencing-Based Technologies

PC001 An overview of the updated and annotated Fathead Minnow genome

The Fathead Minnow (FHM; Pimephales promelas) is an important and widely used organism in aquatic toxicology. Modern ‘omics methods are being employed to characterize FHM responses to toxicants, and the genetic basis of differences in stressor susceptibility. These efforts have been hampered by the lack of a reference genome sequence or a complete collection of annotated full-length gene models for FHM. Assembly of the genome has been difficult due to the highly repetitive and polymorphic nature of the genome, which in turn interfered with development of gene models. Recent advances in long-read DNA sequencing, assembly algorithms and scaffolding technologies have allowed us to generate a more complete, more contiguous genome assembly. This assembly provided the basis for identification and classification of repetitive elements across the FHM genome. We also conducted mRNA of multiple developmental stages and tissues as well as more limited small-RNA sequencing, facilitating delineation of protein coding and non-coding genes. This FHM gene collection allowed us to explore the effects of different RNA-sequencing parameters and other experimental choices on the performance of RNA-seq used for gene expression profiling. We also compared the performance of RNA-seq and microarrays for developing gene expression-based multivariate classifiers of toxicant exposure. Subsequently, we used RNA-seq to evaluate the effects of using various fish ages and durations of exposure on the sensitivity, specificity and functional interpretability of observed gene expression changes after toxicant exposure. We also compared results from mRNA sequencing with miRNA sequencing and mRNA 3′-end targeted sequencing on cost/performance trade-offs of multi-gene toxicant detection assays developed using those types of data.

PC002 De novo assembly of a highly contiguous genome reference of the fathead minnow (pimephales promelas)
W. Huang, A. Biales, D.C. Bencic, US Environmental Protection Agency / ORD/NERL/EMMD; J. Martinson, US Environmental Protection Agency / ORD; W. Huang, G. Toth, R. Flick, US Environmental Protection Agency / ORD/NERL/EMMD; M. See, US Environmental Protection Agency / Office of Research and Development; M. Kostich, USEPA / ORD/NERL/EMMD

The Fathead minnow (Pimephales Promelas), found in most surface water across North America, is an important model organism widely used in both aquatic toxicology research and regulatory testing. To meet research needs for a genome reference, the first draft genome reference (NCBI accession: INCDD000000000) of the fathead minnow was made available in 2015 through a joint effort by DuPont, EPA and the University of Illinois. This first draft genome reference, assembled from short-Illumina reads, however, is incomplete (33.5% N content) and highly fragmented (contig N50 7468b), which can make it difficult if not impossible to obtain full results/conclusions of many omics-based genome-wide studies as relevant genome regions/genes could be missing or split into multiple fragments. As omics-based technologies (RNA-seq, RRBS) are increasingly used for aquatic toxicology and exposure research, it has become a pressing issue for the environmental research community. To address this issue, we carried out the de novo assembly of the fathead minnow genome using the latest genome sequencing technologies and assembling methods. We used the PacBio long reads for the initial de novo assembly, Bionano optical mapping data for hybrid assembly, and Hi-C data for the final scaffolding of the fathead minnow genome assembly. In total, we generated about 70X raw PacBio reads, 113X (effective coverage) Bionano optical mapping data, and 428 million 2x150bp read-pairs of Hi-C data for this project. Additionally, we obtained two sets of Illumina paired-end reads for genome assembly polishing and two sets of Illumina mate-pair reads for assembly scaffolding. We tested multiple different assemblers including CANU and FALCON/FALCON-Unzip, which are the top two assemblers for long PacBio reads. We then used BUSCO to evaluate different assemblers. Our evaluation showed that the FALCON assembler achieved the largest contig N50, however, the CANU assembler performed the best in terms of the complete and single gene coverage BUSCO score. Using our CANU-based assembly pipeline, we successfully assembled a highly contiguous and almost complete fathead minnow genome reference, of which the total size is 1.2Gb with scaffold N50 reaching 13.5Mb (contig N50 0.3 Mb), and the percent complete BUSCOs is 95.1% with only 3.3% duplication. This genome reference as well its complete annotation will be publicly available at NCBI and Ensembl genome databases.

PC003 Annotation of Small Non-coding RNAs From Pimephales promelas, The Fathead Minnow
G. Toth, A. Biales, US Environmental Protection Agency / ORD/NERL/EMMD; J. Martinson, US Environmental Protection Agency / ORD; W. Huang, D.C. Bencic, R. Flick, US Environmental Protection Agency / ORD/NERL/EMMD; D.L. Lattier, M. Kostich, USEPA / ORD/NERL/EMMD

The update of the genome assembly for the fathead minnow (FHM), Pimephales promelas, presented an opportunity to predict and annotate elements of the small non-coding RNA world including transfer RNA (tRNA), ribosomal RNA (rRNA), microRNA (miRNA), piwi-interacting RNA (piRNA), small nuclear RNA (snRNA) and small nucleolar RNA (snoRNA). While the report of numbers of some of the structural and catalytic RNAs (rRNA, snRNA, snoRNA) is of interest for comparison across species as a general biological resource, data are needed on other types of small non-coding RNA (smRNA) that are becoming recognized as critical factors in gene regulation (piRNA, miRNA, tRNA), and, as such, present themselves as candidates for stressor exposure and effects indicators, either as stand-alone indicators or potentially integrated into fuller differential expression studies with mRNAs. tRNAs were detected ab initio based on primary and potential secondary structure using the newly updated genome assembly c18phphsho.fa and the program tRNAscan-SE. The Infernal program, using the new assembly and referencing Rfam (version 14.0), a database of RNA families, detected tRNAs, snRNAs, and snoRNAs as well as confirmed the tRNAs from tRNAscan-SE analysis. Two of the three types of small interfering RNAs, miRNAs and piRNAs, were detected with programs requiring both the FHM assembly and smRNAseq data. TruSeq smallRNA preps were done on brain (male and female), liver (male and female), 8 day post fertilization (4 day post hatch) fry, and unfertilized eggs, and sequenced (Hi-Seq (~ 30M reads/sample). Sequence data mapped to zebrafish (Danio rerio) miRNAs from miRbase.org (56%) and piRNAs from regulatoryRNA.org (11%). FHM piRNAs were identified using Piano, a program directed toward prediction of transposon-related piRNAs, while additional piRNAs were to be identified using piRNN, a neural-network program that can predict piRNAs more globally (e.g., non-transposon miRNA targeted) after training with FHM tRNAs, miRNAs and existing piRNAs. The state of small non-coding RNA in the FHM will be described in the context of general teleost and mammalian small mRNA resources as well as the potential for integrated study in an ecotoxicology context.
PC004 Development and Annotation of Protein Coding Gene Models for the Fathead Minnow Genome

J. Martinson, US Environmental Protection Agency / ORD; W. Huang, PC004 Development and Annotation of Protein Coding Gene Models for the Fathead Minnow Genome

The importance of the Fathead minnow in aquatic toxicology is demonstrated by the thousands of publications on the subject over the last four decades. To make the new assembly of the Fathead genome truly useful, the genomes features must be identified and annotated. Probably the most important features to annotate are the protein coding genes. Exploration of the protein coding gene space is fundamental to developing an understanding of the biological activity occurring at the molecular level within an organism in response to the environments it inhabits. A hybrid approach was employed to develop gene models for the new assembly. Two popular genome annotation pipelines, Maker2, and the Program to Assemble Spliced Alignments/Evidence Modeler (PASA/EVM) were each used to produce protein coding gene models. The ~37.2K PASA/EVM models were fed back into Maker2, primarily to update the Untranslated Regions (UTRs) of their transcript models to improve the mapping rates of RNA-seq reads to the transcript models. The Maker2 adjusted output resulted in ~25.6K gene models. PASA/EVM models that were not involved in the construction of the 25.6K Maker models and that showed no overlap with the Maker models were returned to the model set, resulting in ~36.9K gene models. The 36.9K models were then filtered based on several criteria; apparent presence of BUSCO protein coverage of ~93% (~86% single copy) and RNA-seq-to-annotation homology to reference proteins, and RNA-seq mapping rates. After filtering a final set of ~26.5K models remained, which exhibited complete BUSCO protein coverage of ~93% (~86% single copy) and RNA-seq-to-annotation mapping rates approaching 80%. The results compare favorably with the reference genome of the well-studied and closely related zebrafish, which currently is believed to have ~26K protein coding genes. Gene names and additional annotations were assigned to the models based on subsequent phylogenetic analysis (presented separately). The current set of Fathead gene models will allow detailed exploration of the effects of toxic substances on Fathead minnows and usher in the long-promised era of a deeper, omics-based, understanding of changes that occur at the molecular level due to exposure to different environments. This presentation will provide the details of the process used to develop the gene models and provide updates on the final number of gene models and their relevant statistics.

PC005 Characterizing changes in molecular toxicity pathways to predict adverse outcomes of fluoxetine in adult fathead minnows

C.D. Colville, S.H. Malala Irugal Bandaralage, U. Fuchylko, A.J. Alcaraz, A.J. Masse, University of Saskatchewan / Toxicology; D. Cramp, Environment and Climate Change Canada / National Wildlife Research Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

Fluoxetine (FLX) is the most common selective serotonin reuptake inhibitor pharmaceutical used for the treatment of psychological disorders such as depression and anxiety. Increased prescription use of FLX by human populations has led to its pseudo-persistence in effluent-receiving waterways. Despite its emerging concern as a threat to the aquatic environment, there is currently limited information on effects of FLX, including its specific mechanism of action and the associated toxicity pathways in fish. The main goal of this study is to identify and validate key molecular toxicity pathways that are predictive of apical endpoints induced by exposure to FLX using the fathead minnow (Pimephales promelas), a model species common to North American freshwater systems. Adult fathead minnows were exposed to three concentrations of FLX (7.81, 31.25, & 125 µg/L) and a control for 21 days. After 96 hours, a subset of fish were sampled and liver and brain tissue were collected to characterize molecular toxicity pathways using whole transcriptome, whole proteome and targeted metabolomic analyses. In addition, At the end of the 21-day exposure, individuals were assessed for apical outcomes of regulatory relevance including histopathology, gross morphology, fecundity, and altered secondary sex characteristics. Differential gene expression analysis revealed dysregulation of liver and brain transcripts in male fathead minnows, especially in pathways involved in protein transport processes. A parallel study conducted in our lab found a similar expression pattern in early-life stage fathead minnows. During the final seven days of the 21-day exposure, the fish treated with the highest dose showed a dramatic decrease in fecundity, indicating that chronic FLX exposure could have implications on reproductive success. Correlation analysis of physiological outcomes with early molecular response patterns is ongoing with the goal to establish molecular toxicity pathways that can be used to predict apical outcomes in addition to a better understanding of the environmental relevance of FLX. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

PC006 Assessing risks of selenomethionine toxicity in the fathead minnow using semi-quantitative modeling

D. Green, University of Saskatchewan / Toxicology; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; K. Liber, University of Saskatchewan / Toxicology Center; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; J.A. Alcaraz, University of Saskatchewan / Toxicology Centre; T. Lane, University of Saskatchewan; K. Raes, University of Saskatchewan / Toxicology; K. Bluhm, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre; A. Mangold-Döring, Wageningen University & Research / Environmental Sciences; M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

Selenium (Se) is an atomic element and essential micronutrient released to the environment from natural (ex. volcanic) and anthropogenic (ex. coal mining) activities. Once released, Se oxyanions are taken up by primary producers and biotransformed to the organic form “selenomethionine” (SeMet). Where Se concentrations are elevated, Se is bioaccumulated due to the dose-dependent substitution of SeMet for its biochemical analogue, the essential amino acid, methionine. SeMet can then be maternally transferred to the ova of oviparous animals resulting in teratogenesis and impaired recruitment, likely due to oxidative stress resultant from SeMet metabolism during embryogenesis. Current guidelines indicate whole-body, muscle, or egg/ovary Se concentrations of concern in fish; however, this approach only allows for retrospective risk assessment. The purpose of this study is therefore to use a model species (fathead minnow; Pimephales promelas) to develop a semi-quantitative model capable of predicting SeMet toxicity before it occurs. Adult fish were exposed for 28 days to control (1.18 µg Se/g; background Se), and sublethal low (3.88 µg Se/g), medium (8.75 µg Se/g), and high (29.6 µg Se/g) Se doses via diet (administered as SeMet). Fish were sampled for chemical analysis at days 4, 10, and 28 of exposure, as well as day 35 after one-week of depuration to validate a literature-derived toxico-kinetic model intended to predict tissue concentrations of concern based on oral exposures. Samples were also collected on day 4 for hepatic transcriptomic and proteomic analyses, and on day 28 for hepatic biochemical analysis, in order to derive a sensitive qualitative model of SeMet toxicity in fathead minnows under an adverse outcome pathway framework. Chemical analyses have confirmed muscle Se concentrations near or above those associated with adverse outcomes, and biochemical and transcriptomic results indicate non-significant decreases in hepatic oxidative stress and significant dysregulation of drug metabolism transcripts, respectively. Results thus far suggest this modeling approach may aid in the prospective assessment of SeMet risk posed to the fathead minnow. In future applications, these data are also intended
to help improve regulatory oversight by informing the development of the EcoToxChip (www.ecotoxchip.ca), a high throughput qPCR screening tool for assessing the effects of uncharacterized chemicals released to the aquatic environment in quantities of concern.

**PC007 Determination of an Optimal Age and Duration of Exposure of Larval Fathead Minnows for Gene Expression-based Studies**

R. Flick, D.C. Bencic, M. Kostich, A. Biales, US Environmental Protection Agency / ORD/NERL/EMMD

As genomic-based methods continue to play a greater role in the field of ecotoxicology, attention must be given to the appropriate design of studies. Exposure regimes often appear to be based on existing acute and chronic testing methods, which were designed for entirely different classes of endpoints. Very little work has been done to thoroughly evaluate the effect of exposure regime on genomic endpoints. In order to systematically study this issue, we exposed fathead minnow larvae at three different ages (48, 72 and 96 hours post fertilization) for three different durations (6, 24 and 48 h) to several compounds under static renewal conditions. Chemicals were selected to act along different MOA and have different target tissues. Using RNA-sequencing, we evaluated the global transcriptional profiles of the fish to determine the age and duration that provided the most interpretable and specific transcriptional response. The expression profiles at different ages and durations were found to be chemical-specific, with no one age-duration combination being the best. Based on our findings, we provide suggestions for the design of omics-based ecotoxicological experiments using larval fathead minnows.

**PC008 Fluoxetine-induced molecular toxicity pathways in early-life-stage fathead minnows**

A. Alcaraz, University of Saskatchewan / Toxicology Centre; C. Burbridge, University of Saskatchewan / Global Institute for Food Security; T. Lane, University of Saskatchewan; D. Schneider, University of Saskatchewan / Global Institute for Food Security; N.S. Hogan, University of Saskatchewan / Department of Animal and Poultry Science and Toxicology Centre; D. Crump, Environment and Climate Change Canada / National Wildlife Research Centre; N. Basu, McGill University / Faculty of Agricultural and Environmental Sciences; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

Fluoxetine (FLX) is a highly prescribed selective serotonin reuptake inhibitor (SSRI) commonly found at sub-therapeutic levels in surface waters mainly through wastewater and sewage treatment effluents. There is significant concern regarding the presence of FLX in the aquatic environment due to its ability to induce inadvertent sub-lethal effects in aquatic organisms exposed at low concentrations. However, there is limited understanding regarding the effects of FLX to aquatic organisms, particularly with regards to molecular mechanism(s) of toxicity in non-target, non-mammalian species. Advances in ‘omics technologies can improve our current understanding of FLX toxicity as these technologies offer high-throughput and cost-effective approaches to examine mechanisms of toxicity. Therefore, the objective of this study was to characterize molecular toxicity pathways associated with FLX toxicity in fish using sequence-by-synthesis whole transcriptome analysis. Early-life stage fathead minnows (Pimephales promelas) were exposed to graded concentrations of FLX (31.25, 7.81, 1.98 µg/L) and a water control immediately after fertilization. Embryos were collected four days post-hatch and differential gene expression (DGE) was evaluated. Reads were aligned against the latest FHIM genome assembly and a p< 0.05 cut-off false discovery rate was used to identify differentially expressed transcripts between FLX and control groups. Interestingly, a more pronounced and consistent across-replicate response was observed in the 7.81 µg/L treatment group compared to the 31.25 µg/L treatment group, with 78 and 8 differentially expressed transcripts, respectively. Gene set enrichment and pathway analysis using ontologies based on zebrafish in KEGG and GO Consortium showed a total of 40 perturbed pathways in the 7.81 µg/L treatment group, including those associated with growth and development, morphogenesis, regulation of tight junctions, metabolism, and cardiovascular disorder. The results of this study will be integrated with other ‘omics endpoints to identify closely regulated pathways perturbed across biological levels with the end goal of identifying molecular toxicity pathways that are indicative of adverse effects to predict apical outcomes. This study is part of the EcoToxChip project (www.ecotoxchip.ca).

**Plastic Pollution Research and Solutions**

**PC009 Identification of Microplastics in Surface Water and Australian Freshwater Shrimp in Victoria, Australia**

B. Nan, CAPIM, The University of Melbourne / School of Biosciences; L. Su, CAPIM, The University of Melbourne; M.J. Keough, The University of Melbourne / School of Biosciences; C. Kellar, AQUEST RMIT University; V. J. Pettigrove, RMIT University / Sciences

Compared to marine microplastics studies, there is little research into biomonitoring of microplastics in inland waters. It is also important to understand the microplastics’ uptake and their potential risks on freshwater species. The Australian glass shrimp *Paratya australiensis* (Family: Atyidae) are commonly found in freshwater waterbodies in the eastern part of Australia, a sensitive to anthropogenic stressors but have a wide tolerance range to the natural environmental conditions. This study monitored microplastics across 10 non-industrial sites in water samples and in the shrimp *P. australiensis* in Victoria, try to understand the microplastics’ occurrence, types and biomonitoring’s efficiency. In total, 30 water samples and 100 shrimp individuals were analysed, and shrimp body weights, sizes and gender were determined. Microplastics were picked, photographed and identified using FT-IR microscopy. In water samples, items were randomly selected to identify; all microplastics found in shrimp samples were identified. Results showed water samples had microplastics’ occurrence in each site, with an average abundance of 0.40±0.27 items/L. Shrimp had an average of 0.52±0.55 items/ind (23.73±30.77 items/ind, 35.9% of them displayed microplastics. Fibers were the most common shape and blue was the most frequent colour in both water and shrimp samples. The dominant plastic type in water samples was polyester, and in shrimp samples was rayon. Even though this study shows a relatively low concentration of microplastics in comparison with global studies, it is worth noticing microplastics in clean sites were still significantly presence in Australia. Compared with water samples, shrimp samples contained a wider variety of plastic types, suggesting they have the potential to be a passive sampler to detect microplastics’ pollution in freshwater environments.

**PC010 Microplastic in Polychaetes from the Norwegian Continental Shelf**

J. Cyvin, Norwegian University of Life Sciences (NMBU); H. Knutsen, Norwegian Geotechnical Institute; T. Mørkeland, DNV Kema; A. Pettersen, Norwegian Geotechnical Institute; H. Arp, Norwegian University of Science & Technology / Environmental Technology

Little is known about the presence and effect of microplastics on the seabed and its biological communities. More knowledge about microplastic in relation to benthic fauna is vital to gain further understanding. Polychaetes are present in most benthic environments and are often used as indicator organisms to investigate the impacts of anthropogenic activities and pollutants. Polychaetes have several roles in ecosystems, including the transport of sediments, organic matter and nutrients, between the water column and the upper layer of sediments. Studies on microplastics in polychaetes are only just emerging, but initial studies report microplastics in nearly all samples. In laboratory experiments, polychaetes were found to contribute to fragmentation of microplastics. Here we present a study of microplastics in the polychaete *Owenniida*, and their surrounding sediments, sampled from the Norwegian continental Shelf and the Barents Sea. The sampling areas include both remote areas and nearby offshore oil and gas installations, hundreds of kilometers off.
because each polymer has different chemistry, uses, disposal processes, and Polymer identification is now expected in plastic pollution studies, Research; C. King, Sharkastics J. Lynch, National Institute of Standards and Technology; W. beach plastic marine debris into the aquatic environment. polymer matrices and the release of potentially harmful polymer additives are necessary to elucidate the relationship between nanoparticles within microplastic particles significantly increased leaching of Bisphenol aqueous environment. Results have shown UV exposure and formation of these polymer additives into the environment and their ecotoxicological effects. However, few studies have investigated how the inclusion of carbon nanomaterials in polymer matrices can impact the release of associated polymer additives. Polymer additives may be released through mechanisms of pH-mediated polymer hydrolysis, oxidation, UV degradation, mechanical abrasion, and thermal degradation, among other mechanisms. The release of these additives from microplastic composites into the aquatic environment are of concern due to the known endocrine-disrupting activity of additives such as Bisphenol A and nonylphenol. In this study, a 5 day leaching experiments of cryomilled epoxy containing varying loadings of carbon nanotubes (0, 0.01, 0.05, 0.1%) was completed. The polymer additives that were studied were Bisphenol A (BPA), Bisphenol A diglycidyl ether (BADGE), 4-tert-butylphenol (TBP), 4-tert-butylphenol glycidyl ether (TGBE) and Nonylphenol. The epoxy was incubated in water under dark conditions, and at temperature of 65 °C. This experiment was repeated with epoxy and epoxy microcomposites exposed to 14 days of 750 Watt UV exposure. Daily measurements of polymer additive concentrations in water were made using LC-MS/MS methods to investigate the influence of epoxy surface area, carbon nanotube loading, and UV exposure increase the release of these polymer additives into an aqueous environment. Results have shown UV exposure and formation of microplastic particles significantly increased leaching of Bisphenol A from epoxy microcomposites. However, CNT loading significantly decreased BPA leaching from epoxy microcomposites. Further studies are necessary to elucidate the relationship between nanoparticles within polymer matrices and the release of potentially harmful polymer additives into the aquatic environment.

PC011 The influence of ultraviolet light on release of polymer additives from epoxy-CNT nanocomposite microplastics into the aquatic environment

I. Walker, Duke University / Civil and Environmental Engineering; M.D. Montaño, Western Washington University / Environmental Sciences; L. Ferguson, Duke University / Civil and Environmental Engineering

Engineered nanomaterials and nanoparticles are increasingly used in consumer products due to their properties and ability to be incorporated into performance composites. Nanoparticles such as carbon nanotubes are placed into polymer matrices to improve tensile strength, UV inhibition, flame resistance, electrical and thermal conductivity and reduce gas permeability. Many studies have investigated the impact of release of these nanoparticles into the environment and their ecotoxicological effects. However, few studies have investigated how the inclusion of carbon nanomaterials in polymer matrices can impact the release of associated polymer additives. Polymer additives may be released through mechanisms of pH-mediated polymer hydrolysis, oxidation, UV degradation, mechanical abrasion, and thermal degradation, among other mechanisms. The release of these additives from microplastic composites into the aquatic environment are of concern due to the known endocrine-disrupting activity of additives such as Bisphenol A and nonylphenol. In this study, a 5 day leaching experiments of cryomilled epoxy containing varying loadings of carbon nanotubes (0, 0.01, 0.05, 0.1%) was completed. The polymer additives that were studied were Bisphenol A (BPA), Bisphenol A diglycidyl ether (BADGE), 4-tert-butylphenol (TBP), 4-tert-butylphenol glycidyl ether (TGBE) and Nonylphenol. The epoxy was incubated in water under dark conditions, and at temperature of 65 °C. This experiment was repeated with epoxy and epoxy microcomposites exposed to 14 days of 750 Watt UV exposure. Daily measurements of polymer additive concentrations in water were made using LC-MS/MS methods to investigate the influence of epoxy surface area, carbon nanotube loading, and UV exposure increase the release of these polymer additives into an aqueous environment. Results have shown UV exposure and formation of microplastic particles significantly increased leaching of Bisphenol A from epoxy microcomposites. However, CNT loading significantly decreased BPA leaching from epoxy microcomposites. Further studies are necessary to elucidate the relationship between nanoparticles within polymer matrices and the release of potentially harmful polymer additives into the aquatic environment.

PC013 With growing plastic production, how do we identify sources of pre-production pellets and hold parties responsible for spills and releases?

J.L. Conkle, Texas A&M University, Corpus Christi / Physical and Environmental Sciences

Plastics are essential in our society. They serve many purposes while improving safety and reducing costs. Because of these benefits, their production is growing by >12 million tons annually across the globe. Production in North America grew an average of 0.75 million tons between 2000 and 2016 (48 to 60 million tons) but jumped 4.4 million tons in 2017. This is the start of an upward trend on the continent, with many new pellet plants planned in the U.S. Texas with its ports and nearby oil and gas extraction is leading this growth, where the city of Corpus Christi anticipates opening the two largest polyethylene terephthalate plants in the world before 2024. Coastal Texas is already home to numerous plants that ship their product globally. This current production and its shipping has resulted in the ubiquitous presence of pellets in several bays as well as the entire Texas Seashore. Contamination is particularly high in the Matagorda/Lavaca Bay system, which is home to a polyethylene and polypropylene manufacturer. A local citizen group is suing the manufacturer under the Clean Water Act after collecting over 2,000 samples documenting pellets and plastic powder. They are asking the Court to order changes at the plant to stop the future discharges and are asking that penalties be assessed against the company (these go to the federal government). They are awaiting the Judge’s verdict in the first phase to determine if their permit was violated. If found liable a second trial phase will occur to determine the remedy. The permit language at the heart of the lawsuit states that they shall not discharge pellets at more than “trace amounts.” 171 - 1,658 tons or 7.5 - 75 billion plastic pellets have been obtained from diverse polymer reference materials and determined that microplastics >=0.03 mg can be accurately identified. Polymer identification of marine debris is complicated and a multiple-method work flow is required for complete and accurate identifications.

PC012 A deep dive into polymer identification methods for Hawaiian beach plastic marine debris

J. Lynch, National Institute of Standards and Technology; W. Weatherford, R. Wagner, Chevron Phillips Chemical Company LP; M. Jung, K. Brignac, Hawaii Pacific University / Center for Marine Debris Research; C. King, Sharkastics

Polymer identification is now expected in plastic pollution studies, because each polymer has different chemistry, uses, disposal processes, environmental fates, additive chemicals, affinities for contaminants, thus potentially different impacts on marine organisms. This study further evaluated the most common tool for polymer identification of meso-sized plastic pollution, attenuated total reflectance Fourier transform infrared spectroscopy (ATR FTIR). We expect ATR FTIR will remain the primary tool, but researchers should know its limitations. In 2018, we presented that this method can miss multi-layer composites because it measures only the top 1-2 um surface. The current study assessed additional limitations and solutions. Firstly, we mistakenly listed the same absorbance bands for acrylonitrile butadiene styrene (ABS) and polystyrene (PS) in Jung et al (2018). The acrylonitrile band at 2235 cm⁻¹ was present in ABS and absent in PS standards we analyzed and is necessary to differentiate the two polymers. Also, 24 samples of Hawaiian beach plastic debris that had been tentatively identified by ATR FTIR were examined with three additional methods: total transmission FTIR of heat pressed thin films of each sample, differential scanning calorimetry (DSC), and microscopic assessment of layers from thin sliced cross sections. Multiple polymers were discovered in 15 (63%) samples, and ATR FTIR alone revealed only four (27%) of these. Sixteen samples identified as low density polyethylene (LDPE) by ATR FTIR were analyzed by DSC to definitively differentiate PE densities. Correct identification success by ATR FTIR was dependent on the extent of weathering. All four of the least weathered samples were correctly identified as LDPE by ATR FTIR, whereas all of the severely and 57% of the moderately weathered ones were actually high density (HDPE). The 1377 cm⁻¹ band in the ATR FTIR spectra is unreliable in weathered PE samples. Weathering of HDPE appears to increase branching, resulting in a band at 1377 cm⁻¹ which is typically only expected in highly branched LDPE. We provide DSC melt curves obtained from diverse polymer reference materials and determined that microplastics >=0.03 mg can be accurately identified. Polymer identification of marine debris is complicated and a multiple-method work flow is required for complete and accurate identifications.
scientific community will be called on to provide expertise in tracking the path of pre-production plastics, identifying the source of the discharges and spills and explaining the harm to the ecosystem.

**PC014 Assessing the impacts of microfibers to a sediment-dwelling benthic invertebrate**

*L. Erdle, University of Toronto / Department of Ecology and Evolutionary Biology; T. Watson-Leung, Ministry of the Environment, Conservation and Parks / Aquatic Toxicology Unit; S. Athey, University of Toronto / Earth Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences; C. Parzanini, M.T. Arts, Ryerson University / Department of Chemistry and Biology; C.M. Rochman, University of California, Davis / Department of Ecology and Evolutionary Biology*

Microfibers (anthropogenic fibers < 5mm in size) are ubiquitous in sediment, surface water, and wildlife globally. Research shows negative effects of synthetic microfibers on organisms, including impacts to growth, feeding behaviour, and hepatosomatic index. Researchers have also documented microfiber persistence in the environment; even natural microfibers may persist for months to years. However, knowledge is lacking on the chronic effects to biota from microfiber exposure and whether these effects differ according to exposure to synthetic versus natural microfibers (i.e. polyester and cotton). Our research explores the effects to freshwater aquatic biota from exposure to polyester and cotton microfibers. A chronic life-cycle toxicity test was conducted using the midge Chironomus dilutus. Since Chironomus sp. are sediment-dwelling organisms, they are directly exposed to microplastic accumulation in sediment. We exposed C. dilutus to “clean” cotton and polyester microfibers plus each type of microfiber soaked in wastewater final effluent to examine the effect from the addition of a chemical mixture. Acute exposures (10 d) evaluated biological uptake of microfibers, with results of longer-term exposures (56 d) assessed to determine the effects of microfibers by investigating individual growth and survival, time to emergence, sex ratio, reproductive success, and survival of offspring. We hypothesize that effects on C. dilutus differ according to microfiber type and exposure to the wastewater treatment chemical mixture. Methods for preparing microfiber diets and results of these investigations will discuss techniques to expose organisms via treatment diets. Preliminary results show biological uptake of microfibers by C. dilutus, and ingestion of microfibers >1mm in length. Our study will contribute to a better understanding of organismal and population-level effects on a freshwater species exposed to microfibers and associated chemicals. Results of this work will be considered in conjunction with other ongoing work testing the same microfibers and mixtures on other aquatic species, including rainbow trout (Oncorhyncus mykiss) and fathead minnow (Pimephales promelas) to look for patterns of similarity among different taxa.

**PC015 Microplastic Consumption and Excretion by Fathead minnows (Pimephales promelas): Is it dependent on particle size and organism body shape?**

*M. Felix-Kim, T. Hoang, Loyola University, Chicago / Institute of Environment and Sustainability*

The present research characterizes the dependence of microplastic consumption and excretion on particle size by fathead minnow (Pimephales promelas) over time that has not been studied. Specifically, the study is to answer 4 important questions: 1) how long does it take for larval fathead minnow to consume microplastic particles and what particles size? 2) How long does it take for the organism to excrete microplastic particles after consumption? 3) Will fathead minnow reconsume microplastic particles after excretion? 4) Are consumption and excretion dependent on the size of particles and body shape of organisms? To answer these questions, larval fathead minnow (2-3 day old) were exposed to polyethylene microbeads (PMBs) at two different consumable size ranges of 63-75µm and 125-150µm in moderately hard water. The experiments were designed to allow fish to reconsume the particles that they excreted and not to reconsume the excreted particles by transferring fish to new water every 30 minutes. Results of this study found that fathead minnow consumed significant amount of PMBs after 1h of exposure to 25 mg/L regardless the particle size. The number of consumed PMBs at smaller size range (4.5 PMBs/fish) was up to 10 times higher than that at the larger size range (45 PMBs/fish). After consumption, fish excreted the PMBs over time. For the case of allowing reconsumption, fish started to reconsume the excreted PMBs after 3h regardless the particle size. When reconsumption is not allowed, fish completely excreted 125-150µm PMBs after 12h but it took more than 24h for fish to completely excrete the 63-75µm PMBs. The excretion rate was 3 times higher for 125-150µm PMB (0.182) than for 63-75µm PMB (0.059). Interestingly, it took longer time for bent body fish to excrete PMB than regular straight fish. These results indicate that smaller size particles remain in the fish gut for longer time and hence could have higher potential effect to fish than larger particle size. Our observation showed that excreted PMBs were likely coated with organic substances that stuck the particles together and sunk on the bottom of the exposure chambers. This result suggests that in the nature environment, consumption of plastics by fish can facilitate the movement of plastics from the water column to the sediment. Plastic particles can adsorb hydrophobic organic contaminants from the sediment and can carry them to benthic organisms when plastics are consumed.

**PC016 Gastrointestinal mediated impacts on lipid metabolism following chronic exposure to a phthalate plasticizer in zebrafish**

*A. Buerger, University of Florida / Environmental and Global Health; J. Harris, C.E. Parente, University of Florida; C.J. Martyntyuk, University of Florida / Physiological Sciences; J.H. Bisesi, University of Florida / Environmental and Global Health*

Plastic pollution is an emerging global threat to humans and wildlife. Upon ingestion of plastics, leaching of chemical components can occur in the organism. Diethylhexyl phthalate (DEHP) is a plasticizer that leaches from food containers and PVC breakdown products, resulting in exposure of both humans and wildlife. Evidence suggests that DEHP and other phthalates may alter metabolic processes, particularly when exposed in conjunction with overfeeding, which may be contributing to the increasing obesity epidemic over the last forty years. These effects may be modulated by peroxisome proliferator activated receptors (PPARs), a family of nuclear receptors known to be involved in lipid metabolism and adipogenesis. Using in vitro PPARα transactivation assays, we have demonstrated that though zebrafish PPARα activation by DEHP, and its primary metabolite monoethylhexyl phthalate (MEHP), is less sensitive than humans, these fish are still susceptible to the endocrine disrupting effects of these chemicals. To determine downstream impacts of PPARα activation by DEHP we conducted a 60 day feeding study with adult zebrafish (Danio rerio) which exhibited decreased expression of PPARα in gut tissue, and increased expression of PPARγ in the liver, suggesting these receptors are sensitive to DEHP exposure, however there were no impacts on body mass in these fish. Therefore, we hypothesized that early life stage exposure may result in phenotypic responses to DEHP since PPARs are intimately involved in early adipogenesis. We chronically exposed larval zebrafish to DEHP exposure (6 months) to evaluate the potential for altered lipid metabolism, starting at 3dpf to one of four treatments: Control, Overfed, Regular Fed + DEHP (3ppm), and Overfed + DEHP (3ppm). Lipid staining was conducted at 10dpf, 12dpf, and 15dpf to monitor adipogenesis. At 24 weeks, zebrafish were euthanized, and gut, liver and fecal matter were excised. Differences in expression of PPARα, PPARβ, and PPARγ were monitored at 10dpf, 12dpf, 15dpf, 4 weeks, 12 weeks and 24 weeks. To examine whether alterations in lipid metabolism lead to alterations in body composition and physical fitness, a swim tunnel assay was utilized to assess swimming performance and maximal respiratory capacity. These results demonstrate the need to understand the effects of chemicals leaching from ingested plastics, and the role these chemicals may play in population level outcomes, such as obesity.
Endocrine Disruptors, CECs and Agriculture in Developing Countries: The Nexus Bridging Environmental and Human Health

PC017 Insecticide treated mosquito net fishing in Zambia: A case study for the importance of one health approaches to public health interventions

J.H. Bisesi, T.N. Patel, University of Florida / Environmental and Global Health; D.A. Larsen, R. Welsh, Syracuse University / Public Health, Food Studies and Nutrition

Insecticide treated mosquito nets (ITNs) are considered to be a great public health success story, saving millions of lives in areas with endemic mosquito borne infectious diseases. ITNs are typically treated with pyrethroid insecticides that are effective at killing mosquitos but exhibit little toxicity to humans. While ITN distribution programs are common in areas of sub-Saharan Africa, studies have indicated that utilization of ITNs lags behind distribution, which has fueled speculation of alternative uses of the ITNs. For example, recent evidence from our team, based on qualitative interviews, found that ITNs are regularly used for seine fishing in regions of western Zambia. Participants also reported co-occurring declines in fish catch quality and quantity in areas with ITN fishing. However, little work has focused on understanding whether ITNs contribute to declines in fish population, either through the small mesh size removing vulnerable young of the year from the population, or through bioaccumulation and toxicity associated with insecticides that coat the nets. To begin to address the latter, exposure experiments were conducted with embryonic and larval fathead minnows (Pimephales promelas). Fish were exposed varying areas of ITNs (0, 1, 5, 10, and 20 cm²/ITN) in 300 ml of moderately hard water for 96 hours (embryos) and 7 days (larvae). Fish were monitored daily for any morbidity or mortality associated with exposure. At the end of the experiment fish were weighed to determine growth. Results indicated that even small areas of ITN (1 cm²) impact growth of larval while larger nets cause overt toxicity. Additional experiments are ongoing to examine leaching rates from nets and impacts on endocrine specific endpoints. Result from these studies are currently being used to demonstrate the issues associated with this practice and establish community partnerships with the local traditional hierarchical tribal leadership in hopes of curbing these practices. This study highlights the need to take a holistic, one health approach when implementing public health interventions in developing countries to ensure we protect human health without adversely impacting the environmental resources that drive economic prosperity and nutritional needs in these areas.

PC018 A Comparative Study of Contaminants of Emerging Concern Occurrence and Hazards in Two Major Wastewater Treatment Plants, Taipei, Taiwan

S.R. Burket, Baylor University / Environmental Science; J. Zheng, S. Chung, Hong Kong Baptist University; B.W. Brooks, Baylor University / Department of Environmental Science

Over the next few decades, the most populated cities will face increasing demand for sustainable water quality; however, diverse gradients of wastewater treatment capacities exist throughout Asia. This consideration is increasingly important because the majority of the world population and highest number of megacities are now located in Asia. For example, Taipei, Taiwan ranks among the most densely populated cities globally. We performed an initial study of the occurrence and associated water quality hazards of contaminants of emerging concern (CECs) in Taipei. We specifically evaluated 23 CECs in influent and effluent of two wastewater treatment plants with different treatment technology over two sampling seasons: the 2015 summer monsoon season, and the 2016 winter dry season. We also investigated whether temporal differences in CECs occurrence and hazards existed among and between the two plants. On each sampling event, analytes were extracted, separated and analyzed following previously reported methods using solid phase extraction and isotope dilution LC-MS/MS. We detected 13 of the 23 target analytes (acetaminophen, benzoylecgonine, caffeine, carbamazepine, diclofenac, diltiazem, diphenhydramine, erythromycin, fluoxetine, ketamine, sucralse, sulfamethoxazole, trimethoprim). We then used a fish plasma modeling approach to determine whether water quality hazards differed among each sampling location. We also employed probabilistic environmental hazard assessments for antibiotics to identify probabilities of exceeding the predicted no-effect concentration for promoting antibiotic resistance. Consistent with observations from previous studies, acetaminophen, caffeine and sucralse were detected at the highest levels. While the primary cocaine metabolite benzoylecgonine was occasionally detected at low ng/L levels, ketamine, another drug of abuse, was observed at elevated level in effluents (81 - 447 ng/L). Treatment efficiencies, effluent concentrations and associated water quality hazards differed between the two plants. At the more advanced Dihua plant, acetaminophen removal efficiency approached 100%, while at the Bali plant, which primarily relies on a type of chemically enhanced primary treatment technology removal efficiencies were as low as 1%. Our results indicate that different treatment technologies were more important than season and daily influences on effluent CEC levels and water quality hazards in this pilot investigation.

PC019 Chemical pressures on watersheds in Chile: Chemical, biologic and human concerns

J.S. Kolak, University of Idaho / Fish and Wildlife Science; N. Gouin, University of La Serena / Biology; A. Bertin, University of La Serena; F. Panetti, Catholic University of the North / Biomedical Sciences; P. Davis, University of Nebraska, Omaha / Biology; J.M. Ali, New Hampshire Department of Environmental Services / Environmental Services

In the northern regions of Chile, the dominant arid environment is bisected by rivers that irrigate highly productive agricultural landscapes. Many of these rivers are multi-use in that they provide energy for hydropower, water for irrigation and drinking water for the adjacent human communities, and it is not unusual for human communities to live in close proximity to areas that are involved in intensive, industrial agriculture. While the riverine systems in this environment may contain detectable levels of pesticide contamination, the cascading relationships from chemical occurrence to validated response in aquatic species to adverse impacts on human communities are difficult to establish for a number of reasons. The first is that, in such arid environments, the release of pesticides from agricultural lands is difficult to quantify in a reliable fashion, which makes the water-borne exposure difficult to assess. The second is that the Andes Mountains present a biogeographical barrier to species dispersion, therefore many of the aquatic species of interest are endemics. This creates problems as the molecular biology of these endemic species, in many cases is not well described. Fortunately, recent work on an endemic mayfly Andesiops torrens (Insecta, Ephemeroptera) and an endemic fish species, Trichomycterus areolatus may ameliorate these problems. Finally, the jump from impact on aquatic species to adverse health impacts in humans, is difficult to make as other routes of exposure, such as direct contact by workers, or aerial exposure in adjacent communities, obfuscates the role that water plays in pesticide exposure.

PC020 Organic Contaminants of Interest in Northern Pakistan River Ecosystems

M. Schilling, L.S. Lee, C. de Perre, Purdue University / Department of Agronomy; M.S. Sepulveda, Purdue University / Department of Forestry and Natural Resources; B. Khan, National Research Council of the National Academies / USEPA - AED

Anthropogenic environmental contaminants can adversely impact aquatic ecosystems.Livelihood impacts resulting from decreasing fish diversity have led to a multi-disciplinary collaboration between the US and Pakistan to address these concerns. The main purpose was to identify and quantify organic contaminants in the Swat and Kabul Rivers in Northern Pakistan in order to inform implementation of new and existing policies to improve water quality, fish diversity and overall fish health. Samples
were collected along both the Swat and Kabul Rivers during low and high river flow in 2018 and 2019. Samples were screened for target and non-target contaminants using liquid chromatography tandem quadrupole time-of-flight mass spectrometry. Both rivers contained a suite of phthalates, pharmaceuticals, pesticides, and chemicals in personal care products with the Kabul River system appearing more contaminated than the Swat River system. Detailed occurrence results will be presented and implications on fish diversity, fish health and river-based livelihoods of communities in the region will be discussed.

**PC021 Estrogenicity of agricultural runoff: Rainfall simulation study of worst-case scenarios using fresh farrowing swine manure, layer and broiler litter**

N.W. Shappell, USDA-ARS / Edward T. Schafer Agricultural Research Center; L. Billey, USDA-ARS / Biosciences Research Lab; M.J. Shipitalo, Retired USDA-ARS / formerly National Laboratory for Agriculture and the Environment

Agricultural runoff into surface water has been implicated in the feminization of fish, but field studies have failed to associate estrogens in runoff directly with effects on fish. Therefore, fresh manure from laying hens, roaster chickens, and farrowing swine, animals known to excrete high concentrations of estrogens, was tilled into plots (n = 6 for each manure type), and 24h later rainfall simulation was conducted. Runoff was collected for 30 min. Estrogenic activity (estradiol equivalents, E2Eq) was measured in vitro using E-Screen, in addition to a panel of N, P, and total organic carbon. Rainfall simulations were again conducted at 1- and 3-week post manure application. Year 1, three layer litter plots had E2Eqs that approached the No Effect Concentration of 2 ng/L 24h post-application. While one plot remained at 1.6 ng/L E2Eqs at one week, the other plots ranged from 0.1 - 0.5. In YR 2 and 3, maximum E2Eqs concentrations at 24h ranged from 2.1 to 6.6 ng/L, somewhat above the NOEC. By week 1, concentrations were < 25% of 24h concentrations. In YR 2 roaster litter gave similar results, with 24h E2Eqs of 1.3 to 5.1 ng/L, with similar reductions of E2Eqs by week 1. In YR 3, 24h swine slurry ranged from 0.4 to 4.7 ng/L. Despite plot proximity to one another, there was substantial variability among plots, yet it appears that even these worst-case scenarios failed to result in runoff E2Eqs concentrations high enough to alter biological processes in aquatic organisms.

**PC022 Chemicals of Emerging Concern in SE Asia: Countrywide differences in knowledge bases regarding ecotoxicology and human health risks**

C. Propper, Northern Arizona University / Biological Sciences; G.R. Singleton, A. Stuart, B. Hadi, International Rice Research Institute; M. Shuman-Goodyer, Northern Arizona University / Department of Biological Sciences; S. Yadav, International Rice Research Institute; V. Quynh, Cua Long Rice Research Institute

Rice and other important crops such as bananas, coconuts, sugar cane and oil palms are critically important crops for food and economic security throughout SE Asia. Farming these crops often occurs in monocultures that utilize multiple pesticide applications across the landscape. In the short-term, these agrochemicals provide the farmers with stable crop production, but may also lead to resistance and exposure risks to the farmers and to the biodiversity that may support ecosystem services within the agroecosystem. To understand the knowledge base regarding issues surrounding aquatic contamination and the outcomes to aquatic ecosystems across SE Asia, we conducted a literature search in Pubmed for each SE Asian country. The country names and were paired with the search terms “endocrine *disrupt*”, “aquatic toxicology”, “pesticide” and “fish”, and “wastewater” and “chemical”. Our results found that, within SE Asia, the most peer-reviewed literature is from Malaysia (45.2%) and Thailand (30.1%). There very limited literature published from Myanmar (0.2%), Laos (0.6%) and Cambodia (1.1%), and while not extensive, researchers from the Philippines, Indonesia and Vietnam are publishing regarding the impact of environmental contaminants on the aquatic environment: 4.4%, 5.8% and 12.7% of all SE Asia literature, respectively. In SE Asia, Non-Governmental Organizations and funding partners, including the United Nations Food and Agriculture Organization, have developed programs to support Integrated Pest Management and other sustainability programs such as the Closing Rice Yield Gaps in Asia, (CORIGAP), the Sustainable Rice Platform (SRP), and Land-use Intensity and Ecological Engineering--Assessment Tools for Risks and Opportunities (LEGATO). The interconnectivity of the aquatic systems across SE Asia demonstrates an increased need to understand how pesticide use affects agroecosystems and human health. Integrating alternatives to pesticides, such as the use of natural pest predators, some of which may also support food and economic security, into pest and weed control, will provide the capacity to support the One Health Paradigm in SE Asia.

**PC023 At the Nexus of Water Quality, Food Security and Economic Development: The Lower Volta River in Ghana**

H.L. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory; C. Gordon, University of Ghana / Institute for Environment and Sanitation Studies; P. Edmiston, College of Wooster / Chemistry; A. Huff, University of Minnesota / Department of Civil, Environmental, and Geo-Engineering; S. Bartell, Normandale Community College / Biology; P. Novak, University of Minnesota / Department of Civil, Environmental, and Geo-Engineering

The Lower Volta River in Ghana serves as the drinking water source for the capital Accra and its over four million inhabitants. Additionally, the river is an important site of food production through high-intensity pen-aquaculture and serves as an economic resource for building materials through sand dredging. These competing interests need to be reconciled to maintain high drinking water quality while ensuring food security and economic viability. We assessed water quality and microbial communities along sixteen sampling sites between Lake Volta and the estuary of the river using solid phase extraction and LC-MS/MS analysis. Overall water quality was good but exhibited land-use related deterioration consistent with pen-based aquaculture (occurrence of antibiotics at low ng/L concentrations), agriculture (herbicide presence) and rural development (personal care products at concentrations approaching ug/L concentrations). In addition, herbicides and plasticizers were detected in river water and drinking water at low ng/L concentrations. DNA extracted from surface sediment, water, and sediment core samples and analyzed by Illumina sequencing for 16S rRNA genes broadly concurred with analytical chemistry. Quantitative PCR (qPCR) for 12 different antibiotic resistance genes and qPCR followed by Illumina sequencing for pathogens and virulence genes were also performed on these samples. Sequencing data was processed using QIME2. Based on Bray-Curtis Dissimilarity Analysis, the microbial communities in the water and sediment samples were very distinct from one another; the surface sediment samples demonstrated a clear dependence on location along the river, with those samples most heavily impacted by aquaculture facilities deviating from a simple location dependence. Taxonomic analysis also suggested an impact of two aquaculture facilities on the microbial community make-up. As developing countries advance water quality, food security and economic development, competing interests need to be reconciled. This study may serve as one example of these interests and will be expanded to develop solutions.

**Contaminant Issues in Waste Streams**

**PC024 Global distribution of Decabromodiphenyl ethane through electrical and electronic equipment trade originated in China**

J. Liu, K. Shen, Peking University / College of Environmental Sciences and Engineering; L. Li, University of Toronto / Department of Environmental Sciences; J. Liu, Peking University

Decabromodiphenyl ethane (DBDPE) has been used as a competitor of, and is proposed as an alternative to, the commercial decabromodiphenyl ether (deca-BDE) flame-retardant in electrical and electronic equipment (EEE). However, current studies have indicated that DBDPE has potential persistent, bioaccumulative, toxic characteristics. As the biggest EEE
manufacturing and exporting country in the world, China has inescapably contributed a remarkable amount of DBDPE to international trade flows. DBDPE can be distributed worldwide with the international trade of EEE; it can also be released to the environment throughout the product lifespan (e.g., in in-use and waste stocks). Using a dynamic substance flow analysis, we estimated the time-dependent mass flows, stocks and emissions of DBDPE in China, and the global dispersal of DBDPE originating in China through the international trade of EEE and e-waste. Our analysis indicated that, between 2006 and 2016, ~230 thousand tonnes (kt) of DBDPE has been produced in China, in which ~196 kt of DBDPE were released to the environment during the production, use phase and waste disposal activities. By the end of 2016, ~152 kt of the DBDPE produced resided in in-use products across China. During the period 2000-2016, ~39 kt of DBDPE were exported from China in EEE products, most of which (>50%) ended up in North America. Based on projected trends of China’s DBDPE production, use and EEE exports, we predict that, by 2026, ~74 and ~14 kt of DBDPE originating in China would reside in in-use and waste stocks, respectively, in regions other than mainland China. The in-use and waste stocks of EEE will act as long-term emission sources of DBDPE worldwide and generate continuous risk to the environment and public health. Eventually, an increasing amount of DBDPE in EEE will enter the waste stream in the next decades; the global redistribution of DBDPE within the international waste transfer chain and the contamination in products produced from the recycled materials containing DBDPE deserve our attention in the future.

PC025 Estimation of the fate of HBCD isomers in two waste recycling facilities and their emission to the environment

H. Kuramochi, National Institute for Environmental Studies, Japan / Center for Material Cycles and Waste Management Research; T. Motoki, National Institute for Environmental Studies; H. Matsuakami, National Institute for Environmental Studies / Center for Material Cycles and Waste Management Research; N. Kajiwara, National Institute for Environmental Studies, Japan / Center for Material Cycles and Waste Management Research; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; F. Wang, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

Hexabromocyclododecane (HBCD), which is used as a flame-retardant in a wide range of products, has recently been included in the Stockholm Convention on Persistent Organic Pollutants (POPs). HBCD can be emitted to the environment from waste treatment and recycling plants across China. During the period 2000-2016, ~39 kt of HBCD were exported from China in EEE products, most of which (~50%) ended up in North America. Based on projected trends of China’s HBCD production, use and EEE exports, we predict that, by 2026, ~74 and ~14 kt of HBCD originating in China would reside in in-use and waste stocks, respectively, in regions other than mainland China. The in-use and waste stocks of EEE will act as long-term emission sources of HBCD worldwide and generate continuous risk to the environment and public health. Eventually, an increasing amount of HBCD in EEE will enter the waste stream in the next decades; the global redistribution of HBCD within the international waste transfer chain and the contamination in products produced from the recycled materials containing HBCD deserve our attention in the future.

PC026 Brominated dioxins emission from e-waste recycling facility in Japan

G. Suzuki, C. Michinaka, National Institute for Environmental Studies / Center for Material Cycles and Waste Management Research; S. Hashimoto, National Institute for Environmental Studies / Center for Environmental Measurement and Analysis; H. Matsuakami, National Institute for Environmental Studies / Center for Material Cycles and Waste Management Research

Brominated dioxins such as polybrominated dibenzo-p-dioxins and dibenzofurans (PBDD/DFs) should be detected for their risk assessment according to the review article by the WHO/UNEP expert panel. Since 2002, the Ministry of the Environment of Japan (MOE) has conducted a series of field studies to survey the emissions of brominated dioxins from the potential sources related with brominated flame retardants (BFRs). Past surveys clearly revealed that PBDD/DFs tended to be detected in working air and effluents from the facilities recycling the waste of electric household appliances (e-waste) at concentration in excess of the standards for chlorinated dioxins in Japan. Therefore, this study investigated the current status of brominated dioxins emission from the e-waste recycling facility in Japan. According to the Law for Recycling of Specified Kinds of Home Appliances, e-wastes such as TVs, refrigerators, air conditioner and washing machines were collected and recycled properly in the e-waste recycling facilities. Here, 10 of 47 e-waste recycling facilities were investigated, which were the same facilities as previous MOE investigation. The total amount of materials recycled in 10 facilities was 203 kt for e-waste collected in FY2016, which was about 42% of those in 47 facilities. Working environment air (n=21) in the site of manual dismantling of e-waste were collected using a high-volume air sampler. Final effluents (n=12) in operation were collected in amber glass bottles. Wastewaters (n=4) generated at the separating process before the treatment in the wastewater treatment equipment were also collected. Sampling was conducted during December 2017 to January 2018. 2,3,7,8-TCDD equivalent for extract containing brominated dioxins (TCDD-EQPBDD/DFs) and WHO-toxic equivalent for PBDD/DFs (WHO-TEQPBD/DFs) in samples collected were measured by in vitro cell-based assay and GC-HRMS, suggesting that PBDD/DFs emission at FY2017 was lower than those at FY2002 and FY2011. There was correlation between WHO-TEQPBD/DFs and decaBDE concentration, indicating source of PBDD/DFs. For water samples, but not working air, TCDD-EQPBDD/DFs and decaBDE concentration was extremely higher than WHO-TEQPBD/DFs, suggesting existence of unidentified dioxin-like compounds derived from e-waste. Obtained results also indicate that it is important for the environmentally sound management of brominated dioxins such as PBDD/DFs derived from e-waste to control dust and particulate matter in the facility.

PC027 Is e-waste a source of contamination in a tropical coastal ecosystem?

A. Haarr, University of Oslo; E.B. Mwakalapa, Norwegian University of Life Sciences / Department of Food Safety and Infectious Biology; M. Nipen, University of Oslo / Department of Chemistry; J.L. Lyche, Norwegian University of Life Sciences / Department of Food Safety and Infection Biology; A.J. Mmochi, University of Dar es Salaam / Institute of Marine Sciences; A. Raus, NIVA; Z. Tatrova, Roskilde University / Life Sciences and Chemistry; M. Mark Larsen, University of Aarhus; H. Othman, State University of Zanzibar; K. Borgå, University of Oslo / Department of Biosciences

End-of-life electrical and electronic products (e-waste) is the fastest growing stream of waste globally. As e-waste contains a wide range of
hazardous compounds, handling and recycling of e-waste is a challenge in terms of cost and logistics, and may be a source of environmental contamination. Tanzania represents a growing economy, with increasing demand and import of electronic products, along with poor regulatory guidance and facilities for recycling and disposal of these products. Only a few studies have addressed environmental contamination in Tanzania, and in general little is known regarding the occurrence and dynamics of organic contaminants in tropical food webs. Particular compounds associated with e-waste such as chlorinated paraffins and brominated flame-retardants remain insufficiently studied. Sampling of coastal marine fish from different trophic levels with different dietary niches was conducted during field campaigns in 2018 and 2019. Sample sites include two sites in Dar es Salaam and one site on Unguja Island, Zanzibar, which differ in human activity, policies regarding import of electronic goods and waste, and thus pollution pressure. Fish muscle was analysed for legacy flame-retardants (PCBs and PBDEs), mercury, organochlorine pesticides, and new flame-retardants. Stable isotopes of carbon and nitrogen were analysed to assess dietary carbon source and trophic level, respectively. A recent study from the Anthrotox project shows elevated levels of chlorinated paraffins, deca-BDEs and new brominated flame-retardants in soil, suggesting local contamination from e-waste. In fish samples, however, organochlorine pesticides dominated, and levels of PCBs and flame-retardants were very low, indicating no apparent source of contamination from e-waste. The present study investigates contaminant occurrence and food web dynamics in a region where very little data exist, even on legacy contaminants. In addition, the study highlights the need to target newer types of flame-retardants in order to assess the increasing issue of environmental contamination from e-waste.

PC028 Substance flows and environmental emissions of chemicals associated with industrial waste treatment in Japan

M. Oguchi, National Institute for Environmental Studies / Center for Material Cycles and Waste Management Research; Y. Horii, Center for Environmental Science in Saitama; Y. Miyake, University of Shizuoka / Institute for Environmental Sciences; H. Otsuka, Hokkaido Research Organization / Environmental and Geological Research Department; N. Tanikawa, National Institute for Environmental Studies; M. Tokumura, University of Shizuoka / Graduate School of Nutritional and Environmental Science; S. Urano, Institute of Environment and Resource Systems; Y. Watanabe, Center for Environmental Science in Saitama

Because a large portion of chemical substances would be eventually processed as waste, a sound management of chemicals during waste treatment processes is important for chemical risk reduction throughout their lifecycle. Quantitative data of the flows and the environmental emission of chemical substances, however, is still lacking for waste treatment processes. This study investigated the substance flows and the atmospheric emissions of chemicals associated with waste treatment in Japan, especially focusing on industrial waste incineration. Firstly, we investigated the inflows of chemicals to different waste treatment processes in Japan by different waste categories by analyzing the information obtained from the Japanese Pollutant Release and Transfer Register (PRTR). We also estimated the inflows of heavy metals to the incineration processes based on metal content analysis of incineration residue samples. The results showed that several specific waste categories were dominant in the chemical inflows. For example, the dominant sources of heavy metals for incineration processes were sludge and waste acid/alkali. To accurately estimate environmental emissions, the difference in chemical inflows by the types of waste predominantly processed at each facilities should be considered. Secondly, we estimated emission factors for incineration facilities by measuring the concentrations of heavy metals, volatile organic compounds, and aldehydes in the exhaust gas. The emission factors ranged over a few orders of magnitude, which we attributed to the differences among exhaust treatment systems. The installed technology must be considered to accurately estimate emission factors for incineration facilities. Finally, we estimated the atmospheric chemical emissions from industrial waste incineration facilities in Japan. The accuracy of the estimates were improved when the type of predominant wastes and installed technology at each incineration facility was considered. The results suggested that the emissions of heavy metals, 1,4-dioxane, and acetaldehyde from industrial waste incineration cannot be ignored when compared with those released by other emission sources. By contrast, the emissions of hexavalent chromium, most of the investigated volatile organic compounds and aldehydes were much less than those from other sources. The results indicated that chemical management during waste treatment processes would be important for some chemical substances.

PC029 PFAS in aqueous samples from landfills

T. Townsend, University of Florida / Department of Environmental Engineering Sciences; H. Solo-Gabriele, University of Miami / Department of Civil, Architectural and Environmental Engineering; N. Robey, University of Florida / Department of Environmental Engineering Sciences

One source of concentrated poly- and perfluoroalkyl substances (PFAS) is landfills. These sources include leachates from different landfill types (municipal solid waste, municipal solid waste incineration ash, and construction and demolition), from gas condensates, storm water and groundwater within the landfill boundaries. The objective of this study was to evaluate PFAS from these aqueous landfill sources for 26 PFAS species including 11 perfluorooalkyl carboxylic acids, 7 perfluorooalkyl sulfonates, 5 fluorotelomers, and 3 perfluorooctane sulfonamides. Landfill leachate is typically disposed of off-site at a wastewater treatment facility, and landfills often pre-treat the leachate to make it more acceptable for these facilities. Landfills with leachate these pre-treatment systems (reverse osmosis, powdered activated carbon, biological aerations, and evaporation) were evaluated to determine the effectiveness of treatment systems to remove or concentrate PFAS. Results show that total PFAS concentrations were variable with groundwater and storm water measuring at detectable but low levels (generally < 600 ng/L). Gas condensates and leachates were characterized by higher levels. No statistical differences were observed between gas condensate and the different types of leachate due to the high variability of the results. The maximum total PFAS concentration observed were 54,000 ng/L for an ash leachate sample and 81,000 ng/L for a gas condensate sample. The predominant PFAS species in both of these samples were the perfluoroctane sulfonamides. Among the treatment systems reverse osmosis was the most effective with over 99% reductions in total PFAS within the permeate.

PC030 Presence and Partitioning of 13 Organophosphate Flame Retardants (OPFRs) in the Solid and Liquid Waste Streams of Five Wastewater Treatment Plants in Canada

M. Woudeh, SGS AXYS Analytical Services, Ltd.; S. Smyth, Environment and Climate Change Canada / Environment and Climate Change Canada; R. Grace, B. Chandramouli, SGS AXYS Analytical Services, Ltd.; C. Hamilton, SGS AXYS / Client Services

Organophosphate Flame Retardants (OPFRs) are esters of phosphoric acid that are increasingly used by the flame-retardant industry to replace regulated brominated diphenylethers (BDEs). In this study we investigate the occurrence and distribution of 13 Organophosphate Flame Retardants (OPFRs) in the liquid and solid waste streams of five wastewater treatment plants in Canada. While some analytes showed partition from the liquid waste stream to the solid waste stream and visa versa, all the detected analytes survived secondary wastewater treatment. Results from effluent samples collected in parallel to biosolids were used to estimate field-based solid-water partition coefficients (KD). These values were compared with octanol-water partition coefficients for significance. The values calculated in this study can be used to predict, model and understand the behavior and fate of OPFRs in the environment.
Models as a Tool for Understanding and Communicating Threats to Aquatic Ecosystem Integrity

PC031 Benefits of an Enhanced Adaptive Management Model in Stakeholder Communications

C. Mancini, AECOM / Remediation Practice; S. Thakali, AECOM / DCS Remediation - Risk Assessment; N.R. Grosso, Corteva / Environmental Remediation

Mercury was used in the manufacturing process at a facility in Waynesboro, Virginia between 1929 and 1950, resulting in its release and migration into South River surface water, sediments, soils, and biota. As characterization and remedial planning progressed through the RCRA process, an innovative vehicle was needed to capture baseline characteristics, remediation progress and effects, and monitoring components of this complex system that could be communicated to an equally diverse group of stakeholders. The overall goal was to develop a decision-analytic framework that would capture all key values and parameters that are deemed most relevant to the on-going, decision-making process by all stakeholders. Development of the Enhanced Adaptive Management (EAM) model for the South River underwent several phases. Throughout the development phase until the present, data generated through on-going program activities and stakeholder involvement continue to inform the overall direction of program. The initial phase involved achieving acceptance of the fundamental concept by the South River Science Team. Along with this phase came a conceptual description of what the model could and could not do. Next a framework was developed that allowed for the incorporation of parameters critical to the technical understanding of the complex system, and equally critical parameters valued by the public. Extensive interactions among team members were conducted to ensure all interests were represented accurately. Visualization was a key tool in demonstrating all interests were being included. Once the model components were established, stakeholders were asked to rank model criteria. To assess the model, a series of removal scenarios was tested to demonstrate a range of outcomes for each. Since its inception, the EAM framework has served as a program repository to track, address and incorporate additional or modified remedial options, monitoring elements and stakeholder interests. Its flexibility also permits incorporation of new evaluation and analytical tools as they become available. This case study is a clear demonstration of the benefits in using the EAM decision tool as a focal point in complex remediation programs.

PC032 Predicting fathead minnow tissue selenium concentrations from oral selenomethionine exposure using compartmental toxicokinetic modeling

D. Green, University of Saskatchewan / Toxicology; A. Mangold-Döring, Wageningen University & Research / Environmental Sciences; M. Brinkmann, University of Saskatchewan / School of Environment and Sustainability & Toxicology Centre; D.M. Janz, University of Saskatchewan / Veterinary Biomedical Sciences; K. Liber, University of Saskatchewan / Toxicology Center; M. Hecker, University of Saskatchewan / School of the Environment & Sustainability and Toxicology Centre

Selenium (Se) is a trace element and essential micronutrient for almost all forms of life which has a narrow threshold between beneficial and toxic doses. Though it is found in many bio and geological compartments, Se is particularly enriched in organic (i.e. fossil fuel) deposits and can be released to the aquatic environment by both natural and anthropogenic activities. When liberated to the aquatic environment in excess, aqueous Se oxyanions can be biotransformed to the organic form “selenomethionine” (SeMet), whereupon Se can bioaccumulate due to SeMet’s dose-dependent substitution for the essential amino acid and biochemical SeMet analogue, methionine. Bioaccumulated Se can subsequently pose risks consumers. Oviparous animals dependent upon aquatic environments are at particular risk, as SeMet is shunted to their developing eggs causing oxidative stress during embryogenesis that can lead to terata and/or recruitment failure. Many current protective guidelines rely on tissue threshold approaches to determine whether Se concentrations pose risks to these animals, however these risks could be mitigated further if these concentrations could be predicted before the occurrence. This research presents a compartmental model of Se toxicokinetics in a model organism, the fathead minnow (Pimephales promelas). Rate constants for Se flux across fathead minnow tissues in fish exposed to selenomethionine have been derived using literature values and SAAM II modeling software and subsequently used to inform a model coded in Python, and experimental data are currently being used to validate the model’s fitted values. It is hoped that the finalized model can be used to inform proactive risk assessment of fathead minnows orally exposed to selenomethionine, and that the model may ultimately be extrapolated to other species at risk through the development of species-specific model objects.

PC033 Coupling chemical stressors and inter-specific competition to forecast trout population dynamics: strengths and weaknesses of mechanistic models

C. Accolla, V. Forbes, University of Minnesota / Ecology, Evolution & Behavior

One of the major goals of ecological risk assessment (ERA) is to understand the impacts of chemicals on populations, communities and ecosystems. However, methods for estimating and integrating exposure and effects are often based on individual-level responses, whereas it is crucial to predict impacts of stressors at higher levels of biological organization. Mechanistic models have an essential role to ensure better predictive capacity, integrating the effects of chemicals and inter-specific relationships across multiple spatio-temporal scales. Furthermore, models can extrapolate both stressor impacts and life histories across species that cannot be tested in the lab. The aim of this research is to compare the impacts of generalized stressors affecting different metabolic pathways of two trout species: Salmo trutta (brown trout, BT) and Oncorhynchus clarki stomias (greenback cutthroat trout, GCT). GCT is threatened because of chemical exposure and competition with BT. Many hypotheses exist to explain why BT is a better competitor. For example, BT reproduces in a more favorable season and is bigger (and therefore has a higher energy intake). Furthermore, aggressive behaviors have been reported in the literature. To understand the population dynamics of these two interacting species, we developed an individual-based model. The individual description is based on Dynamic Energy Budget theory, which describes the metabolic organization of organisms. When representing the two species separately in their respective environments, we found that individual-level responses to different stressors were qualitatively comparable; however, results at the population level differed markedly. When modeling inter-specific competition, we show that BT competitive advantages do not emerge from its life-history traits. This result suggests the importance of representing competition explicitly, to reproduce natural patterns and better forecast chemical impacts on populations. Moreover, the choice of temperature profile affects simulation results, showing that we need to consider carefully the ecology of the species of interest. Our research analyzes how models that quantitatively link impacts of chemicals and other stressors on individual life-history traits to consequences for populations can be informative for ERA. We also explore model limitations and strengths when representing complicated population dynamics for management purposes.
Publicly Accessible Data Analytic Tools for Environmental Toxicology, Chemistry, and Risk Assessment

SF001 The EPA CompTox Chemicals Dashboard as a Data Integration Hub for Environmental Chemistry Data

The U.S. Environmental Protection Agency (EPA) Computational Toxicology Program integrates advances in biology, chemistry, and computer science to help prioritize chemicals for further research based on potential human health risks. This involves computational and data-driven approaches that integrate chemistry, exposure and biological data. The National Center for Computational Toxicology (NCCT) has measured, assembled and delivered an enormous quantity and diversity of data for the environmental sciences, including high-throughput in vitro screening data, in vivo and functional use data, exposure models and chemical databases with associated properties. The CompTox Chemicals Dashboard is a web-based application providing access to data associated with ~875,000 chemical substances. New data are continuously added to the database on an ongoing basis, along with registration of new and emerging chemicals. This includes data extracted from the literature, identified by our analytical labs, and otherwise of interest to support specific research projects to the agency. By adding these data, with their associated chemical identifiers (names and CAS Registry Numbers), the dashboard uses linking approaches to allow for automated searching of PubMed, Google Scholar and an array of public databases. This presentation will provide an overview of the CompTox Chemicals Dashboard, how it has developed into an integrated data hub for environmental data, and how it can be used for the analysis of emerging chemicals in terms of sourcing related chemicals of interest, and deriving read-across as well as QSAR predictions in real time. This abstract does not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

SF002 QSARINS and QSARINS-Chem standalone version: Tools for QSAR models development, validation and application
E. Papan, N. Chirico, University of Insurbia / Department of Theoretical and Applied Sciences; A. Sangion, University of Toronto, Scarborough / Department of Physical and Environmental Sciences; P. Gramatica, University of Insurbia / Department of Theoretical and Applied Sciences

Since 2012 the QSAR Research Unit in Environmental Chemistry and Ecotoxicology at University of Insurbia has been developing free tools dedicated to the development, validation and application of models based on Quantitative Structure Activity Relationships (QSARs), and suitable to support the hazard and risk assessment of existing as well as not yet synthesized chemicals. In particular, the software QSARINS (www.qsar.it) is a user-friendly platform, which assists users in the analysis of data, in the development and validation of QSAR models based on Multiple Linear Regression (MLR) following the “OECD guidelines on the Validation of (Q)SAR Models,” and in the application of these MLR-QSARs for screening purposes. This tool includes procedures for data curation (correlation analysis and data filtering), features selection based on a Genetic Algorithm (GA), and diagnostic (internal and external validations, Y-randomization, analysis of the applicability domain, etc...). Furthermore, this software incorporates a database of chemicals (including their 3D structures), which have been collected and curated from the literature and used to generate our QSARs over the last two decades. In addition, to facilitate the application of QSARINS-generated models by non-expert users, we have recently released the QSARINS-Chem standalone software. This tool provides a simplified workflow and assists general users, experienced and non-experienced modelers as well as regulators, in the application of selected MLR-QSARs (supported by the QSAR Model Reporting Format (QMRF)) for screening purposes. This presentation illustrates the functionalities of the QSARINS software and of the new QSARINS-Chem standalone version, and gives examples of how these free tools can be successfully applied to generate and validate QSARs and predictions, for multiple endpoints, according to the “OECD principles for the Validation, for Regulatory Purpose, of (Q)SAR Models.”

SF003 Screening for biological relevance of environmental chemistry data using the toxEval software package

With thousands of potential chemicals in our natural environment, and advancements in instrumentation and analytical capabilities often providing detection levels in the nanogram per liter level and below, evaluating the biological relevance of chemical occurrence remains a challenging task. The U.S. Geological Survey and the U.S. Environmental Protection Agency have collaborated to develop the open-source software package toxEval (https://github.com/USGS-R/toxEval) to simplify this type of evaluation by efficiently examining chemistry data in multiple ways. The toxEval R package was designed to provide an efficient method to evaluate potential adverse biological impacts from user defined environmental chemistry data. Measured chemistry data is compared with benchmark bioeffect concentrations (concentrations at which biological activity may exist) to screen for potential adverse effects and prioritize the potential hazard by chemicals and sites. ToxCast is used as the default benchmark concentration database due to its broad coverage of more than 9000 chemicals and more than 300 bioeffect assays. Since there are often specific, previously compiled benchmark databases (e.g. the EPA aquatic life benchmarks) that are well established, an option is available to override the default bioeffect database in favor of a custom database for screening. These techniques allow for analysis of small to large data sets including capabilities to visualize and examine results for multiple chemicals per sample, multiple samples per site, and numerous sites across a broad geographic area. This demonstration will include an introduction to bioeffect evaluation concepts included in toxEval, results of a case study using water chemistry sampling results from Great Lakes tributaries using ToxCast as the bioeffect database, and a comparison of the results from the ToxCast database to established water quality benchmarks. This approach is intended to provide information for assisting scientists and watershed managers in better understanding where the greatest likelihood of adverse biological effects exists and what types of adverse effects may be impacting resident organisms. This abstract does not necessarily reflect USEPA policy.

SF004 Using lifecycle chemical emission information for high-throughput exposure-based risk assessments
L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting; F. Wania, University of Toronto, Scarborough / Department of Physical and Environmental Sciences

Chemical screening and prioritization assessments are commonly based on chemical hazard indicators (i.e., persistence, bioaccumulation, and toxicity) and/or commercial tonnage (i.e., the quantity produced or on the market). However, realistic ecological and human exposures, and associated risks, are additionally dependent on chemical use and release information (e.g., How and how much of a consumer product is used/released?). Substance flow analysis is a powerful tool to mechanistically derive chemical use and release rates throughout chemical and product lifecycles. Chemical screening and prioritization assessments can therefore benefit from incorporating substance flow analysis into chemical exposure and risk models. Here, we describe a new holistic modeling framework, comprising a substance flow model (a modified version of CiP-CAFE) and chemical exposure and risk models (RAIDAR and RAIDAR-ICE), which enables efficient, defensible screening and
prioritization of chemicals based on exposure- or risk-based assessment metrics. The modeling framework requires only two basic inputs, i.e., the commercial tonnage and molecular structure, and is thus well-suited for screening-level decision-making for a myriad of data-limited commercial chemicals. As a case example, the modeling framework is applied and tested for the estimation of human exposure to 95 neutral organic chemicals released during different lifecycle stages of articles or products. The model predictions are evaluated against an independent dataset of inferred human exposures of the US population; the difference between predicted and inferred exposure rates is within two orders of magnitude for 85 chemicals, and within an order of magnitude for 66 chemicals, with a coefficient of determination (R2) of 0.52, suggesting a reasonable performance of the model system. Our modeling framework allows for a “forward” evaluation of human aggregate exposure to chemicals arising from their actual use, or a “back” calculation of the critical production/import quantities of a chemical that would not cause an unacceptable level of risk. The approach shows promise in high-throughput screening of thousands of commercial chemicals.

**SF005 Using MicrobiomeAnalyst for comprehensive analysis of microbiome data**

*J. Xia, McGill University*

The past few years have witnessed a fast growth in the number of microbiome studies to understand human and environmental health. Despite the development of several powerful pipelines for raw sequence data processing, there is a great demand for user-friendly and easily accessible tools for statistical and functional analyses of microbiome data. Here we introduce MicrobiomeAnalyst, a public cloud/web-based tool for comprehensive analysis of microbiome data. The current version contains four modules - Marker Data Profiling, Shotgun Data Profiling, Taxon Set Enrichment Analysis, and Projection to Public Data. Each module contains a wide array of well-established as well as advanced methods for statistical analysis and visual exploration. MicrobiomeAnalyst has been implemented based on Java and R programming languages. It is hosted on a high-performance Google Cloud instance. Over the past 12 months, the public server processed over 50,000 jobs submitted from over 15,000 users worldwide. MicrobiomeAnalyst is freely available at https://microbiomeanalyst.ca.

**SF006 Using MetaboAnalyst for comprehensive analysis of metabolomics data**

*J. Xia, McGill University*

MetaboAnalyst (metaboanalyst.ca) is an easy-to-use, web-based tool used by >100,000 researchers worldwide for metabolomics data analysis, functional interpretation and biomarker identification. The workshop aims to introduce participants to the key features of the most recent release of MetaboAnalyst (version 4.0), including its comprehensive statistics capacity (univariate and multivariate analysis), pathway and enrichment analysis for both targeted and untargeted metabolomics data, biomarker analysis and meta-analysis, as well as multi-omics data integration through network-based visual analytics. During the workshop, participants will be given an overview of the different modules in MetaboAnalyst and most of its main functionalities. Selected example data sets will be processed using different MetaboAnalyst features as part of a live demonstration. Workshop participants will then continue with a “hands-on” lab using their own laptops. Participants are encouraged to bring their own data and to process it with MetaboAnalyst 4.0. Alternately, they may work with our example data sets and an accompanying tutorial to explore MetaboAnalyst 4.0 on their own.
it is expected that a number of additional high-throughput sequencing experiments will provide greater coverage and more thorough characterization of the fathead minnow genome. We are hopeful that this genome browser will serve as a SETAC-driven, collaborative genome research and development project that will benefit the ecotoxicology and ecological risk assessment communities. The contents of this abstract neither constitute nor reflect USEPA policy.

**SF009 The Adverse Outcome Pathway (AOP)-Wiki: Actionable Knowledge to Support 21st Century Toxicity Testing**
D.L. Villeneuve, US Environmental Protection Agency / Mid-Continent Ecology Division; C. Wittwehr, European Commission DG Joint Research Centre; S. Edwards, RTI International / Research Computing Division

The vision and strategy for toxicity testing in the 21st century addresses the need for data to inform chemical safety assessment by advocating the use of high throughput screening (HTS) approaches that can provide data rapidly and cost-effectively for thousands of compounds. However, data generation is just one part of the solution. For these data to be useful, decision-makers need access to the background information and interpretive context that can be used to transform the data into actionable knowledge that can inform decisions. The adverse outcome pathway (AOP) framework was developed as a systematic approach for organizing and synthesizing the biological plausibility, weight of empirical evidence, and quantitative understanding to explain and contextualize the connection between a pathway-based biological change and the apical adverse effects considered relevant to risk assessment. The AOP framework is rooted in a collaborative spirit in which subject matter experts contribute and combine their expertise to systematically describe cumulative and emergent knowledge that would otherwise be accessible to only a small fragment of the stakeholder community. Knowledge organized in this manner is captured in the AOP knowledgebase, presently represented by the AOP-Wiki (aopwiki.org). Thus, the AOP-Wiki becomes a source of actionable knowledge that supports practical application of the new data streams emerging from 21st century toxicology. This presentation introduces the conceptual and philosophical underpinnings of the AOP-Wiki and then invites the audience to explore the details of how AOP-knowledge is assembled and delivered through the current on-line platform and provide feedback on how the system could be improved for both contributors and users of AOP information. The contents of this abstract neither constitute nor reflect official policy of the USEPA.

**SF010 The USEPA Sequence Alignment to Predict Across Species Susceptibility tool for species extrapolation**
C. LaLong, US Environmental Protection Agency / Office of Research and Development; C. Finnegan, ORISE at USEPA; J. Doering, NRC / USEPA / Mid-Continent Ecology Division

For any given chemical limited toxicity test data exists and typically, if available, the data only represents that generated from a few model species. Therefore, the necessity to extrapolate existing toxicity knowledge collected from one species to others is a prominent challenge in chemical safety evaluations. This challenge is heightened in considering chemical impacts to threatened and endangered species where toxicity testing is impractical. Overall, it is critical to advance innovative methods and technologies for cross species extrapolation to inform chemical safety decisions. One such technology is the US Environmental Protection Agency Sequence Alignment to Predict Across Species Susceptibility tool (SeqAPASS; https://seqapass.epa.gov/seqapass), that capitalizes on existing and continuously expanding protein sequence and structural information to evaluate similarities and differences in chemical molecular targets across species. Based on the similarity of a known sensitive species to other species, a prediction of chemical susceptibility can be elucidated across hundreds to thousands of species. The tool relies on prior knowledge of a chemical protein target and a sensitive species and uses that information as a starting point to compare primary amino acid sequences, functional domains, and critical amino acids across species. SeqAPASS is flexible in that it allows the user to utilize all available information about the chemical protein interaction from the linear protein sequence to understanding of the tertiary structure of the protein. The results from the SeqAPASS tool can be downloaded as tables (.csv or .xlsx files) and visualized through an interactive box-plot graphic, that can also be downloaded. The newest release of SeqAPASS v4.0 will provide help menus and query guidance for the user, as well as rapidly interpretable data summary tables, with continuously improving user friendly features for streamlined navigation of the interface. Methods developed in the SeqAPASS tool aim to capture the state-of-the-science in protein comparison techniques and will continue to evolve as bioinformatic approaches improve and become more automated, particularly surrounding protein structural comparisons across species. The contents of this abstract neither constitute nor reflect official policy of the USEPA.

**SF011 EnviroTox Database: Overview and Applications**

Flexible, rapid, and predictive approaches that do not require the use of large numbers of vertebrate test animals are essential, as the chemical universe remains largely untested. Development of robust new approach methodologies (NAMs) and non-testing approaches requires the use of existing information via curated, integrated datasets. A large, diverse dataset was developed from a range of sources, with harmonization and characterization steps to ensure that the information could be effectively organized and mined. The resulting EnviroTox database (www.envirotox-database.org) contains 91,217 aquatic toxicity records representing 1,563 species, and 4,016 unique chemical CAS/®, Chemical-specific information is linked to each record and includes physical chemical information, chemical descriptors, and mode of action classifications. Toxicity data are associated with the physical chemistry data, mode of action classifications, and curated taxonomic information for the organisms tested. To make these data accessible and useful to stakeholders, the dataset was transitioned from Microsoft Excel and Access into a modern MySQL format, allowing for a format that is relational and scalable, facilitating easy access, sharing, and integration with other datasets and tools. The dataset is accessed via a web-based query system that is integrated with a predicted no effect concentration (PNEC) calculator, an ecological threshold of toxicological concern (eco-TTC) distribution tool, and a chemical toxicity distribution (CTD) tool. The novel interface allows users to explore the data, upload additional datasets, derive threshold values based on specific criteria, and explore the potential use and applications. This presentation will provide an overview of the EnviroTox Database and examples of how the database and its associated tools can be used to inform chemical evaluation and alternative method development.
The ECOTOXicology Knowledgebase (ECOTOX, https://www.epa.gov/ecotox/), is a comprehensive, curated database that summarizes toxicity data from single-chemical exposure studies to aquatic life, terrestrial plants, and wildlife. For over 30 years, ECOTOX has provided ecologically-relevant toxicity data to meet the systematic review and data transparency needs of the USEPA for risk assessments and regulatory decisions. Data are curated from relevant studies after processing through well-established protocols to exhaustively search the literature, review references for applicability and acceptability, and extract data for all study details, including species taxonomic hierarchy, chemical purity, routes of exposure, and all calculated or statistically derived endpoints provided by the authors. ECOTOX currently includes data for more than 11,000 chemicals from over 48,000 references, with additional data uploaded quarterly. To meet the increased demand for relevant empirical toxicity data and the evolution in toxicity testing, ECOTOX was recently updated with a new user interface, enhanced functionality for searching and exploring curated data, and inclusion of more mechanistic (e.g., genetic, enzymatic) and pathway-based (e.g., hormonal, cellular) data. Further, links to databases and tools were integrated, laying the foundation for future interoperability across sources of information on chemicals, species, and effects. Presented here is an overview of the ECOTOX Knowledgebase with vignettes demonstrating: 1) extent, distribution, and types of empirical toxicity data available; 2) exploration and visualization tools to identify relevant toxicity data for focused research questions and decision-making; and 3) efforts to increase interoperability for comparison to in vitro data, species comparisons/extrapolations, evaluation of field contaminants data, and development of adverse outcome pathways. This abstract does not necessarily reflect USEPA policy.

Oh, the Changes I've Seen Over the Past 30 Years

SF013 Evolution of the Science of Ecotoxicology: A 30 (Plus) Year Retrospective

G.T. Ankley, US Environmental Protection Agency / Mid-Continent Ecology Division

The contributions of Paracelsus notwithstanding, toxicology as a formal scientific discipline is a comparatively new endeavor and, within the broader field, ecotoxicology is in its relative infancy. Consequently, it is still possible for a scientist who has been engaged in the field for just a few decades (such as me) to have directly seen/participated in enormous changes in expectations and approaches relative to the assessment of chemical impacts on the environment. In this talk I will use examples from my career to illustrate the following timeline/evolution of the field of ecotoxicology. Initial concerns in the field focused largely on direct effects of chemicals or chemical mixtures on survival and, to a somewhat lesser extent, subtle effects on growth and reproduction. While these types of apical, population-relevant responses remain a cornerstone for ecological risk assessment, the techniques and actual endpoints employed to assess them have--and continue to--change substantially. Much of this transformation has been driven by (often legislated) expectations to consider possible ecological effects of an ever-greater number of chemicals (and chemical mixtures) on a wider array of endpoints in an era of steadily diminishing resources for conventional testing, including increased concern over animal use. This has accentuated the development of rapid, inexpensive, high-content tools based on early perturbation of biological pathways. However, as pathway-based approaches/tools in areas such as 'omics and high throughput testing become commonplace in ecotoxicology, the core challenge of translation of test data into responses meaningful to risk assessment increases. Basically, we are faced with the reality that more data/information--however elegantly measured--does not directly translate into increased knowledge, without a concurrent advance in understanding. Developing this understanding is one of the "big challenges" for the next generation of ecotoxicologists. The contents of this talk do not reflect USEPA policy.

SF014 From Microcosms to Mesocosms Via the Cairns' (VPI&SU) School of Ecotoxicology

S.E. Belanger, Procter & Gamble Company / Global Product Stewardship

At the formation of SETAC, Professor John Cairns, Jr. of VPI&SU (now known more commonly as Virginia Tech) was at the front of advocating the incorporation of ecology into aquatic toxicology and experimentation in the field of human-induced perturbations. The principles were formed during an extended period as a protege of Dr. Ruth Patrick at the Academy of Sciences of Philadelphia researching impacts of industrial wastes on rivers of the eastern and southern United States. Many of those principles were articulated in a report of the National Academy of Sciences committee in 1981, which Cairn’s chaired, on use of model ecosystems in environmental assessment. Those same principles shaped approximately 3 decades of research at leading private sector environmental labs including those of Procter & Gamble, Shell Chemicals and its related businesses, Unilever, NCASI, as well as important public sector sites such as USEPA Monticello Research Station, Kellogg Biological Station, the Savannah River Ecology Laboratory and a number of NSF funded sites. In this presentation, I will review the motivations for the emphasis by the Cairns lab on model ecosystems and how industry put these into play in researching effects of contaminants, chemicals and effluents, particularly in the consumer products industry. We will touch on some of the major scientific and technical advances brought about either directly or in parallel with these efforts in a pictorial guide of many facilities and how they remain relevant and still needed today and into the future.

SF015 Yesterday's Primary Consumers Become Tomorrow's Secondary Producers

C. Mancini, AECOM / Remediation Practice

Who knew that coming of age post National Environmental Policy Act would lay the foundation for such a diverse, predictably, unpredictable career! The past 50 years have seen unprecedented environmental awareness and regulation that has created an entire industry which many scientists have participated in! The National Environmental Policy Act (1970), Federal Water Pollution Control Act (1972), Resource Conservation and Recovery Act (1976), Comprehensive Environmental Response Compensation and Liability Act (1980) and guidance and further regulation that followed all necessiated consideration of ‘protection of human health and the environment’. The interest and application of principles of bentic taxonomy and ecology followed a parallel path. Understanding of bentic assemblages as indicators of habitat characteristics was mainly an academic endeavor prior to the 70’s. In conjunction with sediment chemical analyses, benthic community analyses became more important in assessing habitat health and ‘clean vs polluted’ systems; toxicity and bioassay protocols in the 1990s formed the three-pronged Sediment Quality Triad approach we now use routinely for sediment and other types of assessment. Advances in field, laboratory and communication technologies further fueled the utility of benthos as a key metric for aquatic systems. Graduating with degrees in biology in the 70s and 80s gave many passionate ‘naturalists’ a new and expanding platform to stand on that had not existed previously. This ‘case study’ exemplifies the significance of sometimes random, early career events and suggests future, random events for new scientists to consider.
The Clean Water Act (CWA) establishes the structure for regulating discharges of pollutants into the waters of the United States and regulating quality standards for surface waters. With updates in 1972, the CWA gave EPA the authority to implement pollution control programs such as setting wastewater standards for industry and water quality standards for contaminants in surface waters. Applying water quality criteria to control the release of chemicals into water bodies was quickly identified as insufficient to manage all potentially toxic pollutants in an effluent, nor did it predict biological effects in the receiving waters. New methods to estimate chronic toxicity were developed for effluent testing and validated with interlaboratory studies and in field studies that demonstrated the connection between effluent/ambient water toxicity and effects on instream communities. Techniques to identify the cause(s) of toxicity were developed and EPA created a technology transfer center for the water-quality-based permits, technical assistance, Toxicity Identification Evaluations (TIEs), and training at EPA-Duluth. During this time, we identified many chemicals that were not covered under the chemical-specific limits included in NPDES permits or were not expected to cause toxicity at concentrations present. The sediment program followed the steps of the WET program by developing sediment toxicity methods to address the causes of toxicity and develop numerical criteria for specific sediment toxics to address the challenge of bioavailability of sediment contaminants. This presentation will provide an overview of the development of the methods, technical challenges, and scientific accomplishments, as well as link how the methods and most importantly, how these approaches were vetted through SETAC journals and public meetings, which was essential for the environmental management decisions within EPA. Disclaimer: This presentation does not necessarily reflect the views or the policies of the USEPA.

SF018 This Just In!! Everything IS an Endocrine Disruptor: Perspectives from an EDSTAC groupie!
E.M. Mihaich, ER2
Long before the phrase endocrine disruption became a household term even your mother knows, casual observations made by amateur and trained scientists around the world began to tell a story of possible adverse effects on wildlife and humans from exposure to chemicals that might be interfering with the endocrine systems of wildlife and humans.

Thousands of papers, news articles, blogs, and tweets later, along with a staggering amount of research dollars, it is time to take stock of where we have been and what lessons we have learned (or not learned) in this seemingly always “emerging” field. Terms such as weight of evidence, mode of action, adverse outcome pathways, and in silico and in vitro screens have been coming out of the mouths of ecotoxicologists at an unprecedented rate in the last 20 years because of this “emerging” field. This is all for the good and SETAC members have been central to much of the development and advancement in the science and interpretation of the data. This talk will walk the audience through those early days of casual observations and regulatory interest to where we are today with drilling down to specific definitions and hypotheses, identifying modes of action, and deciding on hazard versus risk approaches to evaluating the adverse consequences of exposure to both natural and anthropogenic chemicals. The trade-offs inherent in narrowing the focus of an assessment to target specific modes of action versus a more holistic, population-relevant approach, taking into account all adverse responses, will be discussed and the consequences of toxicologists and ecotoxicologists actually talking now and into the future will be explored.

SF019 Development and application of ecosystem services concepts: Evolution or devolution?
P.N. Booth, Ramboll Environ / Ecological Sciences; D. Pelletier, Ramboll US Corporation / E&H
William Foster Lloy first proposed the dilemma of overexploitation of resources in shared-resource systems in 1833 by postulating a hypothetical example of unregulated grazing on common land. The idea that individual users acting independently in their own self-interest will almost inevitably behave contrary to the common good by depleting or spoiling a resource, led to the ecologist Garret Hardin coining the term “tragedy of the commons” in 1968. From an economics standpoint, such a dynamic arises because external costs such as the depletion or pollution of a resource are not accounted for in the decisions made by individual users of the resource. The concept of ecosystem services, or “the benefits ecosystems provide to human wellbeing” emerged in the 1980s in a parallel fashion with concepts of sustainable development and has been increasingly applied to a wide range of environmental decision-making
as a means of internalizing environmental externalities. In theory, if
decision-makers had the ability to fully account for impacts to or depend-
dence on ecosystem services, humankind's development strategies would
be economically and ecologically efficient. This talk will summarize the
trials and tribulations in the evolution of ecosystem services thinking,
touching on major events in policy development including adoption of the
concept of payment for ecosystem services (the Costa Rica example), to
the inception and conception of the Millennium Ecosystem Assessment,
and the creation of the Intergovernmental Science-Policy Platform on
Biodiversity and Ecosystem Services, and the alphabet soup of NGO and
governmental organizations and programs that have come of age in the
last decade. Along the way, the talk will raise a series of questions about
whether and to what extent ecosystem services approaches have contrib-
uted to the sustainability of the planet's resources and poses questions
for the audience to ponder regarding the future direction of the concept
of ecosystem services in environmental decision-making. For example,
from a logistical standpoint, will approaches to classifying and measur-
ing ecosystems converge, or might it make more sense to have different
approaches for different applications?

SF020 Exposure Science in Transition - The Case for Exposure-
Informed Decisions

A. Guiseppi-Elie, US Environmental Protection Agency / OCSPP/ RAD

We are exposed daily - be it in the foods we eat, the water we drink,
the air we breathe, and personal products we use - to different physi-
cal, chemical, biological stressors that can potentially affect our health.
Exposure science, in general, develops information on “what we are
exposed to” and “how much.” Exposure assessments apply this informa-
tion to specific decision contexts, where it may be necessary to predict
and potentially mitigate adverse health outcomes, or alternately, enhance
positive health endpoints. Exposure science has broad applicability
including, for example, in food safety, public health and industrial hygiene
and, hence, the focus of exposure assessments can vary by discipline with
a key example being its use in risk assessments. It can be successfully
argued that without exposure, regardless of the hazard potential of any
stressor (chemical or otherwise), there can be no risk. This follows the
widely accepted risk paradigm that equates risk to the combined effects
of hazard and exposure. History, however, is on the side of hazard regardless
of exposure. For example, the exposure element of the “dose makes the
poison” adage was somehow lost in the centuries of toxicity testing that
followed Paracelsus’ observation. In the past, exposure has been relegated
to a secondary role in risk-based decisions. Fortunately, in the 21st cen-
tury, exposure science has evolved significantly moving the field from
discrete “external” exposures to “internal” and personal measurements.
Technological advancement in measurements (e.g., analytical techniques,
sensors) as well as high-throughput in silico methods have expanded and
diversified the exposure toolset. These advancements have revived the
critical place of exposure as requisite to hazard assessment to inform the
best decision-making in light of complex 21st century issues. This story
will focus on a few of the examples that abound, such as the evolution to
personal sensors and high-throughput exposure methods. Coupled with
a renewed energy around collaboration, practitioners are equipped now
more than ever to work together to solve real world problems.

SF021 Putting ecology and risk back into ecological risk assessment

W.R. Gala, Chevron Energy Technology Company / HES

The devaluation and distrust of science found in many sectors of the
public have taken a toll on the conduct and quality of ecological risk
assessments (ERAs). Thirty years ago, practitioners and researchers
were advancing the science and practice of ecological risk assessment
to improve the incorporation of ecological conditions into ERAs, to
obtain greater accuracy in exposure point concentrations and improve
the understanding of the toxicity of constituents of concern to an ever-
broader range of ecological receptors. The goal was to collect data and
perform studies to reduce uncertainty and conservatism to improve the
accuracy of ecological risk estimates. Rather than a continuing improve-
ment in ERA, we have seen a digression to conservative screening-level
risk assessments protecting ghost receptors from phantom exposures. As
a long-time SETAC member and Industry ecotoxicologist, I will provide
my perspective on the great promise we had for ecological risk assess-
ment in the early days and the errors we have allowed into the process
that undermine the application of high-quality science in ecological risk
assessments today. I remain hopeful that we can return to the optimism
of our youth and focus our efforts to: improve assessment and estimates
of ecologically relevant exposures by incorporating advance sampling
techniques and knowledge of how ecological receptors utilize and distrib-
ute themselves in impacted environments; develop ever more accurate
ecological benchmarks that are based on toxicologically and ecologically
significant endpoints; and improve the communication of ecological risk
by providing accurate descriptions of the likelihood and consequences of
exposures to constituents of concern.
